

WELCOME MESSAGE

11TH INTERNATIONAL CONGRESS ON THE CHEMISTRY OF CEMENT

ICCC
2 0 0 3

DURBAN, SOUTH AFRICA
11 - 16 MAY

May 2003

A warm South African welcome is extended to all delegates at the 11th International Congress on the Chemistry of Cement, which, after a journey of 100 years, has at last reached the African continent and is this year, being held in Durban.

With more than 240 technical papers, a comprehensive exhibition running concurrently with the Congress, a choice of technical tours and a social programme that delegates will always remember, ICCC 2003 promises to provide members of the world cement industry a very stimulating and exciting 5 days.

The Congress has received the official endorsement of the South African Minister of Trade and Industry, Mr. Alec Irwin, MP, and he has urged visitors to our 'world in one country', to enjoy not only the scientific programme, but also the sights and sounds of Africa.

With the planning and preparation now behind us, it remains for me to welcome you all to the Congress and invite you to participate as actively as possible throughout the whole proceedings.

John Sheath
Chairman - ICCC 2003 Organising Committee

ORGANISATION STRUCTURE

11TH INTERNATIONAL CONGRESS ON THE CHEMISTRY OF CEMENT

CONGRESS PATRONS:

<p>Alpha</p>  <p>THE A1 CHOICE</p> <p> Holcim Group</p> <p>http://www.alpha.co.za</p>	<p>Lafarge</p>  <p>http://www.lafarge.co.za</p>
<p>Natal Portland Cement</p>  <p>http://www.npc-eagle.co.za</p>	<p>Pretoria Portland Cement</p>  <p>http://www.ppc.co.za</p>

CONGRESS ORGANISERS:

The Congress was organised under the auspices of:

Cement & Concrete Institute

P O Box 168
Halfway House, 1685
South Africa

THE EFFECT OF COMPLEX ADMIXTURES ON STRENGTH OF ULTRA HIGH- STRENGTH CEMENT

Konstantin Sobolev and Svetlana Soboleva

Department of Civil Engineering, European University of Lefke, TRNC. E-mail: sobolev@lefke.edu.tr

ABSTRACT

Recent research has shown that a state-of-the-art process for high-performance (HP) cement adds a new dimension to “classical” cement technology. The key idea of the process involves the mechano-chemical activation of cement at the grinding stage. A silica-based complex admixture is used for the activation of the cement which imparts high strength and improved durability to mortars and concrete. This paper describes the effect of different complex admixtures on the strength of HP cement. According to the available results, mortars based on HP cement possess a compressive strength of up to 148 MPa. A comparison of alternative evaluation methods helps to recommend the test procedure for HP and high- strength cement.

1. INTRODUCTION

The latest developments in cement and concrete science show the following trends [1,2]:

- *Increasing Strength*: Major breakthroughs in knowledge have led to the design of cement based materials with greater strength; this has resulted in the development and application of super high-strength concretes with a compressive strength of up to 135-250 MPa, high flexural strength and improved ductility [3-12].
- *Application of Chemical Admixtures*: Added to the concrete mixture, relatively small amounts of chemical admixtures can alter the behavior of fresh or hardened concrete. Chemical admixtures can improve almost any problematic property of concrete: they are one of the essential components of modern concrete which help control strength and durability [13,14].
- *Utilization of industrial by-products and waste (IBPW)*: The use of IBPW as mineral additives has become an important part in cement and concrete technology. According to wide- ranging investigations [1,2,13-16], the performance of conventional concrete can be significantly improved by adding IBPW in specific quantities. Well-known mineral additives include granulated blast furnace slag, fly ash, and silica fume. These mineral additives not only yield a concrete which has better properties and is more cost effective, but they also reduce the environmental impact of construction activities [16].

Following these developments, the concept of high performance concrete (HPC) has been put forward and successfully applied worldwide. It is generally accepted that concrete with improved properties (workability, strength, permeability, durability, etc.) above the conventional benchmarks can be specified as HPC. According to Forster [17], HPC is “a concrete made with appropriate materials combined according to a selected mix design and properly mixed, transported, placed, consolidated, and cured so that the resulting concrete will give excellent performance in the structure in which it will be exposed, and with the loads to which it will be subjected for its design life”.

To realize the HPC concept, a range of chemical admixtures and mineral additives are required, and consequently, a modern concrete batching plant must use appropriate equipment for precise control, dispatching, dosing and batch processing [7-14]. This modernization of production facilities is an unavoidable cost for improved performance since variations in dosing or mixing the components of the concrete may affect the performance of the final product. The compatibility of the admixtures is yet another problem for the production and application of HPC [13,14].

However, an alternative method of controlling the concrete properties and design of HPC is the use of special cements possessing higher strength and better resistance to the deterioration caused by various physical, chemical, and mechanical factors [18-26]. These superior cements are often based on special clinkers or blended cements such as shrinkage compensating or expansive cements, high early strength cements, regulated-set and jet-cements [3]. The group of these cements also includes newly developed Ultimex cement, blended Pyrament and SF cements [20-24].

An advanced approach to improving cement performance arises from the application of chemical admixtures, which modify the cement grinding process [19]. Using this method, a number of chemical admixtures and cement products have been developed. Well-known examples include air-entraining, hydrophobic and plasticized cements, and also the family of cements which are manufactured using grinding aids. It has been suggested that the action of these modifiers is based on mechano-chemical activation [19].

The theory of mechano-chemical activation has been successfully applied to processing nanopowders, pigments, fillers, binders, ceramic and ferromagnetic materials. Using this method, an improvement of cement strength can also be achieved [19,20,23,26]. Low Water Demand Binder (LWDB) is produced by intergrinding cement and a dry modifier at a high energy [25]. In spite of a similar technique already suggested in [19,20], only the application of a specially selected admixture- modifier at a relatively high dosage (up to 4%) resulted in the manufacture of a cement with both reduced water demand and high strength.

The group of mineral-and-organic complex admixtures for application in cement technology was proposed [18]. Basically, these admixtures contain a reactive silica-based sorbent as a mineral constituent and a surfactant as its organic constituent plus some minor corrective admixtures (Figure 1, further details are provided in [18]). Supersilica, a reactive silica-based complex admixture was developed using this principle [16,18]. Although all the effects of Supersilica have not been completely investigated, it is hypothesized that, when added during the cement grinding process, Supersilica modifies the surface of cement particles and also promotes the formation of highly reactive amorphous structures and pre-hydrates [18]. Further, the reactive silica component also acts as a micro-filler and participates in a pozzolanic reaction. The mechano-chemical activation of cement with Supersilica at the grinding stage results in a high performance (HP) cement.

HP cement can be defined as a product manufactured by the mechano-chemical activation of certain proportions of clinker, gypsum, complex admixture and, optionally, a mineral additive of industrial (IBPW) or natural origin (Figure 1), which imparts high strength and extreme durability to the concrete or mortar made from such cement [18,26]. Such high strength can be used for the engineering of a cement with high volume mineral additives (HVMA). As a result, relatively large amounts (up to 70%) of portland cement clinker can be replaced with inexpensive locally available mineral additives. Natural pozzolanic materials, sand, limestone, granulated blast furnace slag, fly ash, glass cullet and ceramic waste, all can be used as mineral additives in HVMA cements [16].

There are two types of HP cement:

- Type A Basic HP cement;
- Type B Blended HP cement.

Basic Type A cement involves intergrinding the clinker, gypsum and a complex admixture. Blended Type B cement covers a wide range of HP cements with mineral additives. The content of a mineral additive in blended HP cement varies with the specified level of the properties and with the type of additive used. Preliminary research [16] demonstrated that Type B Blended HP cements with a mineral additive content within the standard limitations (25-50% as specified in EN 197-1, [27]) can be produced. Furthermore, the range of mineral additives can be extended for HVMA cement. New types of mineral additives (quartz sand, glass cullet and ceramic waste) can be used as components of the Blended HP or HVMA cements [16,18].

The application of granulated blast furnace slag (GBFS) in Blended HP cement in addition to high ultimate strength (more than 80 MPa), results in a product possessing high resistance to chemical attack and to elevated temperatures (up to 700 °C) [26].

Figure 1. Flow Chart of HP Cement Technology

2. RESEARCH SIGNIFICANCE

The effect of silica fume on the behavior of cement- based materials has been extensively reported in the literature [1-14]. A number of published papers on HP cement deals with the application of a silica fume based complex admixture [16,26]. At the same time the use of other types of reactive silica products as a component of the complex admixture have been proposed [18]. Consequently, the evaluation of the effect of different reactive silica materials on the cement strength is important for the manufacture and practical application of HP cement based materials.

3. EXPERIMENTAL PROGRAM

3.1 Materials used

Three different reactive silica components were used in the complex admixture: silica fume (SF), natural microsilica (MS), and metakaolin (MK). The reference cements were: portland cement CEM-I 42.5 [27] (NPC-I, Type I according to ASTM C150 [28]) and low water demand binder (LWDB). The samples of optimized high-performance cement Type A (HPC-A) and Type B (HPC-BS containing 50% of GBFS and HPC-BL containing 35% of limestone, LS) were also tested for comparison [26]. The chemical composition of these materials is presented in Table 1. Standard Rilem Cembereau sand [29] was used in the preparation of the mortars.

Table 1. Chemical Analysis of Cementitious Materials

Composition	SF	MS	MK	NPC-I	BFS	LS	LWDB	HPC-A	HPC-BS	HPC-BL
SiO ₂	90.00	84.60	86.80	19.42	37.4 3	-	19.77	28.47	34.28	20.87
Al ₂ O ₃	0.40	5.14	5.17	5.27	10.9 1	-	5.15	4.18	7.83	4.74

Na ₂ O	0.50	-	0.24	0.70	0.35	-	0.25	1.02	1.01	-
K ₂ O	2.28	-	0.46	1.00	1.17	-	0.42	0.38	0.19	-
SO ₃	0.44	0.99	-	2.30	2.06	-	3.82	2.61	2.35	1.89
LOI	3.03	6.15	1.20	3.50	-	42.9 0	2.7	2.83	1.50	15.89

3.2 Research Program

The experimental program had two main components:

- The investigation of cement compressive strength at constant W/C according to EN 196 [30];
- The investigation of cement compressive strength at constant flow according to ASTM C109 [31-32].

3.3 Notations Used

The following notations were applied to distinguish the samples:

- NPC-# reference portland cement;
- LWDB-# reference low water demand binder;
- HPC-A-# reference high performance cement Type A;
- HPC-BS-# reference high performance cement Type B (50% of GBFS);
- HPC-BL-# reference high performance cement Type B (35% of LS);
- SFC-# high performance cement produced using SF admixture;
- MSC-# high performance cement produced using MS admixture;
- MKC-# high performance cement produced using MK admixture.

The additional letter after the main notation identifies of the test procedure as follows:

- I reference portland cement CEM-I 42.5 (without additional grinding);
- W for EN 196 mortars (constant W/C);
- F for ASTM C109 mortars (constant flow).

3.4 Mixture Proportioning

The strength properties of eight different cements were investigated. These included HP cements produced using different complex admixtures (SFC, MSC and MKC) and reference cements. Ten percent (by weight) of complex admixture was used to produce these cements. Quartz sand (S) was used in small amounts (5%) in the composition of the cements investigated in order to facilitate grinding in the ball mill. The composition of the cements investigated is given in Table 2.

Two sets of mortars were prepared: W according to EN 196 and F according to ASTM C109. For W mortars a constant W/C of 0.5 and a sand-to-cement ratio of 3.0 were used. F mortars were produced at W/C adjusted to constant flow (as described in ASTM C109). A sand-to-cement ratio (S/C) of 2.75 was applied for F mortars.

Table 2. Composition and Fineness of Cements Investigated

Cement Type	Cement Composition								Blaine Specific Surface, m ² /kg
	NPC-I	LWDB	LS	BFS	S	Complex Admixture			
						SF	MS	MK	
NPC	100	-	-	-	-	-	-	-	516
SFC	85	-	-	-	5	10	-	-	477
MSC	85	-	-	-	5	-	10	-	505
MKC	85	-	-	-	5	-	-	10	422
LWDB	-	100	-	-	-	-	-	-	409
HPC-A	85	-	-	-	5	10	-	-	570
HPC-BS	40	-	-	50	-	10	-	-	580
HPC-BL	50	-	35	-	5	-	-	10	416

3.5 Preparation of Specimens

Samples of high performance cement were obtained by grinding the mixtures specified in Table 2 in a laboratory ball mill. The sample batch weight was 5 kg and grinding media weight was 65 kg. Grinding time was 30 minutes. In order to eliminate the effect of the additional grinding on the properties of cements investigated, the reference portland cement NPC-I was also ground for an equivalent time. The resulting specific surface data of the investigated cements are summarized in Table 2.

Mortars based on these cements were prepared following EN 196 [30]. For F mortars the flow table was applied to obtain the standard flow of 105-115 mm. The mortars for the strength test were cast into three-gang (40x40x160 mm) prism molds, and compacted in accordance with EN 196 [30].

3.6 Curing of Specimens

After the compaction procedure, the molds were placed in a humidity cabinet for 24 hours (keeping a relative humidity of 95% and a temperature of 20°C). Following this period, the specimens were removed from the molds and kept in water until the testing age.

3.7 Tests Performed

Compressive strength tests were conducted using the portions of prisms broken in flexure [28]. The compressive strength results indicated are the average of the six values and flexural strength results are the average of the three values. Different age conditions reflecting the requirements of [25-27] were applied: W-mortars were tested at the age of 2, 7 and 28 days; and F-mortars tests were carried out at the age of 1, 3, 7 and 28 days.

4. TEST RESULTS

4.1 Compressive Strength of Mortars with Constant W/C

The test results of W- mortars (following EN 196) are presented in Table 3 and Figure 2. According to the obtained results the best 28-day compressive strength value of 62.1 MPa was obtained from the cement produced with metakaolin (MKC). This value is close to the strength demonstrated by an optimized sample of HPC-A (67.0 MPa). The silica fume (SFC) and natural microsilica (MSC) based cements reached 51.4 and 51.9 MPa, respectively, which is close to the 28-day compressive strength of HPC-BS (52.1 MPa). The reference sample of NPC demonstrated a compressive strength of 43.8 MPa (which meets the requirements for 42.5 Grade cement), while the strength of LWDB sample was only 26.6 MPa (outside the limits specified by EN 196 for a cement of the lowest Grade of 32.5). The strength of investigated HP cements at the 2-day age is almost the same for all investigated cements and lies in the range of 25.5-28.6 MPa, with the best value for MSC.

Table 3. Compressive Strength of W- Mortars (EN 196)

Mix Type	S/C	W/C	Compressive Strength, MPa at age, days		
			2	7	28
NPC-W	3.00	0.50	21.6	32.8	43.8
SFC-W	3.00	0.50	25.5	32.6	51.4
MSC-W	3.00	0.50	28.6	38.4	51.9
MKC-W	3.00	0.50	25.5	49.2	62.1
LWDB-W	3.00	0.50	14.3	22.6	26.6
HPC-A-W	3.00	0.50	31.5	45.6	67.0
HPC-BS-W	3.00	0.50	7.5	21.9	52.1
HPC-BL-W	3.00	0.50	13.3	25.4	33.0

At the 7 days MK- based cement demonstrated an even better strength value than optimized HPC-A, gaining 49.2 against 45.6 MPa. The intermediate level of 38.4 MPa was shown by MSC. In this group SFC was the least satisfactory, developing slightly lower strength compared with NPC : 32.6 and 32.8 MPa, respectively. The lowest 7-day strengths were obtained from HPC-BL, LWDB and HPC-BS with 25.4, 22.6 and 21.9 MPa, respectively.

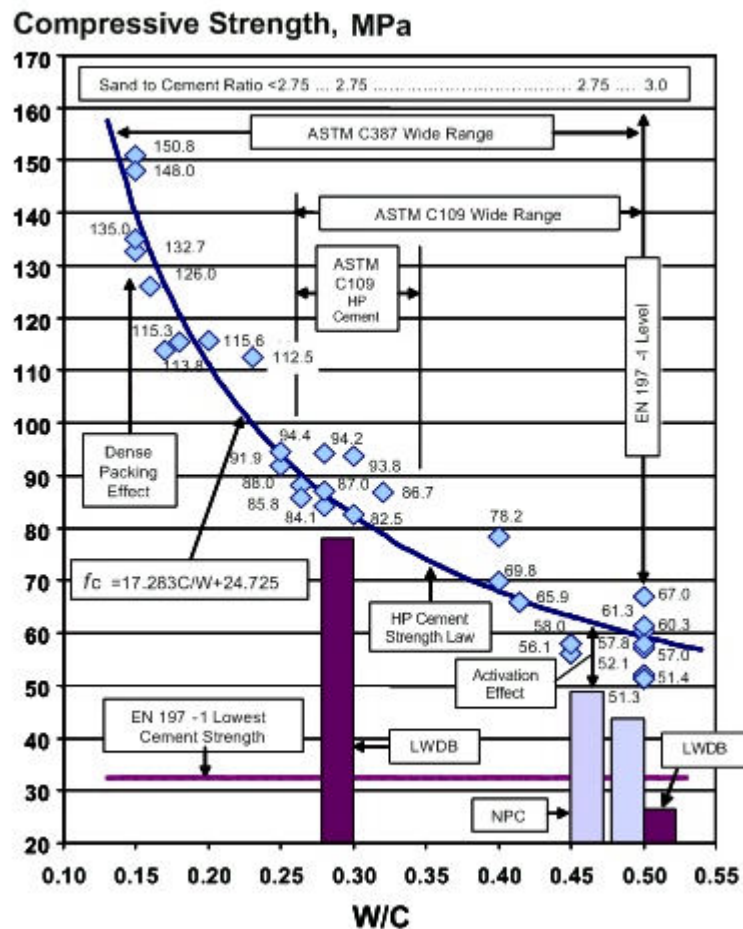

Figure 2. W/C Law for High Performance Cement

4.2 Compressive Strength of Mortars with Constant Flow

The test results of F- mortars (ASTM C109) are presented in Table 4 and Figure 2. Based on the flow test, a W/C ratio was selected for the mortars. It was found that all cements (except reference NPC) required a W/C in the range of 0.28-0.30 in order to obtain the standard flow of 105-115 mm. Due to its special design, the complex admixture overcomes the relatively high water absorption of

reactive silica component; yet, conversely, it also provides a strong water reducing effect, resulting in a cement with water demand comparable to or less than that of LWDB.

The results demonstrated that cement produced with a SF-based complex admixture (SFC) possessed the highest compressive strength of 84.1 MPa at 28 days. However, this value is lower than the strength of optimized samples of HPC-A and HPC-BS (94.4 and 92.7 MPa, respectively). The microsilica cement (MSC) demonstrated a strength value of 74.5 MPa, slightly lower than LWDB strength of 78.7 MPa. The lowest 28-day strength (66.8 MPa) was obtained for metakaolin cement (MKC), which is comparable to the strength of reference HPC-BL (66.7 MPa). The strength of NPC reference sample was only 48.9 MPa.

Table 4. Compressive Strength of F- Mortars (ASTM C109)

Mix Type	S/C	W/C	Compressive Strength, MPa at age, days			
			1	3	7	28
NPC-F	2.75	0.45	16.9	36.6	39.8	48.9
SFC-F	2.75	0.28	40.6	43.5	53.3	84.1
MSC-F	2.75	0.30	36.5	51.1	55.7	74.5
MKC-F	2.75	0.30	33.0	38.4	45.5	66.8
LWDB-F	2.75	0.30	35.1	59.2	69.0	78.7
HPC-A-F	2.75	0.28	44.3	62.2	74.1	94.4
HPC-BS-F	2.75	0.28	35.2	54.2	65.6	92.7
HPC-BL-F	2.75	0.28	21.6	40.7	54.8	66.7

The 1-day strength of all investigated HP cements was found to be very high: between 40.6 and 33.0 MPa, with the best value for SFC. Similar strength was also developed by HPC-BS. The strength of optimized HPC-A exceeded these values and reached 44.3 MPa. The strength of LWDB was found to be close to the strength of MSC and MKC. All these strength values are much higher than 16.9 MPa demonstrated by NPC.

The behavior of investigated cements at 3- and 7- days age was similar: microsilica- based HP cement (MSC) demonstrated the best strength 51.1 and 55.7 MPa, respectively. The NPC strength was lower than that of all tested cements.

5. DISCUSSION

5.1 Strength Development

The test results confirmed a similar effect of different reactive silica products on the strength properties of HP cement at a reduced W/C. The three different stages of cement strength development can be specified as follows:

- 1st Stage: Very rapid strength growth during first day of hardening;
- 2nd Stage: Latent period between 1 and 3 days characterized by a delay in hardening, especially noticeable for SFC and MKC;
- 3rd Stage: More intensive, strength development of SFC and MKC, comparing to HPC-A and MSC, at the age of 3- 28 days.

The strength development of investigated cements at a constant W/C of 0.50 has a clearly defined critical point at 2 days age (Table 3). According to the test results, MKC maintained a very high strength up to 7 days, giving remarkable strength values. The continuous strength growth up to 28 days was observed for HPC-BS. LWDB demonstrated very little increase in strength after 7 days.

5.2 HP Cement vs LWDB

The research has demonstrated the advantage of HP cement over LWDB for early and 28-day strength in the range of the investigated W/C. This advantage is even multiplied at high W/C, when HP cement showed 2- 2.5 times higher strength (Figure 2). It can be suggested that the criterion similar to the performance of plasticizers or superplasticizers in concrete [13], which allows only very small strength loss of modified concrete (being tested at the same W/C), must be applied in the case of new cements with low water demand. This procedure could provide a better understanding of the behavior of these cements and also, prevent an unexpected strength loss of the concrete at high W/C.

5.3 W/C Effect

The function of the HP cement compressive strength vs. W/C is presented in Figure 2. The 28-day compressive strength value for HP cement mortars can be estimated by the following equation:

$$f_{28} = \frac{17.283}{W/C} + 24.725$$

According to the empirical rule stated in [1,2], the pozzolanic effect of highly reactive silica dioxide materials (such as silica fume) is approximately equal to the strength of the cement used. In this case, the difference in strength between NPC and HP cement (or SF cement) at the same W/C can be explained by the contribution of mechano- chemical activation, which was also observed in [23]. The optimal composition of HP cement allows a significant reduction of the W/C ratio keeping a high workability level with consequent increase in strength due to super-dense packing.

5.4 The Comparison of EN 196 and ASTM C109 Test Procedures

The comparison of the test results demonstrated that the EN 196 procedure cannot be adopted for measuring the performance of newly developed high strength cements. Designed to compare portland cements of different manufacturers by its adjustment to a “common divider”, the compressive strength obtained at constant W/C is not sufficient to predict the performance of the different types of cement in concrete (for example, pozzolanic cements with high value of normal consistency). In the practical application of these types of cement the comparison of its performance in concrete may be required when the EN 196 test procedure is used. This test should consider not only the strength of concrete, but also cement effect on workability of concrete mixtures.

Since the constant flow procedure of ASTM C109 returns a compressive strength as an integrated value involving a workability parameter, it can be applied as a performance criterion to a wide range of cements. As a result, the ASTM strength can be directly used for the prediction of concrete strength based on different types cement. Therefore, the ASTM C109 procedure is suggested as the most appropriate strength test for high strength cements such as HP cement or LWDB.

6. CONCLUSIONS

1. Reactive silica additives like silica fume, natural microsilica, and metakaolin increase the early and ultimate strength of cement and concrete. These materials can be used as components of a complex admixture for consequent application in high performance cement. The test results demonstrated similar behaviors of different reactive silica additives in high performance cement.
2. Using the HP cement approach, cements with 28-day strength (according to ASTM C109) in the range of 66.8- 94.4 MPa were obtained.
3. The W/C ratio was recognized to be the most critical parameter in measuring the performance of high strength cement. The difference in strength according to different standards (EN 196 vs.

ASTM C109) was found to be in the range of 10-60% for different types of HP cement, and about 200% for LWDB. Based on completed research, the ASTM C109 is proposed as the most convenient procedure for testing high strength cements.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the receipt of samples of metakaolin from PIERI-GRACE, natural microsilica from Microsilica NZ, HP cement from SCI Con Technologies, and LWDB from KOCA. The authors are grateful to the staff of Quality Control Laboratories of NIGBAS Precast Concrete, BEM and OYSA Cement for their help in conducting the tests. The suggestions of Dr. C. Podmore are highly appreciated.

MECHANOCHEMISTRY SYNTHESIS OF NEW COMPOSITE BINDER FROM SECONDARY MINERAL RESOURCES

S.I. Pavlenko, Yu.M. Bazhenov, E.G. Avvakumov and A.V. Aksenov

ABSTRACT

The Siberian State University of Industry (SSUI) in association with the institutes of the Siberian Branch of the Russian Academy of Sciences has created a new composite binder consisting of high-calcium fly ash from the Abakan thermal power plant, waste molding sand mixture ("burnt sand") from foundry, Abakanvagonmash, and waste product from the Yurga abrasion plant. The fly ash contains up to 40 % SiO_2 and 35 % CaO including above 15 % free CaO . The waste sand mixture includes more than 90 % SiO_2 , mostly in the amorphous state. The waste product of the abrasion production (high-alumina product) contains 80 % and more Al_2O_3 .

The ash is a good binder, but the presence of free CaO destroys its binding properties during service. Grinding ash, sand and high-alumina product (HAP) together by means of mechano-chemical activation in planetary ball mills to the fineness of $750 \text{ m}^2/\text{kg}$ and using thermal treatment produced a binder with a compressive strength above 50 MPa at 28 days.

It was found that during the process of mechano-chemical treatment, free CaO reacts with SiO_2 (chemistry of a solid), reduces its content in the mixture by 60 to 80 % and increases the strength by 1,5 to 2 times eliminating the process of concrete expansion.

The creation of a binder from industrial wastes and making good concretes with slag sand as an aggregate gives both economic (its cost is half that of Portland cement) and ecological benefits by eliminating landfills and reducing the CO_2 discharge into the atmosphere (the production of a ton of cement discharges above 0,5 ton CO_2).

Keywords: High-calcium Fly Ash, Burnt Sand, High-alumina Product, Amorphous Material, Mechanochemical Process, Planetary Mill, Reaction, Cementless Composite Binder.

1. INTRODUCTION

The department of civil engineering, SSUI, supported financially by the Ministry of Education of Russia, has created fine cementless ash – slag concrete from wastes of thermal power plants and ferroalloy plant (1). Concrete has been patented (patent № 2065420). A project for the construction of the binder and a silicate brick shop (2, 3) at the Abakan thermal power plant has been developed and approved. A technical certificate by the Government of Russia has been received. But as the Abakan thermal power plant is a part of the Abakanvagonmash with a large foundry which dumps used molding sand mixtures (1 ton of sand per 1 ton of founding), we thought of replacing silica fume with molding sand as a silica component of a new binder for concretes. Supported by the Federal INTEGRATION Program, the investigation was carried out in the laboratories of the SSUI, Associated Institute of Geology, Geophysics and Mineralogy (AIGGM) and the Institute of Chemistry of Solids and Mechanochemistry (ICSM), Siberian branch of the Russian Academy of Sciences (SBRAS).

As known, the following compounds are in composition of cement: $3\text{CaO} \cdot \text{SiO}_2$ (mass portion of 40 – 60 %); $2\text{CaO} \cdot \text{SiO}_2$ (15 – 35 %); $3\text{CaO} \cdot \text{Al}_2\text{O}_3$ (4 – 14 %); $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ (10 – 18 %) (4). The indicated compounds and also the initial components for their synthesis are in ashes from

coal combustion, in waste products of casting and abrasives production. Therefore these wastes are used for the production of cementless binding materials from them (5).

The quality of binding materials from wastes depends on the following factors:

- 1) selection of composition in order to correspond to a large extent to the composition of cement;
- 2) mixture of composition in order to have possibly the chemical interaction between them.

Thermal method in this case are less suitable for the reason of their high energy consumption, therefore the mechanical activation of mixture is used in grinding apparatuses (6 - 8).

However, the mechanochemical reaction with participation of waterless oxides is not so effective. Thermodynamically, the reactions with participation of hydrated oxides are more advantageous which are formed during addition to mixtures of waterless oxides to water. So, for reaction:

here Gibbs energy equals to 89.4 and 117.2 kJ/mole respectively. The experiment shows that the coherence of calcium in the second case proceeds more effectively in some cases than during the interaction of waterless oxides.

Roentgenamorphic hydrosilicates relating to the tobermorite group ($\text{Ca}(\text{OH})_2 \cdot \text{Si}_6\text{O}_{16} \cdot 4\text{H}_2\text{O}$) are the products of mechanical activation in relation to components $\text{Ca}(\text{OH})_2 : \text{SiO}_2 \cdot \text{H}_2\text{O} = 1 : 1$; during their scaling, pure wollastonite $\beta\text{-CaSiO}_2$ (9) is obtained.

It is possible to get dicalcium silicate by the indicated method. The work (10) the activation of calcium oxide and amorphous silica gel was being carried out in the presence of water, the quantity of which was larger than calculated on theoretical composition of $2\text{CaO} \cdot \text{SiO}_2 \cdot 2\text{H}_2\text{O}$. After activation over 14 hours in a vibration mill the roentgenamorphic product is obtained, in which the form of dicalcium silicate is obtained. After heating up to 550°C , the peak appears belonging to $\beta\text{-}2\text{CaO} \cdot \text{SiO}_2$, but during heating to 1000°C the product is already well crystallized.

By analogy during mechanical activation of calcium hydroxide mixtures and of aluminium the hydroaluminates of calcium $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$ and $2\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$ are formed, which are decomposed by heating to temperatures of $700 - 1000^\circ\text{C}$ with the formation of $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$ and $2\text{CaO} \cdot \text{Al}_2\text{O}_3$ having viscous properties (11 - 13).

In this work the use of mechanical activation for synthesizing of a composite binder from industrial waste containing the oxides of calcium, silicon and aluminium has been researched.

2. MATERIALS

2.1 Fly Ash

According to Ivanov (14), high – calcium fly ash from the electrostatic filters of the Abakan thermal plant is a coarse polydispersed ash with the surface area below $250 \text{ m}^2/\text{kg}$. It consists mostly of irregular agglomerated particles (Figure 1). The bulk density, absolute density and effective specific activity of the ash are 1120 , 2680 kg/m^3 and $118,9 \text{ Bq/kg}$, respectively. Chemical analysis of the ash is given in Table 1.

Figure 1. Structure of fly ash from the Abakan thermal power plant x 1000

Table 1. Chemical analysis of ash

Component	Compound, %								
	SiO ₂	CaO total	Free CaO	MgO	Al ₂ O ₃	Fe ₂ O ₃	Na ₂ O + K ₂ O	TiO ₂	LoI
Fly ash from Abakan TPP	40.47	34.94	15.75	7.28	4.87	10.32	1.1	0.80	1.02

As can be seen from the data, the ash has to be ground to break its agglomerated particles and expose free CaO, the presence of which would induce expansion and fracture of concrete. Furthermore, the method of Ovcharenko (15) showed that 58 % free CaO was in a glass phase which prevented it from hydration prior to strength gain.

2.2 Molding Sand Mixture

The molding sand mixture consists of 92 % quartz sand, 6 % bentonite and 2 % water glass. After its use in the foundry and after removing gritty scale from the material, it has a form of a black sand ("burnt" sand) with a fineness modulus of 1,91 (Figure 2). The bulk density, absolute density and the effective specific activity of the sand are 1450, 2380 kg/m³ and 98 Bq/kg, respectively. Chemical analysis of the burnt sand is given in Table 2.

Figure 2. Structure of burnt sand x 1000

Table 2. Chemical analysis of burnt sand

Component	Compound, %						
	SiO ₂	CaO	MgO	Al ₂ O ₃	Fe ₂ O ₃	Na ₂ O + K ₂ O	LoI
Burnt sand	92.28	1.80	0.2	2.71	2.38	1.02	-

The burnt sand has high content of silicon oxide in the amorphous state (thanks to a high – temperature treatment) which enhances the possibility of chemically binding free CaO in the ash into calcium silicates.

2.3 High – Alumina Product (HAP)

High – alumina product, the waste from the Yurga abrasion plant, is a grey powder (Figure 3). Its chemical analysis is shown in Table 3.

This powder is used to enhance strength and fire resistance in the binder and concrete.

Figure 3. Structure of HAP x 400

Table 3. Chemical analysis of HAP

Component	Compound, %							
	SiO ₂	TiO ₂	Al ₂ O ₃	FeO + Fe ₂ O ₃	MgO	CaO	K ₂ O + Na ₂ O	LoI
HAP	4.51	2.36	34.00	5.17	1.64	1.14	0.34	0.12

3. TESTING PROCEDURES

The following test series were undertaken.

3.1 Determining Optimum Mixture Proportions of a Binder

Correlation of the two components (fly ash and burnt sand) were determined. Fly ash was ground in a laboratory ball mill to the fineness of 400 m²/kg, and the burnt sand was ground to a powder with the residue of 15 % on the sieve No 008. Strength and waterproofness of a binder versus fly – ash – to – burnt sand ratios are in Table 4.

Table 4. Compressive strength and waterproofness of a composite binder

Components, % by weight		Compressive strength, MPa		Coefficient of softening	Notes
sand	ash	R dry	R sat		
40	60	24.85	5.45	0.22	non-waterproof
30	70	34.4	6.70	0.13	non-waterproof
20	80	41.4	21.55	0.52	non-waterproof
10	90	21.2	31.75	1.5	higher waterproofness

The results of the initial investigation showed that a cementless binder can be produced from the above wastes of thermal power plant and foundry. The optimum components ratio as determined by a computerized analysis was 85 to 90 % fly ash and 10 to 15 % ground burnt sand. However, long – term testing in water and a chemical analysis of the binder showed that less than 50 % after free CaO interacted with SiO₂ with resulting cracks in specimens.

3.2 Mixture Activation

The preliminary researches were being carried out in a laboratory planetary mill AGO-2 (16) with samples of 10 gr. processed mixtures and in a large planetary mill AGO-3 (17) with total 1 kg mixture charge.

The power characteristics of the mills are close to each other. Mixtures made of chemically pure oxides of calcium, silicon and aluminium and also mixtures composed of wastes were activated in the mills. Roentgenphase analysis was carried out on device DRON-3 (radiation of CuK α). Determination of the content of calcium oxide was made by method described in work (15). The measurement of basic indices of binder and manufactured articles from it was made in accordance with State Standard 310 "Cement".

The influence of mechanical activation on interaction in mixture of oxides CaO, Al₂O₃, SiO₂ was investigated. Mixtures were activated for 10 minutes. Data of roentgenphase analysis of mixtures are presented in Figure 4.

Figure 4. Diffractogrammes of activated mixtures CaO + Al₂O₃ + SiO₂ :
1 – waterless oxides; 2 – mixture contains 20 % H₂O

In the absence of water the chemical interaction, as seen from Figure 4, is practically absent (i.e. the dispersion and amorphisation of oxides are carried out). By adding water the responses of Ca(OH)₂

and also the responses corresponding to formation of calcium aluminate $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$ appear. Thermodynamic calculations of hydrosilicates and hydroaluminates formation by reactions

show that the probabilities of forming the products mentioned above are approximately the same.

Gibbs energy for the first reaction equals to 303 kJ/mole (18) and for the second one it is equal to 303.2 kJ/mole (19). It means that hydrosilicates of calcium also may be present in product but, probably they are less crystallised and do not give a diffraction picture.

For obtaining the composite binder the high-calcium ash from Abakan TPS (Thermal Power Station), waste mould mixture (burnt sand) of casting production AO "Abakanwaggonmachine" and high-alumina product, i.e. the wastes from Yurginsk abrasive production were taken.

For mechanical activation the mixture of 80 % ash and 20 % of burnt ground were selected and 5 % high-alumina product was added to it.

To enhance the activity of the binder components, a blend of 80 % fly ash, 10 % burnt sand and 10 % HAP was ground in a planetary activator mill AGO-3 (0,1 – 100 μm) designed by the ICSM, Siberian branch of the RAS (Figure 5).

Figure 5. The laboratory activator mill AGO-3

The composition mentioned above was subject to different processing times in the mill AGO-3. It should be noted that water was not added to the mixture, but nevertheless one cannot consider that the process was carried out without water. One can believe that water adsorbed on the surface of initial products, the content of which, as it follows from data on LOI, is at the level of 2 %, will take part.

Grinding in this mill is performed in the field of three inertia forces (two centrifugal forces and the Koriolis force), due to which fact the electric tension of AGO-3 is 2 to 3 times higher than that of gravity ball mills (Figure 6). Mechanochemical activation of the components (chemistry of solids)

and partial interaction of the amorphous silica and CaO takes place during the process. The data on the free CaO content and the degree of the blend dispersity with respect to the duration of grinding in the planetary mill are shown in Table 5. In Figure 7 the structure of mixture after grinding is shown.

Figure 6. The scheme of activator mill AGO-3

Table 5. Free CaO content of the blend versus duration of treatment in AGO-3 mill

Mixture No	Duration of treatment, min	Dispersity, m^2/kg	Free CaO content, %
1	without treatment	200	12.60
2	1	400	6.33
3	3	500	4.82
4	6	600	3.92
5	10	750	2.80
6	15	1000	2.02

3.3 Casting and Testing of Specimens of a New Binder

2 – cms cubes of specimens were cast from the activated mixture at normal consistency. The test results are given in Table 6.

From the data shown in Table 6, it can be seen that the best results were obtained with the activator mill after 10 minutes (the dispersity of the blend was $750 \text{ m}^2/\text{kg}$). The binder exhibited high compressive strength and waterproofness. It was found that with further treatment (above 10 min, dispersity of $1000 \text{ m}^2/\text{kg}$), water demand and setting time of the mixture sharply increased, and a drop in the compressive strength was observed.

Figure 7. Structure of ground mixture of three wastes x 8000

Table 6. Strength and waterproofness of a composite binder

Mixture No	Compressive strength, MPa		Coefficient of Softening	Notes
	R dry	R sat		
1	27.82	6.36	0.49	non-waterproof
2	35.63	9.87	0.57	non-waterproof
3	41.35	25.73	0.88	non-waterproof

Tests for expansion (State Standard 310.3-76* Cements, Methods for Determining Normal Consistency, Setting Time and expansion) were carried out by boiling cakes in a bath and in an autoclave. Cakes made from the mixture No 1 had fractures and radial cracks while cakes from the mixture No 2 had smaller defects but with some warping. The remainder mixtures (nos 3 to 6) sustained both boiling and autoclave tests without cracks. The test results showed that the new binder was in accordance with the requirements of the State Standard 310 Cement.

4. PERSPECTIVE FOR PRODUCTION OF THE NEW COMPOSITE BINDER WITH THE HELP OF MECHANOCHEMICAL ACTIVATION

In practice the inter-grinding of the components of the new composite binder can be done in vibrating mills ICSM SBRAS (VCM-10G) shown in Figure 8 or in flowing mills made in Japan.

Figure 8. The scheme of mill VCM-10G

5. CONCLUSIONS

1. Previous investigation shows that wastes from thermal power plants burning brown coals of the KATPC in combination with silica by – products from other industries can be used for composite high – class binders (up to 60 MPa) and concretes on their basis which are equivalent to the traditional binders and concretes.
2. To bind free CaO in brown coal ashes, mechanochemical activation of the components has to be made through inter-grinding in planetary activator mills. This assists interaction of more than 50% CaO and SiO₂ and prevents destructive processes in concretes with a cementless binder.
3. Creation of binders from secondary mineral resources contributes much to environment protection and also helps towards the solving of economic and social problems (construction of dwellings from concretes with cementless binders).
4. Vibrating mills ICSM SBRAS or flowing mills made in Japan can be recommended for production of the worked out composite binder.

DETERMINATION OF OPTIMUM GYPSUM CONTENT OF PORTLAND CEMENT USING THE HYDRATION CRITERION OF MAXIMUM ULTIMATE COMPRESSIVE STRENGTH

K. K. Sideris, P. Manita and K. Sideris

Laboratory of Building Materials, School of Engineering, Democritus University of Thrace,
Xanthi, Greece.

ABSTRACT

In this study the determination of optimum SO_3 content of Portland cement was investigated. The optimum SO_3 content can be determined using as a criterion the maximum ultimate compressive strength, determined by the analysis of mortar's compressive strength with the aid of the cement hydration equation. For this purpose the measured values of mortar compressive strength, taken from Lerch, were analyzed with the aid of the cement hydration equation. The SO_3 content significantly influences compressive strength of Portland cement III at early and later ages. The influence of SO_3 content is significant for cement type IV at later ages, especially at ultimate strength. This method can be used in any concrete laboratory without the aid of special equipment since only simple measurements are needed (mortar compressive strength).

1. INTRODUCTION

Gypsum is added during grinding of the clinker in order to regulate the setting time of Portland cement. However, it also affects some other properties, such as strength,¹ contraction,¹ size of pores in hydrated cement paste etc. at early and later ages. Lerch¹ investigated the way added gypsum controls the setting of cement in respect to protection against the abnormal expansion that might result from use of excess amount of gypsum. For this purpose the investigator measured the rate of hydration using conduction calorimetry on net cement pastes. Physical tests (compressive strength, expansion and contraction) were also performed on mortar prisms.

By the investigations of Lerch¹ and others,²⁻³ the ultimate compressive strength was not taken in account because of the inability to comprehend the final hydration. This can be made now with the aid of the cement hydration equation,⁴⁻⁵ which enables the determination of final hydration. Because of the validity of equal fractional rate of hydration of all components in the hardened paste of Portland cement,⁶⁻⁷ the hydration products are the same at all stages of hydration, and therefore compressive strength could be considered as a measure for porosity and drying shrinkage. This is shown by the results of Lerch¹ concerning compressive strength and contraction, and by Sersale et al.² concerning strength and porosity. Consequently, it may be expected that porosity and drying shrinkage appear a minimum value when the maximum strength of a given mortar or concrete is achieved.

When the 1-day strength test (according to ASTM C 543-84) is used, it is not clear if the amounts needed to optimize strength, porosity, shrinkage and expansion are the same during the whole hydration period.³ Hence, the determination of optimum gypsum content, which depends on aluminates and ferrite phases,³ alkali content and on fineness of the cement,¹ has to be carefully watched. This was investigated in this study by using the measured values concerning mortar compressive strength, setting time, contraction and expansion of two Portland cements (type III and

IV according to ASTM specifications), taken from Lerch.¹ The measured values of mortar compressive strength were analyzed with the aid of the cement hydration equation⁴⁻⁵ in order to determine the ultimate compressive strength as a function of SO₃ content (i.e. gypsum content) to determine its maximum ultimate strength, which gives the optimum gypsum content.

Figure 1. Compressive strength of concrete prepared with Portland cement as a function of hydration time. Portland cement 485 Kg/m³. W/C = 0.27. Compressive strength of 100x200-mm cores taken from 2.0x1.2x1.35-m thick concrete blocks, cast, cured, and left exposed to elements in Toronto, Canada [measured values taken from Malhorta⁸]

1.1 Analyzing the data of Lerch concerning the measured values of mortar's compressive strength of Portland cement type III and IV

According to the results given elsewhere,⁴⁻⁵ the cement hydration equation is applicable to compressive strength. This is also shown by the example given in Figure 1 concerning the long-term compressive strength of concrete, where the first and second phase of hydration⁴⁻⁵ are discernible. For this reason, the measured values of compressive strength obtained at different test ages constitute an established hydration criterion usable for analysis made with the aid of the cement hydration equation. In this case the cement hydration equation ($K = K_{\infty} \pm b \cdot t^{-p}$),⁴⁻⁵ takes the following form (Eqs. 1) by using the hydration criterion of mortar's compressive strength (f_M).

$$f_M = f_{M\infty} - bt^{-p} \quad (1)$$

According to the results of previous studies⁴⁻⁷ the paste hydration of Portland cement ends at the age of 15 years.

The measured values of compressive strength of cement type III and IV for different SO₃ content, taken from Lerch,¹ were analyzed with the aid of the cement hydration equation in Table 1 and 2, respectively. For this purpose, the hydration number (p) and the hydration equation (i.e. the compressive strength equations) of cement type III and IV examined (Tables 1-2) were determined according to the procedure given in previous studies⁴⁻⁵. The accurate values of compressive strength were further calculated (f_{Mcalc}) at different ages up to the final hydration at 5475 days (Tables 1-2) based on the defined hydration equations. The measured values of contraction and expansion of each cement used, taken from Lerch,¹ were also presented in Tables 1 and 2 in order to focus the discussion. The calculated values of cement III and IV mortar compressive strength (f_{Mcalc}) at the ages of 1, 3, 7, 28 and 5475 days were plotted in Figures 2 and 3 as a function of SO₃ content in order to localize the region of optimum SO₃ content. In the same figures the respective measured values were also plotted.

2. DISCUSSION

1. From Tables 1-2 and Figures 2 and 3 it is shown that SO_3 content significantly influences the compressive strength of mortars prepared with cement type III. This finding is in agreement with the results given elsewhere.⁵ The significant influence of SO_3 content appears at later ages when cement type IV was used. Hence, the optimum SO_3 content may be carefully monitored for each given cement and it strongly depends on its particular characteristics (i.e. composition, fineness etc.)
2. It is clearly shown from figures 2 and 3 that the SO_3 content needed to achieve the maximum compressive strength is not the same during the whole hydration period. This implies that the optimum SO_3 content determined according to ASTM C 543-84 (1-day strength) does not give the optimum SO_3 content needed to achieve the maximum ultimate strength at which ultimate porosity and shrinkage appear at their minimal values. In the same Figures is also shown that the region of the maximum ultimate strength appears between 1.9 and 2.4 % for cement III, and between 1.0 and 2.4 % SO_3 for cement IV. In these regions are also shown the values of contraction and expansion which are acceptable¹ (Tables 1-2). Consequently, the criterion of maximum ultimate compressive strength is preferable for determining the optimum SO_3 content, by using the cement hydration equation. The maximum ultimate strength can be determined with the aid of the cement hydration equation using compressive tests performed at several ages up to 28 days.⁵ Better accuracy is obtained for the ultimate compressive strength, if more than 6 test ages belonging to the second phase of hydration⁴⁻⁵ are used (e.g., for cement type I and III, the test ages of 3, 5, 8, 11, 14, 18, 22 and 28 days do belong to the second phase of hydration). For cement type II, IV and blended cement (with natural pozzolans, fly ash, silica fume, slags etc.), where the second phase of hydration (Figure 1) usually begins after 7 days, the test ages have to be extended after 28 days.
3. The method proposed for determining the optimum gypsum content of Portland cement leads to reliable results, and since only simple measurements are needed (mortar compressive strength), it can be used in any concrete laboratory without the aid of special equipment and special tests.

3. CONCLUSIONS

The SO_3 content significantly influences the compressive strength of Portland cement III at early and later ages. The influence of SO_3 content is significant for cement type IV at later ages, and especially, at ultimate strength.

The optimum SO_3 content can be determined using the criterion of the maximum ultimate compressive strength, analyzed with the aid of cement hydration equation. This method can be used in any concrete laboratory without the aid of special equipment and special tests since only simple measurements are needed (mortar compressive strength).

20-5-1969 : Born in Athens, Greece

1992 : M.Sc. in Civil Engineering

1992 - 1994: Military Service.

1992-1996 : Ph. D. candidate of Democritus Univercity of Thrace

1997-1998: Research assistant at the laboratory of building materials, Democritus University of Thrace

1998: Lecturer at the lab. Of Building Materials, Democritus University of Thrace

2. PROFESSIONAL EXPERIENCE

I have worked in several construction offices in Athens as a consultant in terms of concrete technology and durability aspects. During my military service, I have worked in the construction of a military airport in Greece (buildings, motorways, shelters etc).

3. TEACHING AREA

Since 1997 I am teaching several lessons at the civil engineering department in the areas of Building Materials, Concrete Technology and Concrete Durability

4. RESEARCH INTERESTS

My research interests are in the area of cement hydration (empacized in the hydration of blended cements), concrete technology and concrete durability.

MICROSTRUCTURE AND THE DEVELOPMENT OF STRENGTH IN RPC CURED AT VARIOUS TEMPERATURES

ABSTRACT

Reactive Powder Concretes (RPCs) with common ingredients were produced by a simple processing method, in which a high pressure was not applied. Mechanical properties of the RPC cured at various temperatures were investigated with the emphasis on their relation to characteristic microstructure and hydration products. In spite of a relatively high value of 0.21 as a water/binder ratio for RPC, a high compressive strength of about 250MPa was attained by simple heating at 200°C in an oven under atmospheric pressure. However, elevating the curing temperature to 300°C remarkably decreased the strength. Crystalline products such as xonotlite and α -C₂SH were identified in the specimens autoclaved at 300°C. Curing at a high temperature decreased capillary porosity in the RPC mixtures. It was suggested that further reduction of the capillary porosity for coarse pores was necessary to obtain a higher strength when the RPC was cured under 200°C. The reduction in strength in the autoclaved RPC may result from the increase in porosity for much finer pores, which were due to the formation of the crystalline products with high density. The processing on post-setting heating must be optimised for obtaining an ultra high strength in RPC.

1. INTRODUCTION

RPC (Reactive Powder Concrete) is an ultra high strength concrete, of which mix proportions are quite different from those of ordinary high strength concretes. The ultra high strength has been attained on the basis of the principles of an extremely low water/binder ratio, homogenisation of microstructure, dense granular packing of particles and post-setting heating [1]. These principles are easily attained by several ingenious methods in selecting materials and processing for RPC. RPC also has the great advantage of being cast and cured at practical construction site conditions. Recently, the RPC has been widely available around the world [2] as a commercial product. RPC may be one of the most promising high performance concretes in the 21st century.

However, when a RPC is produced with local common materials, a suitable mix proportion and a processing method must be carefully designed to obtain an ultra high performance concrete. It is also necessary to rigorously choose appropriate ingredients available at the local sites. However, information available for mix proportions and suitable processing methods of RPC is limited. For example, it is pointed out that post-setting heating is necessary to obtain an ultra high strength greater than 200MPa. Such a thermal treatment for cementitious materials usually aims at growing hard crystalline products, which are considered to increase strength of the materials. This situation is very similar to the manufacture of synthesized silicate building materials. However, the process and reactions in the treatments are so complex that a universal optimum heating method to enhance the strength of the synthesized CSH systems has not been proposed. Performances of the hardened mixture depend on the types and quantity of reaction products of CSH. Many factors such as sizes of siliceous powder, the initial CaO/SiO₂ ratios and heating conditions sensitively affect mechanical properties of the mixture [3]. A specific mix proportion recommended for a RPC may not always

result in the designed ultra high strength if ingredients with different qualities are used. Therefore, it is important to establish the way of designing mix proportions of RPC with desired performances, taking into account variable properties of each ingredient and curing conditions. Furthermore, it is also necessary to understand the sensitive dependence of properties of RPC on variation of ingredients.

The purpose of this study is to reveal effects of the amounts and types of siliceous materials used in RPC on the performance of the mixture. Effects of the addition of silica fume, fine quartz powder and silica sand on the microstructure of RPC were investigated in relation to the development of the compressive strength of RPC cured at different temperatures. Characteristics of microstructure in RPC at various curing temperatures were examined by the quantitative scanning electron microscopy-backscattered electron (SEM-BSE) image analysis for capillary porosity and X-ray diffraction (XRD) patterns for crystalline products. Roles of the siliceous materials such as silica fume and quartz powder in the formation of dense microstructure were discussed in relation to the types of CSH products and characteristic pore structures at various curing temperatures.

300		in water at 20°C		autoclaving at 300°C			

2. EXPERIMENTAL

2.1 Materials and Mix Proportions of RPC

The cement used was ordinary Portland cement ($C_3S=52$, $C_2S=24$, $C_3A=9$, $C_4AF=9\%$). A commercial silica fume (specific surface area= $20m^2/g$, Ig.Loss= 1.85% , $SiO_2=90.79\%$, density= $2.2g/cm^3$) was used with the combination of polycarboxylic acid type superplasticizer. The dosage of the superplasticizer was 5% by weight of binders. It was confirmed that no segregation was observed during mixing and subsequent setting periods. The size of silica sand used as a coarse sand ranged from 100 to 300 μm . Crushed quartz with the mean size of 5.9 μm was also used as a reactive siliceous powder (Ig.Loss= 0.52% , $SiO_2=79.6$, $Al_2O_3=11.28$, $Fe_2O_3=1.09$, $TiO_2=0.32$, $CaO=0.93$, $MgO=0.37$, $K_2O=3.31$, $Na_2O=2.00\%$).

The mix proportions of the RPC mixtures are presented in Table 1. The water/binder ratio of mixtures was 0.21. The ratio of silica fume to cement varied from 0.24 to 0.413. The ratio of the silica sand and the quartz powder to the binder (i.e. cement and silica fume) was 1.3. The ratio of silica fume and quartz powder to cement was 0.62. These three factors relation to silica and lime content are determinants for the density of granular packing and types of reaction products formed

at various temperatures. In this study, these ratios were established based on the pioneering works by Richard and Cheyrezy [1] and Bonneau et al[4].

2.2 Tests and Image Analysis

2.2.1 Compressive strength

Two types of cylinder specimens with 50mm diameter and 100mm height, and 20mm in diameter and 40mm in height were prepared. The smaller cylinder specimens were used in the autoclaving curing regimen at 300°C. In order to obtain workable mixtures, the total mixing time was changed about 20 minutes [4]. The specimens to be cured at 20, 90 and 300°C were demolded at 24 hours after casting, and then placed in water at 20°C for the subsequent 48 hours. For specimens to be cured at 200°C, in order to prevent them from drying at a high temperature under atmospheric pressure, the specimens with moulds were put in water directly for two days. After the initial water curing until the age of 3days, each specimen was stored under four different curing regimens. The curing regimens are summarized in Table 2. Compressive strength tests were conducted at the age of 3, 4 and 7days.

2.2.2 X-ray diffraction

Small portions of concrete were taken from RPC and cement paste specimens after the completion of compressive strength tests. They were finely ground with a mill. XRD patterns for the powders were obtained. The Cu-K α radiation was used in the diffractometer.

2.2.3 Capillary porosity measurement by the quantitative SEM-BSE image analysis

The same cylinder specimens as the specimens for the compressive strength test were prepared. They were also cured under the same regimens as described previously. At prescribed ages, slices with about 10mm thickness were cut out from the middle portion of the specimens. They were immersed in ethanol, and then impregnated with epoxy resin. After the resin hardened at room temperature, the slices were polished with SiC papers and diamond slurry.

The polished surfaces were examined using the SEM equipped with a quadruple backscatter detector. BSE images were acquired at the magnification of $\times 500$. Each image consists of 1148×1000 pixels. The size of one pixel is about $0.22 \times 0.22 \mu\text{m}$. After the binary segmentation, the number of pixels corresponding to unhydrated cement particles and pores were tallied. Pore size distributions for coarse capillary pores were obtained by calculating equivalent diameters of pores

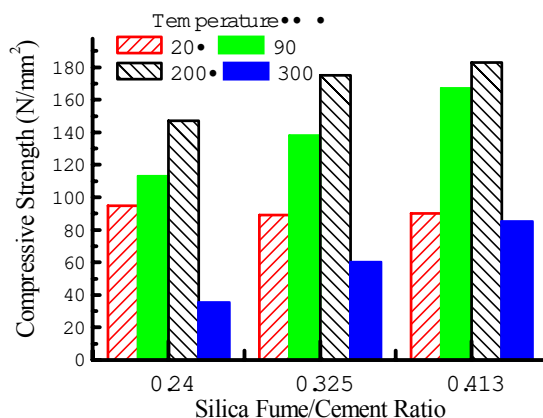

Figure 1. Compressive strength of cement pastes with various silica fume/cement ratios (Age=7days)

[5,6]. The measured size range of pores in the image analysis is much greater than that determined from mercury intrusion porosimetry (MIP). However, the image analysis technique can give

quantitative information of large capillary pores, which are not correctly resolved in the MIP method [6].

3. RESULTS

3.1 Compressive Strength

Figure 1 shows compressive strength of cement pastes with various silica fume/cement ratios. Silica fume contents did not substantially affect the compressive strength in pastes that were continuously cured in water at 20°C. However, if cement paste specimens were cured at 90°C, the higher the silica fume/cement ratio resulted in the greater compressive strength. The pozzolanic reaction of silica fume is dominant in the development of strength at 90°C. The paste specimens cured at 200°C exhibited greater strength than at 90°C. However, the rate of increase in compressive strength was dependent on the ratio of silica fume to cement. The compressive strength of the paste with the silica fume/cement ratio of 0.413 did not appreciably increase even when the curing temperature was elevated from 90 to 200°C.

The strength of cement paste cured at 200°C was greater than those cured at 90°C, as mentioned above. However, cement pastes cured at 300°C exhibited far lower compressive strength. The strength of some cement pastes cured at 300°C was even smaller than the pastes cured at 20°C. However, it should be noted that the reduction in strength by autoclaving was also dependent upon the silica fume content in cement pastes. Some cement pastes cured at 300°C exhibited almost the same strength as that at 20°C when they contained a greater amount of silica fume.

Comparisons in compressive strength between the cement pastes and RPC containing siliceous materials are shown in Figure 2. When the specimens are continuously cured in water at 20°C, there is little difference in compressive strength between cement pastes and RPC. Namely, quartz powder and silica sand did not play a role in increasing strength. However, when cured at 90 and 200°C, the RPCs exhibited greater strength than the corresponding cement pastes. Particularly, the higher the curing temperature except 300°C, the greater differences in the strength between pastes and RPC. The compressive strengths of RPC with the siliceous materials at 300°C were smaller than those at 90 and 200°C. However, the reduction in strength due to autoclaving in paste specimens was reduced in RPC to some degree. The strength of autoclaved RPCs was greater than the corresponding cement pastes. It is found from Figures 1 and 2 that the strength of cement pastes and

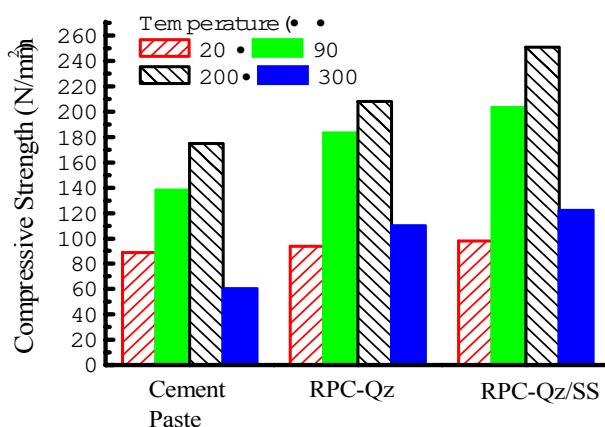

Figure 2. Comparison of compressive strength between cement pastes and RPCs (Age=7days)

RPCs was dependent on the content of silica, especially in the specimens cured at the high temperatures.

Figure 3. Pore size distributions of cement pastes cured at different temperatures (Age=7days)

3.2 Pore Size Distributions

Pore size distributions of cement pastes cured at various temperatures are shown in Figure 3. It should be noted that there were coarse capillary pores even in mature cement pastes with an extremely low water/binder ratio of 0.21. When cured at 20°C, the porosity of cement paste was not greatly influenced by silica fume content. Namely, the silica fume content did not affect the formation of coarse capillary pore structures. However, in the cement pastes cured at a high temperature of 90°C, the porosity of cement pastes decreased. Furthermore, the greater the silica fume content, the lower the porosity of coarse pores. At 200°C, the porosity was further decreased, but differences in porosity between different silica fume: cement ratios were found.

The pore structures formed by autoclaving at 300°C were considerably different from those formed

Figure 4. Comparison of pore size distributions between cement pastes and RPCs (Silica fume /Cement Ratio=0.325, Age=7days)

at lower temperatures. The cement pastes with high silica fume contents of 0.325 and 0.413 had little porosity for coarse pores. A threshold diameter of pores in the cement pastes was greatly decreased by heating at 300°C. Autoclaving is very effective to develop dense microstructure for these cement pastes. However, the cement paste with a silica fume content of 0.24 exhibited a

greater porosity than the one without any heating treatment. Such a heat treatment resulted in an increase in coarser pores in the cement paste with a less silica fume content. It is found that the effectiveness of autoclaving in the reduction in porosity was dependent on the content of silica fume in mixtures.

Pore size distributions for both RPCs and cement pastes are shown in Figure 4. From Figure 4, threshold diameters of pores are found to be reduced by the addition of quartz powder and silica sand. It is also found that the total porosity was decreased by the addition of siliceous materials in the specimens cured at 90 and 200°C. However, the porosity of RPC autoclaved at 300°C was almost the same as that of the cement paste. Figures 3 and 4 clearly show that heat treatments greatly changed porosities of RPC [7]. However, heat treatments should be carefully optimised for reducing porosity.

3.3 Identification of Reaction Products by XRD Patterns

XRD patterns for cement pastes are given in Figure 5. The diffraction patterns do not change with the ratio of silica fume to cement in the cement pastes cured at 90°C. Crystalline products such as calcium hydroxide are not present in the pastes. Addition of silica fume had no substantial effects on the types of hydration products as far as cured at 90°C. XRD patterns for cement pastes cured 200°C are almost the same as those at 90°C. However, slight peaks of 11Å tobermorite were detected in cement pastes cured at 200°C.

Figure 5. X-ray diffraction patterns of cement pastes at various curing temperatures (Age = 7 days)

When cement pastes were autoclaved at 300°C, the broad background around $2\theta=30^\circ$ was not so remarkable as cured at 90 and 200°C. This result suggests that parts of the amorphous CSH products transferred into crystalline ones. Actually, more peaks were present in the pastes cured at 300°C, compared with the pastes cured at 90 and 200°C. At a low silica fume to cement ratio of 0.24, xonotlite, α -C₂SH and tobermorite were identified in the autoclaved paste. Namely, these three crystalline CSH products with different Ca/Si ratios coexisted in the pastes. In the cement pastes with higher ratios of silica fume to cement, conspicuous xonotlite was found. This result implies the increase in the initial amount of amorphous silica such as silica fume led to the formation of xonotlite at 300°C. On the other hand, the increase in the initial amount of amorphous silica seems to reduce the intensity of peaks of α -C₂SH, as found in Figure 5(c). It is found from Figure 5 that differences in the initial content of silica fume results in different reaction products.

The addition of quartz powder and silica sand also affected the formation of crystalline products at high curing temperatures, as shown in Figure 6.

Figure 6. X-ray diffraction patterns of RPCs (Silica fume/cement ratio =0.325, Age=7days)

Those materials are expected to supply additional silica growing an optimum content of crystalline products. The intensity of tobermorite peaks in RPC with quartz powder cured at 200°C was not so conspicuous as in the corresponding cement paste cured at 200°C. At 300°C, all the X-ray diffraction peaks of quartz completely disappeared in the quartz powder-containing RPC. Quartz powder was fully consumed as a source of silica in the reaction with lime at a high temperature. This consumption of the silica from quartz, on the other hand, also contributes to the formation of amorphous CSH products judging from the fact that the background around $2\theta=30^\circ$ was slightly higher than in the paste cured at 300°C. Production of amorphous CSH products was also appreciable in RPC with quartz powder and silica sand. As shown in Figure 6, the background around $2\theta=30^\circ$ was raised further. It is found from Figures 5 and 6 that the addition of crystalline silica of quartz powder and silica sand promoted the growth of crystalline CSH products as well as amorphous CSH. Supply of so much silica from crystalline and amorphous original materials may result in different microstructures from the pastes without additional silica materials.

4. DISCUSSION

Post setting heating may be the most crucial treatment in enhancing strength at an extremely low water/binder ratio in RPC. The heating treatment is expected to reduce porosity of the system due to the formation of dense crystalline products.

Figure 7 shows the relationship between compressive strength and porosity obtained by the SEM-BSE image analysis in RPC with quartz powder and silica sand. A good correlation exists between both. It is found from Figure 7 that the strength of RPC with an extremely low water/binder ratio closely correlates with the porosity of large capillary pores, which were not occupied by reaction products. Therefore, in order to further increase the strength, it is necessary to remove those large pores from the system. However, it should be noted that the RPC cured at 300°C exhibited an extremely low strength whereas its porosity was quite low at 7days. Variation of porosity is closely

related not only to the degree of reaction but also to the types of reaction products. Therefore, such a dependence of compressive strength on the porosity should be also discussed from the viewpoint of effects of temperatures on the types of reaction products.

4.1 Strength Development of RPC Cured at 20°C and 90°C

The strength of RPC cured at 20°C is not so different from the strength of conventional high strength concrete. However, the mixture of RPC had an optimised granular packing. In other words, the homogeneity of constituent phases in RPC was also improved by granular packing without coarse aggregate. Nevertheless, the dense packing and homogeneity did not increase the strength in the RPC cured at 20°C. Therefore, it is realized that heating is the most important process to obtain an ultra high strength in RPC [7]. The homogenisation in terms of granular packing only had the secondary effect on the evolution of strength in RPC as far as cured at a room temperature.

Curing at 90°C in RPC increased strength, as shown in Figure 2. The increase in strength with curing temperature is found to be due to the lower porosity in RPC cured at 90°C when we compared it to the porosity of RPC cured at 20°C (Figure 3). Furthermore, as shown in Figures 5 and 6, X-ray diffraction peaks of calcium hydroxide crystals completely disappeared in the mixture cured at 90°C. Therefore, it is clearly found that the increase in compressive strength resulted from the acceleration of hydration of cement and pozzolanic reaction of silica fume [1]. The greater strength of RPC with quartz powder and silica sand than the paste is also derived from the reduction in porosity, as shown in Figure 4. However, quartz powder may be generally stable and inert at 90°C so that, probably, it does not take part in chemical reactions. Further research is necessary for the reduction in porosity when quartz powder is included in the system.

4.2 Strength Development of RPC Cured at 200 and 300°C

Curing at 200 and 300°C produced crystalline products in addition to the acceleration of chemical

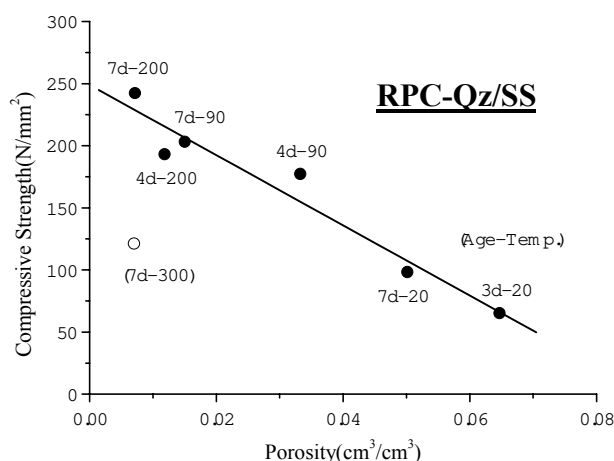

Figure 7. Compressive strength vs. capillary porosity determined by the SEM-BSE image analysis (Silica Fume/Cement =0.325)

reactions in the system. In CaO-SiO₂-H₂O systems, the amount and size of siliceous materials affect the process of the production of CSH. Namely, the final products of CSH depend on the reactivity and surface area of silica initially available for reactions. Generally, if the silica is crystalline, then tobermorite is easy to grow in the system at a high temperature of 200 and 300°C. When much amorphous silica is supplied to the reaction at hydrothermal conditions, the system prefers to transfer amorphous CSH gel into xonotlite as a final product [8]. Those products with different

CaO/SiO₂ ratios are also different in morphology and density. Therefore, the porosity of the system is influenced by the type of reaction products.

11Å tobermorite was identified as a main crystalline product in the cement paste cured at 200°C. This situation was not changed by the addition of fine quartz powder. Furthermore, the addition of quartz powder and silica sand raised background around 2θ=30° in XRD patterns. This rising of the background may be due to the formation of amorphous CSH products. Taking account of the characteristics of hydration products and the pore size distributions obtained by the BSE image analysis, it may be concluded that the densification due to coexistence of the crystalline tobermorite with large amounts of CSH gel led to an ultra high strength of about 250MPa. A suitable mixture of well and poorly crystalline materials appears to lead to an ultra high strength in RPC cured at a high temperature of 200°C.

On the other hand, curing at 300°C reduced the strength significantly. The porosity for coarse pore was decreased remarkably in the RPCs with higher ratios of silica fume to cement. As found from XRD patterns of Figure 5, regardless of the ratio of silica fume to cement, X-ray diffraction peaks of α-C₂SH, 11Å tobermorite and xonotlite were detected in cement pastes. In particular, the peaks for xonotlite are conspicuous in the RPCs cured at 300°C. Even when fine quartz powder was incorporated into the RPCs, no remarkable differences in XRD patterns were found. Originally, the fine quartz powder is used to form reaction products with a low density at a high temperature. However, the addition of the quartz powder in the mixtures effectively failed to form crystalline materials, which contributed to the increase in strength. It is also pointed out that the addition of much silica is necessary so that α-C₂SH is not deposited in hydrothermal reactions of CaO-SiO₂ systems for producing a high strength cement system [9]. Feldman and Beaudoin [10] showed that formation of α-C₂SH with a high density resulted in the increase of porosity in the system. They also pointed out that poor bonding of the crystalline products resulted in low strength of the cement mixtures. Differences in the initial silica fume content in mixtures seem to relate to differences of amounts of silica available for reactions. In the RPC with insufficient silica fume in this study, so much α-C₂SH had been produced that the strength was decreased.

It should be also noted that the formation of xonotlite with a high density in the RPCs also increases the porosity of the paste. On the other hand, as shown in Figures 5 and 7, the RPCs cured at 300°C had a quite low porosity for coarse pores. Taking account of the low strength of the RPCs with a low porosity for coarse pores, the silica contents in the mixtures were not appropriate for increasing strength by autoclaving in this study. Such an improper combination of mix proportions with thermal treatments resulted in the formation of α-C₂SH with a high density so that porous pore structures were formed in the systems at a level of microscopic scale at least less than the resolution of image analysis of 0.22μm.

It is pointed out that the formation of crystalline products such as xonotlite contributes to an ultra high strength of RPC[1]. As reported by Richard and Cheyrezy [1], an ultra high strength of 800MPa was obtained for the RPC treated at high temperature of 250-400°C. Actually, the effectiveness of xonotlite has been also recognized in the synthesized CSH. Simple heating for RPC may make up hydrothermal conditions for producing xonotlite [1]. However, as mentioned above, the formation of xonotlite does not always increase the strength of RPC in this study. An excess formation of xonotlite should be avoided to obtain RPCs with an ultra high strength. It is necessary to establish appropriate curing regimen for a RPC, corresponding to its mix proportion and the property of ingredients.

5. CONCLUSIONS

- A RPC with an ultra high strength of 250MPa was obtained by heating at 200°C in a combination of relatively high water/binder ratio of 0.21 and common siliceous materials.
- A high strength of RPC at 90°C resulted from the reduction of porosity due to the acceleration of hydration and pozzolanic reaction. There were no crystalline products which contributed to the increase in strength.
- Heating at 200°C without applying a pressure led to the formation of a crystalline product of 11Å tobermorite. The coexistence of the crystalline materials with much CSH gel resulted in an ultra high strength.
- Autoclaving at 300°C drastically decreased the strength of RPC. Deposition of high density products of xonotlite and α -C₂SH may give rise to the formation of porous microstructures at a microscopic scale less than the resolution of the image analysis. Formation of much xonotlite should be avoided for producing RPCs with an ultra high strength.
- Large capillary pores still existed even in the mature RPC with an extremely low water/binder ratio. There was a good correlation between the strength of RPC and the porosity for large pores.
- Post-setting heating as a curing method is not always effective for increasing strength of RPC. The processing, especially heating temperature must be carefully optimised for obtaining an ultra high strength in RPC with variable ingredients.

ABSTRACT

Most of the recent works [1] on cement additives focused the attention on their effectiveness on cement performances in terms of mechanical and rheological properties. Our mission has been to monitor the interface between the components of cement additive and the cement grain surface, in the presence of small (cement grinding) and large (cement hydration) amount of water.

We assembled data concerning mill output, specific surface area, particle size analysis, electrophoretic mobility and particularly microstructures of hydrated cement products investigated by Environmental Scanning Electron Microscopy - Field Electron Gun (ESEM – FEG). Even if this work is still in progress, we can make a reliable hypothesis about the pre-hydration of clinker during grinding process, which is significantly influenced by the presence of the active components (alkanolamines and glycols) of cement additive, or better of Grinding Aids (GA).

1. INTRODUCTION

The introduction of GA, started more than 50 years ago, has as its ultimate task the prevention of cement particle re-agglomeration during and after the milling process [2]. What makes GA application even more desirable is their significant effects on mechanical properties of cement, whose particle size distribution narrows and shifts towards smaller diameters [3].

Their influence on cement chemico-physical behaviour has been attributed to the reduction of surface energy forces generated on cement grains during comminution. According to this thesis [4], GA are constituted of polar organic compounds such as alkanolamines, which arrange their dipoles so that they saturate the charges on the newly formed particle surface, reducing re-agglomeration. Nevertheless, this kind of additive is efficient even at very low dosage (< 500 ppm), which cannot give a complete cover on cement particle surfaces, that is for a complete screening of the free charges. Moreover, it cannot explain their effects on subsequent mechanical properties of cement paste.

Various research groups followed different approaches to go further in the interpretation of the GA action. Some authors [5] have been involved in the analysis of alkanolamines and glycols based GA, extracted from dry cement by different technics. Besides the intrinsic difficulty in the extraction of these polar compounds once they interact with cement, it has been hypothesized [5(a)] that either an irreversible physical adsorption or a chemical interaction with cement salts occurs, favoured by high temperatures (100-120°C) reached inside the mill during grinding.

Much more interest has been shown on the influence of these alkanolamines or glycols as admixtures on cement hydration and strength development. It is well known [6], for example, and well accepted that alkanolamines (especially TriIsoPropanolAmine - TIPA) interact preferentially

with iron based phases of cement [6(b)] . In the same way the effect of TriEthanolAmine (TEA) on cement setting time is still debated [1(a),7].

Our approach to the study of the GA mechanism of action took advantage of our experience of cement behaviour during hydration and tried to focus the attention on the morphological effects of GA on cement.

2. EXPERIMENTAL

2.1 Materials

Beside the reference Portland clinker describe before, an OPC type I cement were used, whose chemical composition, expressed in element oxides, is reported in Table 3.

Table 3. Chemical Composition of the Reference Portland Clinker

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	Na ₂ O	K ₂ O
20.98	4.64	1.89	63.79	2.05	3.33	0.20	0.84

For Zeta potential measurements we also utilized other commercial cements: a Fondue, a white Portland cement and a ferric clinker.

Alkanolamines and glycols used in our experiments are commercial products which have been added by a sprinkler inside the mill or mixed with water before addition to cement in the concentrations indicated. The PolyCarboxylic Acid Esters (PCAE) superplasticizer is a laboratory test product (MW 50.000 D), while the poly-Naphtalene-Sulphonate (NS) comes from our production.

2.2 Chemical analysis (ICP-AES)

The sample is subjected to acid attack with concentrated HCl in a Parr bomb, using a microwave oven. The solution is filtered, diluted and analyzed by atomic emission spectroscopy on a Varian Liberty 220 ICP-AES.

2.3 Grinding process

For grinding experiments a laboratory mill type Bond for clinker grindability test has been used: rounds/minute = 70; grinding media = 32,5 kg (balls Ø = 17-40 mm). 2 kg of clinker is loaded after comminution to a grain diameter < 3 mm.

2.4 Blaine specific surface area measurements

After 30, 45 and 90 minutes a sample of 5 g of clinker is taken from the mill and its specific surface area is measured according to EN 196/6 (Blaine method).

2.5 BET surface area measurements

For the measurement of BET surface area of ground clinker powder a COULTER SA 3100 porosimeter has been utilized. Sample weight is 10 g and adsorbate gas is an He/N₂ mixture.

2.6 Alpine mechanical sieving

20 g of ground clinker is analyzed by an air-jet Alpine sieve 200 LS-N

2.7 Zeta potential measurements

For the measurement of Z potential of cement powder a COULTER DELSA 440 Multi-angle electrophoretic light scattering analyzer has been used. The sample powder has been dispersed in phosphate buffer pH 12 (12 mS).

2.8 ESEM-FEG analysis

The samples have been analyzed by scanning electron microscopy, without any previous treatment. We have used a Philips XL30 ESEM-FEG (Environmental Scanning Electron Microscope, equipped with a Field Emission Gun) in secondary electron mode. The instrumental configuration allows us to obtain a much higher brilliance of the electronic source than the one of an ordinary SEM, and to work in low vacuum conditions (6 Torr), with a voltage of 10kV, at a temperature of 5°C.

2.9 Temperature profile analysis.

The temperature variation during the first 24 hours of the hydration period is continuously recorded by a TESTO 781 digital thermometer, equipped with a TESTO DQF 826 probe (sensitivity: $1/1000$ °C). The probe is dept into the cement paste (500 g cement) immediately after mixing the cement with water. The system is kept in a thermostatic bath maintained at 20°C (reference temperature).

3. RESULTS AND DISCUSSION

We set up a grinding procedure utilizing a Bond type lab mill, in order to check the effectiveness of GA components we were going to study and to prepare all the samples we tested. Obviously our procedure has not much to do with the industrial process, since both particle size distribution and specific surface area are quite different in the two case. Nevertheless, we could easily verify its internal consistency.

We chose an Ordinary Portland clinker as a reference substrate, whose specific gravity is 3,11 g/cm³ and chemical composition, expressed in element oxides, is shown in Table 1.

Table 1. Chemical Composition of the Reference Portland Clinker

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	Na ₂ O	K ₂ O
25,21	5,13	3,97	59,99	1,29	1,32	0,25	0,64

As a grindability parameter we used Blaine Specific Surface Area (BSS) development during the milling process. In Figure 1 we show BSS development utilizing some typical raw materials of GA at the dosage indicated.

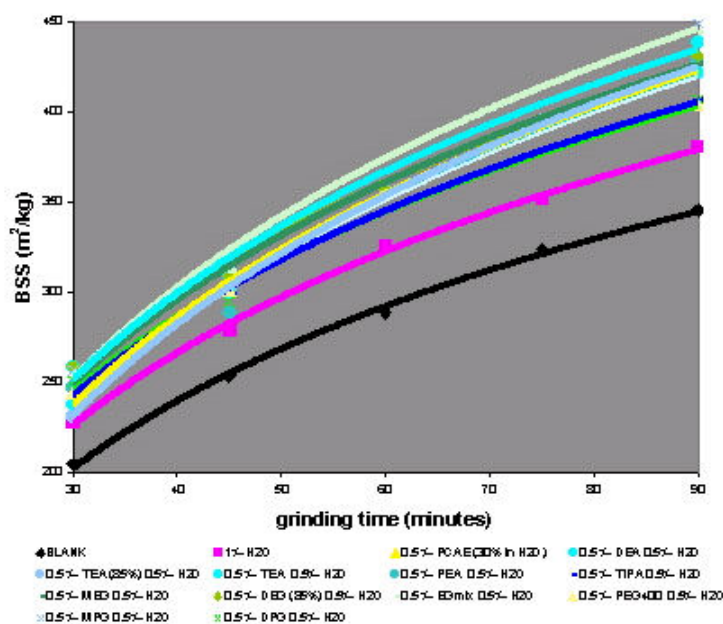

Figure 1. Blaine Specific Surface (BSS) area development of reference OP clinker ground in a lab mill Bond type.

These data clearly show that water is a decent GA, as is long known [4], but other components such as ethylene- and propylene-glycols or ethanol- and isopropyl-amines give a much larger contribution. Also PolyCarboxylic Acid Esters (PCAE), largely utilized as superplasticizers in concrete prove themselves to be as good GA. This lead us to hypothesize that also the further contribution by small organic molecules such as alkanolamines and glycols does not come necessarily and only from a further electrostatic screening, but also from steric or chemical interactions with cement particles. These BSS data has been confirmed by accurate adsorption/desorption isotherms measurements by BET calculation. Results are shown in Figure 2.

Figure 2. B.E.T. Specific Surface Area of reference clinker powder after 90 minutes' grinding

Also particle size analysis was performed using a mechanical Alpine sieve (Table 2): laser scattering of some of these samples give more or less the same trend.

Table 2. Sieve data with different grinding agents

Grinding Agents	Passing (%)		
	32 μm	40 μm	63 μm
Blank	77,0	83,9	94,8
1,0 ‰ H₂O	80,0	86,8	97,2
0,5 ‰ H₂O + 0,5 ‰ TEA	95,2	97,7	99,5
0,5 ‰ H₂O + 0,5 ‰ TIPA	96,4	98,1	99,5
0,5 ‰ H₂O + 0,5 ‰ DiEthyleneGlycol (DEG)	92,1	95,9	98,3
0,5 ‰ H₂O + 0,5 ‰ PolyEthyleneGlycol (PEG) 400	84,8	90,6	97,6
0,5 ‰ H₂O + 0,5 ‰ PCAE	74,8	83,6	92,0

Evident exceptions are PCAE and PEG, which do not give good results in term of granulometry. We hypothesized that sliding friction generates local heat, which makes polymers on grain surface sticky, preventing flowability of cement powder.

Z potential can give some indication of Ga influence on grain surface charge distribution, since in a suspension it is a function of the electrophoretic mobility due to the electrostatic forces at the particle surfaces. Its values associated with cement particles suspended in an aqueous solution with fixed ionic strength and pH (see experimental) has been measured by multi-angle electrophoretic light scattering (ELS). The scattering angle of detection chosen was 17.1°, because it gives the highest resolution for particles with diameter less than 10 μm , the most significant for this kind of measurement. In Figure 3, the differences between Z potential values, obtained with and without admixtures, of particles from mineralogically different cements are reported. Since it is defined as the electric potential at the shared plane, this is the layer of water molecules which moves together with the particle, Z potential has negative absolute values. This means that the more positive difference value the higher the module of the negative potential and vice versa.

Figure 3. Z potential variation due to some admixture components

We compared TEA, a typical polar GA component, with two concrete superplasticizers admixtures such as PCAE and poly Naphthalene Sulphonate (NS), whose mechanism of action on cement paste is quite different. The former acts according to a steric mechanism coating cement grains, as is evident from the negligible, eventually negative, influence on Zeta potential of any kind of cement powder. The latter, instead, induce a strong electrostatic interaction between its sulphonate groups and positive charges on grain surfaces, which means a strong enhancement in Zeta potential values. TEA action is somehow in between the two situations. When C-A phases/C-Z-F phases > 1, TEA act as Zeta potential enhancer, while if C-A phases/C-A-F phases < 1, as in Portland cement clinker, its electrostatic effect is negligible. This can be explained by the well known chemical complex of TEA with the ferrite phase, which gives higher importance to steric effect.

In order to make a definite breakthrough in we exploited the potential of the ESEM-FEG to explore the microstructure of cement (and clinker) paste in the early hydration period. We used an Environmental Scanning Electron Microscope equipped with a FEG source (ESEM-FEG), which allows to study the samples without any previous treatment, like gold or graphite sputtering, and in the presence of some residual water. We chose working parameters (pressure = 6 Torr; temperature = 5°C), in order to discriminate the kind of water present in the sample. Under these conditions, it is possible to see only the water saturated with salts or bound to gel-like structures, while free water has a sufficient vapor pressure to evaporate.

This powerful technique enabled us to observe directly the “supramolecular structures” forming on the surface of a cement grain, when it comes in contact with water, and to follow the details of the hydration process. We developed the following model mechanism of cement hydration, based also on our preceding observations [8].

When the cement comes in contact with water, we observe the almost immediate formation of a gel on the grain surface. This gel, based on complex sulfoaluminate hydrates, is rich in water and salts. It exerts a barrier effect and governs the mass flow between inner part of the grain and pore water, thus controlling the hydration of silicate phases.

This gel evolves with time, becoming “structured” and forming colloidal crystals that connect cement grains. All additives and admixtures that work on the plastic phase of cement paste interact with this gel and become part of it, modifying its structure in terms of quantity and quality. These modifications also depend on the chemical composition of the cement itself.

After an intermediate phase when the gel appears partially destructured, the first gel converts to a second one, from which calcium silicate hydrates (C-S-H) and ettringite form, not by precipitation but by mineralogical growth, probably influenced by free hydrated lime.

On one hand, the structures that arise from the second gel account for cement mechanical properties. On the other hand, timing and mode of the second gel “growth” strongly depend on the characteristics of the first gel in terms of thickness, chemical composition and stability. In the light of these considerations, we suppose that all kind of admixtures work on the first gel.

The hypothesis of a chemical composition based on sulfoaluminate hydrates comes from the fact that aluminate phases (C_3A and C_4AF) are the first to react with water, forming the corresponding aluminate hydrates, and that sulfate is present as a consequence of gypsum (or other forms of calcium sulfate) dissolution.

The delayed setting of cement is then caused by the formation of the gel, a form of colloidal ettringite, and not by precipitation of ettringite itself. Its distinct long hexagonal rods appear only after few hours from the beginning of the hydration, as a consequence of the sulfoaluminate gel transformation.

The relative amounts of Ca^{2+} , Al^{3+} and SO_4^{2-} changes with time, modifying the “permeability” of the gel and allowing the hydration of the silicate phases, that proceeds toward the inner part of the cement grain. This means that the C-S-H structures grow from and through the gel layer, rather than precipitate from the external pore water solution.

Since the gel forms within few seconds and covers cement grains completely, it actually represents the grain surface when water is present, and any substance added to the cement must interact with the gel.

This means, for example, that during industrial grinding process of clinker, carried out in presence of water and GA, we just have the conditions for a preliminary hydration of clinker: in fact the addition of aqueous additives, the high temperature (up to $150^{\circ}C$) and the presence of steam promote the hydration of clinker grain. For this reason in our investigation on the “mode” of action of alkanolamines based GA we focused our attention on morphological modifications of hydration products of clinker and cement. As a matter of fact, only small amounts of GA (3-5‰) are usually added into the mill, but they become significant, if we consider that only the 2-5% of clinker participates in the hydration process.

In this paper we describe only the effect of alkanolamines on morphological structures of calcium aluminate hydrates by ESEM-FEG analysis, also compared with PCAE used as a GA.

In order to emphasize the action of the additives, we used the clinker ground in the lab mill without gypsum in our experiments.

As shown in Figure 4, the dry clinker powder, ground with or without additives, does not show any particular morphological structure of hydrated products.

Figure 4. ESEM-FEG images of a Portland dry clinker grain ground with: a) no additive; b) 1,0 % H₂O; c) 0.5 % H₂O + 0.5 % of TEA.

In our opinion, this is an effect due to a mechanical action of grinding media, which break the hydrates that, therefore, become too small to be seen by ESEM-FEG analysis. When we analyzed the morphological structures of a ground clinker paste with a water/clinker ratio of 0.4 (Figure 5), we noticed that the clinker grains still look well separated, but become covered with pseudo-regular gel-like structures, which cannot be observed in dry powder. It is evident that the gel formed by the paste of the clinker ground without GA (a) is less structured than that of the clinker ground with TEA (b).

Figure 5. ESEM-FEG images of a Portland clinker paste (w/c = 0.40) ground with: a) no additive; b) 0.5 % H₂O + 0.5 % of TEA.

The chemical composition of this gel is based on aluminate hydrates: in fact the aluminate phases (C₃A and C₄AF) are the first to react with water, forming the corresponding aluminate hydrates which directly interact with TEA [7]. A great surprise comes from the morphological analysis of a clinker ground without GA and formed into paste with water and TEA (w/c = 0.4, TEA = 0.5% w/w on the clinker), shown in Figure 6.

Figure 6. ESEM-FEG image of a clinker ground without GA and formed into paste with water and TEA (w/c = 0.4, TEA = 0.5% w/w on the clinker).

Comparing Figures 5b and 6, we can deduce that TEA produces the same kind of calcium aluminate hydrates added both into the mill and into the mixing water.

This observation suggests that the clinker maintains a “memory” of the manufacturing process. The shape of these hydrates looks like the hydration products of C_4AF , synthesized in our laboratory (Figure 7).

Figure 7. ESEM-FEG image of synthetic C_4AF paste (water/ C_4AF = 0.4).

Figure 8 shows the gel formed during the hydration of a clinker ground with PCAE, with a water/clinker ratio of 0.4; as we can see, this gel does not show typical morphological changes on aluminate hydrates, even if the grinding process indicates the efficiency of this admixture as a GA.

Figure 8. ESEM-FEG image of a clinker ground with 0.5% of PCAE + 0.5% of H_2O and pasted with water (w/c = 0.4).

Considering that, when PCAE is used as a superplasticizer, we observe a huge formation of structured gel (Figure 9), we can hypothesize that PCAE actually works on sulfoaluminate hydrates, that we can call colloidal-ettringite, rather than on aluminate hydrates.

Figure 9. ESEM-FEG image of an OPC type I paste ($w/c = 0.35$), with the addition of 0.5% (w/w on the cement) of PCAE.

Since it is well known that TEA based GA also improve the cement performance, especially compressive strengths at 24 hours, we tested the effect of this component on the clinker mixed with gypsum (as in Portland cement) during hydration. This behavior is reflected in the temperature profile experiment. We recorded the temperature variation of two different “cementitious” pastes: one is a mixture of clinker ground with TEA and 5% of gypsum, the other a mixture of clinker ground without GA and 5% of gypsum. Both mixtures were hydrated with a water/cement ratio of 0.5. As shown in Figure 10, two distinct peaks are present: the first is very sharp and can be ascribed to the formation of hydrated sulfoaluminate phases, which is a quite exothermic reaction; the second peak is broad and is related to the formation of free lime and C-S-H, which develop the mechanical properties of cement.

Figure 10. Temperature profile of clinker hydration with 5 % gypsum and $w/c = 0,5$.

From these analytical data it becomes apparent that TEA acts as an accelerator of C_3S hydration, then enhancing compressive strength of cement at the early ages. Morphological analysis of the two pastes reveals that the sulfoaluminate gel is the same in term of structures, which means that addition of gypsum hides any qualitative information. But, comparing structures at the same time of hydration, in the case of clinker ground with GA, C_3S hydration, and so the growth of C-S-H, is clearly faster and at 4 hours we already note the complete cross-linking of the grains by the structured gel.

With this work we have shown that alkanolamines interact with calcium aluminate hydrates, inducing morphological changes on the gel that covers clinker powder. In our opinion these structures could be the key point of clinker particles dispersion during grinding process and of their fluidizing effect. Therefore we can hypothesize both an electrostatic and a steric repulsive effect on the cement grain, probably related to the different chemical compositions of the gel.

4. CONCLUSIONS

According to these results GA, in particular alkanolamines, influence the early period of clinker and cement hydration and induce morphological changes in calcium aluminate (C_3A and C_4AF) hydrates. We can also remark that clinker undergoes a pre-hydration reaction when it is ground in the presence of water and GA, and that it somehow keeps memory of the effect of alkanolamines on the hydration products formed during the milling process. This study is part of a more general investigation, whose target is to evaluate the chemical composition of the gel and to clarify the “mechanism of action” of other classes of admixtures on the formation of the gel. At present time we are studying the characterization of the first gel. A direct chemical analysis (by ESEM-EDX or XRD) is not possible because the “structures” are too small (< 100 nm) and the gel layer is very thin (10-100 nm): in these condition the influence of the matrix (the cement grain) is too strong.

ABSTRACT

The influence of some activators (Portland clinker, gypsum, sodium silicate solution), just as found, or blended, on strength development and durability of cementitious materials, prepared with large amounts of granulated blast furnace slag, has been examined. It has been pointed out that small amounts of clinker and gypsum in the blends are determining factors for obtaining a binder with good compressive strength, resistant to carbonation, sulphate attack, freezing/thawing, and, most likely, to alkali-aggregate reaction, too.

Keywords: alkali-aggregate reaction, blast furnace slag, carbonation, compressive strength, durability, freezing/thawing, sulphate resistance.

1. INTRODUCTION

There is considerable interest [1] in utilising industrial by-products for preparing high-performance cementing materials, firstly for low production cost, energy saving and environmental protection through abatement of the greenhouse effect. Granulated blast furnace slag, ground to an appropriate fineness, appears to be well-suited for manufacturing through stimulation with a proper activator. High-performance cementing materials endowed with properties at least comparable, or sometimes better, than those of Portland cement [2] and therefore right for playing an important role in different construction fields, including waste storage. Among the various activators, - Portland clinker, gypsum, alkalis - sodium silicate solutions have shown many benefits in terms of upsurge of the latent hydraulic activity of the granulated slag and of the development of the strength of the related works.

Several aspects, however, are in need of further investigation, of which the first is the durability of the works. Considering that granulated blast furnace slag shows different properties, depending on nature and concentration of activators employed [3], we have thought worthwhile to assess the influence of some activators, just as found, or in blend, on the durability of cementing materials with high slag contents, against some agents, in order to optimise its composition in view of the performance expected.

2. EXPERIMENTAL

2.1 Materials

The select activators have been:

Portland clinker, gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ 97%), sodium silicate solution ($\text{SiO}_2/\text{Na}_2\text{O}$) = 1.0), and some blends of the above mentioned activators.

The influence of the replacement of different amounts of Portland clinker and gypsum has been examined. As mixing liquid has been used not only water, but also sodium silicate solution, respectively. Terms of reference have been: plain granulated slag mixed with water and with sodium silicate solution, respectively, and a cement Type III/B (according to EN 197-1 Specification) containing 70% slag, 27% Portland clinker and 3% gypsum.

Fineness of clinker and slag has been $360 \text{ m}^2/\text{kg}$ Blaine. Gypsum has been screened through a 63-micron sieve. The chemical compositions of the slag and Portland clinker used are summarised in Table 1.

Table 1. Composition of the Slag and Portland Clinker

Material	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	loi	$\text{K}_2\text{O} + \text{Na}_2\text{O}$	C_3S	C_2S	C_3A	C_4AF
Granulated Slag	36.4	10.8	0.7	42.3	8.1	0.8	0.3				
Portland Clinker	21.2	4.9	3.3	66.2	1.8	0.1	0.9	56	18	7.3	10.0

The compositions of the blends, with the identification number quoted also in Figures are shown in Table 2.

Table 2. Composition of the Blends

2.2 Test Procedures

Mortar prisms (40 x 40 x 160 mm) were produced from blends with standard aggregate, in accordance with EN 196-1 Specification, using, as mixing medium, water or sodium silicate solution, respectively. After 24 hours at 20°C and RH > 95%, the specimens were demoulded. All specimens were cured for 27 days in water before placement into its final environmental condition.

Triplet specimens of each blend was subjected to the following tests:

- compressive strength at 28 days age;
- compressive strength after storage of 365 days in water;
- compressive strength after storage of 365 days in air;
- depths of carbonation measured after 365 days on specimens stored at 20°C, RH 65% at normal CO₂ concentration (0.03% by volume). The prisms were split so that a fresh face was exposed for measuring the penetration of carbon dioxide. The face was sprayed with phenolphthalein so that the carbonation could be measured;
- resistance in magnesium sulphate solution: storage in a 5% MgSO₄ solution. After 365 days the specimens were visually inspected and characterised by a durability index;
- resistance in sodium sulphate solution: storage in a 2.1% Na₂SO₄ solution. After two years the specimens were visually inspected and characterised by a durability index;
- freezing/thawing resistance, through assessment of the specimen weight after every cycle of 20 hours in air at -18°C and 4 hours in a 5% sodium chloride solution or in water, respectively, at 20°C [4];
- resistance to alkali-aggregate reaction [6] according to ASTM C 227 Specification. Mortar bars were made with Pyrex glass.

3. RESULTS AND DISCUSSION

3.1 Compressive strength

Figure 1 shows the effects of storage conditions on compressive strength development.

It can be seen that using alkaline solution as mixing medium, after 27 days in water, specimens can achieve values higher than those using water. However, blends containing Portland clinker and gypsum, mixed with alkaline solution, give mortar specimens with lower strength values than those recorded for specimens prepared with slag alone. Blends containing 5% gypsum, mixed with water, achieve compressive strength values very near to those recorded for blends containing 25% clinker.

A subsequent one-year storage in water increases compressive strength both of specimens made with blends mixed with water and with alkaline solution, respectively. Alkaline solution however causes lower strength values than those recorded for specimens made with slag all by itself. Good results have been obtained by blends containing slag and gypsum, mixed with water and stored one year in water.

One-year storage in air of specimens produced with blends mixed with water causes a slight strength decrease, in comparison to values achieved after storage, for the same time, in water. The use of alkaline solution does not improve compressive strength values recorded after 28 days storage in water. Gypsum-free blends show a slight strength increase. There is therefore evidence that the use of an alkaline solution increases the compressive strength only for specimens produced with slag alone. On the contrary, the use of an alkaline solution as mixing medium of blends made with granulated slag and Portland clinker, or with slag and gypsum, respectively, does not prove to be effective.

Figure 1. Compressive Strengths

Figure 2. Durability Tests

3.2 Resistance to carbonation penetration.

Figure 2 shows carbonation behaviour. There is evidence of steady carbonation abatement for specimens mixed with sodium silicate solution, a benefit from the viewpoint of protection of reinforcement [7]. There is likewise evidence of a benefit attributable to increasing additions of Portland clinker and gypsum, within the limits, of course, of the compositions examined, both for specimens mixed with water and for those mixed with sodium silicate solution. Portland clinker-free specimens, prepared adding 5% gypsum to slag, have shown low carbonation depth. Carbonation increases with the increase in gypsum content in the blend.

3.3 Resistance to sulphate solution

Figure 2 shows durability assessment for specimens stored in a magnesium sulphate solution. A numerical index between 0 (specimen disrupted) and 10 (sound) has been adopted. There is evidence of a general benefit provided by using alkaline solution as mixing medium, with negligible fluctuations. All the blends, regardless of the nature of activator and mixing medium, stay completely sound after two years of immersion in the sodium sulphate solution.

3.4 Freezing/ thawing resistance through immersion in NaCl solution.

Figure 2 also shows the number of cycles required for a 30% weight loss of the specimens, as a function of blend composition. There is evidence of an adverse contribution of sodium silicate solution as mixing medium, whereas Portland clinker amount in a blends mixed with water exerts a favourable contribution. Anomalous, in this case, the action of the gypsum alone, even if it does not appear to exert a significant influence.

3.5 Freezing/ thawing resistance through immersion in water.

Finally, Figure 2 shows that the outlines of the curves are pretty similar to those, reported in the same figure, resulting from immersion of the specimens in chloride solution, both for blends mixed with water and with sodium silicate solution, respectively. With the exception of the slag alone, blends mixed with water show higher durability than those mixed with sodium silicate solution.

3.6 Resistance to alkali aggregate reaction.

The test has been performed using, of course, sodium silicate solution as mixing medium. Blend compositions examined are those reported in Table 2 with numbers 10, 11, 14 and 18. The first three blends revealed no expansion of the related mortars, after 56 days. Mortar prepared with blend no. 18, showed expansion. In the same case, the use of standard sand (EN 196-1) in the place of the reactive Pyrex glass indicated that the unsoundness is very likely due to high sulphate content present.

4. CONCLUSIONS

The test results described in this paper have confirmed the advantageous properties of blast furnace slag-based cementing materials, manufactured with the help of activation by means of moderate amounts of a mixture of Portland clinker/gypsum and sometimes with sodium silicate solution as mixing medium. The presence of 5 - 10% Portland clinker in the blends and that of small amounts of gypsum seem essential to produce the best properties of such a binder. It shows indeed good strength, resistance to carbonation penetration, to sulphate attack and to freezing/thawing. Alkali-aggregate reaction resistance was not well assessed during the short length of time of the test.

Thus, prefabricated components appear to be a suitable utilisation of such a binder.

ABSTRACT

This paper presents the results of pozzolanic activity studies on synthetic high silica zeolites, their contribution to development of compressive strength of Portland-pozzolanic cements and the performance of high performance concretes (HPC) based on synthetic zeolites. Two types of zeolites (TON and MFI) in silica form and one (BEA) with a low aluminium content were prepared. Zeolites with sub-micronic particle sizes were also prepared.

The pozzolanic activity was determined in terms of zeolite's capacity for binding lime and the rate of the pozzolanic reaction. The contribution of synthetic zeolite to compressive strength development of Portland-pozzolanic cement was evaluated at 2, 7 and 28 days according to EN 196-1. The behaviour of HPC with synthetic zeolite was evaluated in terms of compressive strength and durability. The results were compared with those obtained by using silica fume.

From the experimental results the following observations were derived: the zeolite offering the best pozzolanic behaviour was TON; the zeolite producing in mortars and in concretes the higher mechanical properties was BEA; the general behaviour of zeolites was in any case superior to that obtained with silica fume.

Finally, the performance of HPC based on synthetic zeolites is in all cases similar or higher than that of concretes produced with silica fume.

Keywords: Pozzolanic activity, Silica fume, Synthetic zeolite, High Performance Concrete.

1. INTRODUCTION

The use of silica fume continues to increase despite its relatively high cost. The extensive utilization of silica fume in the concrete is due to its high degree of pozzolanic activity and its very high specific surface area. The pozzolanic and filler effects of silica fume reduce the porosity of the hydrated cement paste and the transition zone between the paste and aggregate. Therefore, the incorporation of silica fume in concrete increases the compressive strength and durability. However, the use of silica fume is limited to the geographic areas where its local supply is abundant [1]. In fact, its price is 2 to 20 times higher than the cement price, depending on the geographic area where it is used.

Pozzolanic activity includes two parameters, namely the maximum amount of lime that a pozzolan can combine and the rate at which such combination occurs. The high pozzolanic activity of silica fume derives from its chemical composition - very high silica content - and from the sub-micronic particle-size dimensions [2]. The small size of the particles speeds up the reaction with calcium hydroxide produced by the hydration of Portland cement [1].

The aim of this research was to study the production and utilization of a pozzolanic material that is suitable for use in the cement and concrete industries as a substitute for expensive silica fume.

Sersale and Frigione [3-7] have demonstrated that natural zeolites are excellent pozzolans and showed their use as constituents of blended cements and concrete. Katovic *et al.* [8-10] synthesized various zeolite types with very small particle sizes. So, the purpose was to transfer this knowledge to the cement and concrete field in order to find an effective substitute of silica fume.

For this purpose various zeolite-types having high specific surface areas were prepared. These synthetic zeolites were characterized on the basis of their pozzolanic activity, their contribution to the development of the mechanical resistance and the durability of the cement and concrete. The results were compared with those obtained by using silica fume.

2. MATERIALS AND EXPERIMENTAL PROGRAM

Three different synthetic zeolite types having small particle sizes were prepared [11]: BEA, TON, MFI (nomenclature according to the *Structure Commission of the International Zeolite Association* [12]):

- Silica fume (SF) "Force 10,000" by Grace;
- Cement CEM I 52,5R (EN 197/1): a commercial product. In Table 1 its characteristics are reported;
- Aggregate crushed limestone.
- Superplasticizer "Adva Flow" by Grace.

Table 1. Characteristics of the Portland Cement

s.s.a. Blaine, m ² /kg	Bogue Potential Compound Composition (%)				
	C ₃ S	C ₂ S	C ₃ A	C ₄ AF	CaSO ₄ · 2 H ₂ O
390	55	19	7	11	5

2.1 Preparation of Zeolites

In this study the zeolites were prepared starting from the following initial reaction mixture:

where:

$x = 0.1$; $y = 0.1$; $z = 0.02$; $w = 20$ for BEA;

$x = 0.1$; $y = 0.08$; $z = 0.0$; $w = 20$ for MFI;

$x = 0.06$; $y = 15$; $z = 0.0$; $w = 10$ for TON;

and ORG stays for the organic compound that is:

- tetraethylammonium hydroxide and bromide in the case of BEA type;
- tetrapropylammonium bromide in the case of MFI type and
- methanol for the TON type zeolite.

The synthesis procedure was the following: sodium aluminate was added to a sodium-hydroxide solution and after the homogenisation the organic compound and the silica source were added. For the synthesis of zeolites MFI and TON the procedure was identical but without the introduction of the aluminium source.

The zeolites BEA and MFI were prepared in Teflon lined autoclaves in static conditions under autogeneous pressure in a temperature range varying from 140 to 170 °C as a function of the zeolite type. The zeolite TON was prepared in a stainless steel autoclave under stirring (500 rpm) and

under autogeneous pressure at 140 °C. The products were cooled down to room temperature, washed and dried at 105 °C overnight. Further details on the synthesis procedures are reported in Katovic *et al.* [8-10].

The characterisation of the samples was performed by the following techniques: powder X-ray diffraction (Philips PW 1730/10, Cu K α_1 radiation), atomic absorption spectrophotometry (GBC 932 AA), scanning electron microscopy equipped with an EDX facility (Stereoscan 360 Cambridge Instruments) and, finally, nitrogen adsorption-desorption isotherms at 25°C were recorded using an automatic porosimeter (Micromeritics Asap 2000).

The chemical characteristics of synthetic zeolites and silica fume are shown in Table 2. The shape and particle size of samples under investigation obtained by SEM and the values of specific surface area (BET) are also reported in Table 2.

Table 2. The Pozzolan Material Characteristics

Material	Particle size (μm)	Shape	s.s.a. BET (m^2/g)	SiO ₂ (%)	Na ₂ O (%)	Al ₂ O ₃ (%)
TON	0.6 ÷ 1.0	needles	32	98.6	1.3	-
BEA	0.1 ÷ 0.3	spheres	70	93.0	2.0	4.9
MFI	0.3 ÷ 0.7	spheres	13	98.6	1.2	-
Silica Fume	0.1 ÷ 0.8	spheres	26	97.1	0.1	0.5

2.2 Materials Characterization

2.2.1 Pozzolan Activity

The various synthetic zeolites were studied concerning the pozzolanic activity - in terms of both capacity of binding lime and rate of pozzolanic reaction. For this aim, the "pozzolanic test" following the European Standard (EN 196-5) was performed. The capacity of binding lime was determined by defining the minimum zeolite/fixed Portland cement (Z/PC) ratio that is necessary for complying with the test. The test is "positive" if the concentration of calcium hydroxide in the solution is lower than the concentration of saturation. The rate of pozzolanic reaction was determined from the time at which the lime combination occurs by defining a zeolite/Portland cement fixed ratio Z/PC = 15/85. The time needed to obtain a positive response to the pozzolanicity test was determined from data collected daily.

2.2.2 Consistency and Compressive Strength on Mortar

The contribution of synthetic zeolites as a partial substitute for Portland cement so as to produce pozzolanic cement (Type IV according to EN 197-1) to the development of compressive strength was evaluated on mortar after 2, 7 and 28 days according to EN 196-1. The cement mortar consistency was determined according to UNI 7044 [13]. For this purpose, mixtures with Portland cement CEM I class 52.5 substituting one part with one of the pozzolanic materials in quantities that made a sample positive after 8 days were prepared. The results were compared with those obtained by using silica fume.

2.2.3 Compressive Strength on Concretes

The contribution of synthetic zeolite addition to concrete at a high dosage and a low w/c ratio was evaluated after 2, 7 and 28 days in order to obtain high performance concretes (HPC). The concrete mixture proportions are given in Table 3. The concrete was mixed in a laboratory pan mixer. The compressive strength measurements were obtained on 100 mm cubes. These were fully compacted on a vibrating table, damp for 24 hours before demoulding, and then cured at 20°C and 95% RH until testing. Each reported strength measurement is the average of six cubes.

Table 3. Concrete Mixture Composition

Material	Kg/m ³
CEM I 52.5 R	500
Crashed limestone ø 12.5 – 8 mm	595
Crashed limestone ø 8 – 4 mm	265
Sand ø 4 – 0 mm	850
Superplasticizer	5.2
Water	165
Slump Test (UNI 9418) mm	50

2.2.4 Durability Measurements

The potential concrete durability may be inferred by measuring the resistance of the cover layer to transport mechanisms for different types of fluid [14, 15]. Three durability tests have been developed: oxygen permeability, capillary water absorption and chloride conductivity.

Oxygen permeability tests were performed for all mixtures (with 14 days curing 20°C and RH>95%) at the age of 56 days. Until testing the specimens were stored at 20°C and 70% RH. Details of curing and preparation of specimens can be found in [16]. Oxygen diffusion through concrete is strongly affected by moist curing. The moisture condition of the concrete under test also has a large influence because water in the pores significantly reduces the diffusion. However the purpose of our tests is not to determine absolute material characteristics but to produce reliable values to be used for comparative purposes. The test procedure is based on the Cembureau method; details of the equipment and test procedure are given in [17]. The test procedure applied for capillary water absorption can be found in [18]. The chloride penetration resistance of concrete was determined according to the AASHTO T 277 rapid test method [19]. The fresh concrete (w/c = 0.35) was cast into cylinders (Ø = 11 cm, h = 22 cm) and 50 mm thick discs were sawed after one day of wet curing at 20°C. The specimens were stored at 20°C in 55% RH for 56 days before the chloride diffusivity measurements.

3. RESULTS AND DISCUSSION

The Ca²⁺ concentration values and the total alkalinity, expressed as hydroxide ion concentration (OH), that characterise the capacity and the rate of the pozzolanic reaction are reported in Table 4 and 5, respectively.

These data show that for complying with the pozzolanic test, the threshold amounts of zeolite in the mixture are, in the case of:

- TON type: 6 per cent;
- MFI type: 9 per cent;
- BEA type: 13 per cent;
- silica fume: 10 per cent.

From the results reported in Table 5, regarding the rate of the pozzolanic reaction, it can be seen that in the case of TON zeolite unsaturated solution in Ca(OH)₂ (positive test) appears just after 2 days. In the case of BEA zeolite the positive pozzolanic test is obtained after 3 days, while in the case of zeolite MFI and silica fume after 5 days.

In conclusion, for both capacity and rate of pozzolanic reaction, the best behaviour is showed by TON, with the pozzolanic activity greater than that of silica fume. The behaviour of BEA, MFI and silica fume is quite similar.

Table 4. Pozzolanic Capacity (after 8 days ageing)

Material	Conc. mmol/l	Pozzolanic Material/Cement					
		4/96	6/94	8/92	9/91	10/90	13/87
TON	Ca ²⁺	9.2	7.1				
	OH ⁻	59.4	53.1				
test		negative	positive				
BEA	Ca ²⁺					7.1	5.5
	OH ⁻					69.1	68.8
test						negative	positive
MFI	Ca ²⁺			7.9	7.5 p		
	OH ⁻			60.0	58.8		
test				negative	positive		
SF	Ca ²⁺		10.5	10.6	9.3	8.4	
	OH ⁻		57.2	54.3	54.0	51.6	
test			negative	negative	negative	positive	

Table 5. Rate of Pozzolanic Reaction (Pozzolanic material/Portland cement = 15/85)

Material	Conc. mmol/l	Days				
		1	2	3	4	5
TON	Ca ²⁺	13.6	7.5			
	OH ⁻	46.4	43.3			
test		negative	positive			
BEA	Ca ²⁺		8.6	6.5		
	OH ⁻		55.2	59.5		
test			negative	positive		
MFI	Ca ²⁺			11.3	8.0	
	OH ⁻			60.8	55.3	
test				negative	positive	
SF	Ca ²⁺				10.2	8.6
	OH ⁻				50.1	46.3
test					negative	positive

The compressive strength and the consistence of the standard mortars are given in Table 6. It can be seen that the compressive strength of the mortar incorporating silica fume and syntetic zeolites were approximately the same at 2 days as well as at 7 and 28 days, with values higher for the mixtures with BEA in both cases. As regards the workability, the behaviour of the zeolite TON is not satisfactory. The partial addition of the zeolitic material in the Portland cement does not reduce the early and final compressive strength. However, it can be observed that it is possible to produce pozzolanic cements (Type IV EN 197-1) that exhibit high resistance on compression also in the case of short curing.

Table 6. Consistency and Mechanical Strength of the Mortars

Cement	%	Pozzolanic material	%	2 days MPa	7 days MPa	28 days MPa	Consistency %
CEM I	100	-	-	36.4	47.7	56.2	68
CEM I	87	Zeolite BEA	13	37.1	49.2	64.3	57
CEM I	91	Zeolite MFI	9	37.0	46.1	56.0	72
CEM I	94	Zeolite TON	6	32.2	41.4	54.8	7
CEM I	90	Silica fume	10	34.9	44.8	58.9	52

Regarding the compressive strength of concretes, as seen in Table 7, the concrete made with addition of the zeolite BEA exhibits superior mechanical behaviour to those obtained with additions of silica fume.

Table 7. Concretes Compressive Strength

Concrete (made with)	w/c	compressive strength 2 days MPa	compressive strength 7 days MPa	compressive strength 28 days MPa
Zeolite BEA	0.35	78.5	89.3	102,7
Zeolite MFI	0.35	78.0	90.2	93,8
Zeolite TON	0.60	70.1	84.1	57,9
Silica fume	0.35	30.8	42.7	100,3

The concrete prepared with the addition of the zeolite MFI shows slightly inferior mechanical behaviour. In the case of the concretes prepared with the zeolite TON, it was necessary to operate at a w/c ratio equal to 0.60 in order to obtain a workability shown by other concretes. The obtained resistance values were, of course, substantially inferior to those shown by concretes with silica fume.

Regarding the durability, the results obtained are reported in Table 8.

Table 8. Durability test results

Concrete (made with)	Coefficient of Oxygen Permeability K (10^{-16} m^2)	Coefficient of absorption ($\text{g/m}^2/\text{s}^{0.5}$)	Chloride conductivity Coulombs
Zeolite BEA	0.049	9.5	111
Zeolite MFI	0.052	9.2	108
Silica fume	0.051	9.4	110

As seen from our aim, the tests on the concretes prepared with the zeolite TON were not made. From the results reported in Table 8, it can be seen that all the concretes tested have shown an excellent concrete performance.

4. CONCLUSIONS

Based on the studies of the pozzolanic behaviour, compressive strength and durability, the zeolites BEA and MFI exhibit a pozzolanic activity similar to that of silica fume and can be used as pozzolanic admixtures with high reactivity. The performances of concretes based on these synthetic

zeolites are in all cases similar or higher than those relative to cement and concretes produced with silica fume. The zeolite TON, even though it presented a high pozzolanic activity, is not suitable for the preparation of cements and high performance concrete (HPC) because the mixtures that contain it require a high w/c ratio.

In conclusion, zeolite materials obtained under particular conditions – high specific surface area – can favourably substitute silica fume either to obtain pozzolanic cements with high initial and final resistance or as an active addition to the HCP concrete.

USE OF FLUIDIZED BED COMBUSTION WASTES FOR THE SYNTHESIS OF LOW-ENERGY CEMENTS

Graziella Bernardo, Milena Marroccoli, Fabio Montagnaro and Gian Lorenzo Valenti

Dipartimento di Ingegneria e Fisica dell'Ambiente, Università degli Studi della Basilicata
Contrada Macchia Romana, 85100 Potenza (Italy), E-mail: valenti@unibas.it

ABSTRACT

Among the low-energy binders, calcium sulphoaluminate cements are worthy of consideration also because a wide range of industrial solid wastes can be utilized in their manufacture. In this paper, it has been proposed the use of mixtures composed of fluidized bed combustion wastes as raw materials for the synthesis of calcium sulphoaluminate cements. Several systems based on two fluidized bed combustion-derived wastes (a sulpho-calcic fly ash and a silico-aluminous fly ash), and a solid waste generated within a traditional coal-fired power plant, were heated in a laboratory electric oven for 2 hours at temperatures ranging from 1050°C to 1300°C. Calcium sulphoaluminate was often obtained and its formation was related to the waste nature and the burning temperature.

1. INTRODUCTION

In the last two decades much attention has been paid to low-energy cements which, compared to Ordinary Portland Cements (OPC), require lower synthesis temperatures or less grinding energy or inexpensive industrial wastes and by-products as raw materials [1-2].

All these features belong to calcium sulphoaluminate ($C_4A_3\bar{S}$)-based cements [3-9], inasmuch as they can be obtained at temperatures of 1300-1350 °C and the resulting clinkers are relatively friable. Furthermore, in the manufacture of Calcium Sulpho-Aluminate (CSA) cements a wide range of solid residues such as metallurgical slag, fly ash, chemical gypsum and other waste materials containing CaO, SiO₂, Al₂O₃ and SO₃ can be employed.

The aim of this work is to assess the suitability of Fluidized Bed Combustion (FBC) wastes as raw mix components for the CSA cements manufacture, and to investigate the influence of the thermal treatment on the synthesis process. This paper follows some preliminary investigations on residues generated in a FBC laboratory apparatus, whose results are reported elsewhere [10].

2. PROPERTIES AND USES OF CSA CEMENTS

The performance of sulphoaluminate cements is mainly due to the generation of ettringite, $C_6\bar{A}S_3H_{32}$, upon $C_4A_3\bar{S}$ hydration. Calcium sulphoaluminate can react with water in two ways: *i*) together with lime and calcium sulphate to give only ettringite, reaction (1); *ii*) combined with calcium sulphate alone to give ettringite and aluminium hydroxide, reaction (2):

Ettringite synthesized in the reaction (1) has expansive characteristics which can be exploited by special binders like shrinkage-resistant and self-stressing cements [11-12]. On the other hand, ettringite formed in the reaction (2) is not expansive and has the important property of giving high mechanical strength at early ages [13, 7].

Besides calcium sulphoaluminate, C_2S , C_4AF , $C_5S_2\bar{S}$, C_2AS , CA , $C_{12}A_7$ and C_3A can occur in CSA cements depending on the composition and proportioning of the raw materials employed for their manufacture. Among these compounds only C_2S , which reacts with water to produce calcium silicate hydrates like in OPC, is able to regulate strength and durability of the hydrated cements, especially at medium and long ages. The other above-mentioned phases have a poor hydraulic behaviour and provide a small contribution to the mechanical properties [14-15].

The commercially employed $C_4A_3\bar{S}$ -based products are generally used in expansive binders for special applications. There are two types of these formulations: *i*) cements having a high $C_4A_3\bar{S}$ content acting as additives for OPC; *ii*) modified OPC containing $C_4A_3\bar{S}$ instead of C_3A . In both cases $Ca(OH)_2$, derived from hydration of C_3S and C_2S present in OPC, produces the desired expansive effect, due to its combination with $C_4A_3\bar{S}$ and $CaSO_4$.

Applications on industrial scale of CSA cements as structural and dimensionally stable materials have been made only in China. The first Chinese $C_4A_3\bar{S}$ -based binders were manufactured about 30 years ago and the present production is about 1 million tons per year. The main features of these cements are, besides a high early strength, good impermeability and freezing-resistance, low dry-shrinkage and solution alkalinity, outstanding chemical corrosion resistance [8]. In other countries the synthesis of rapid-hardening CSA cements has been already performed at laboratory scale or in pilot plants and there is an increasing interest, especially in Europe, towards them [9].

3. CHARACTERISTICS OF FBC ASHES

The FBC technology is very effective in the burning of solid fuels ensuring also a low environmental impact. Among the main advantages of this technique there is the possibility of removing sulphur dioxide generated by coal combustion through the *in situ* injection of calcium-based sorbents (*e.g.* limestone). Under the common FBC operating conditions (850°C and 1atmosphere), a limestone-based sorbent is able to capture SO_2 by means of a two-step reaction mechanism:

Sorbent particles are subject to a rapid calcination, reaction (3), in which calcium carbonate fast decomposes into a porous CaO , further involved in a sulphation reaction (2) thus giving $CaSO_4$. Due to peculiar mechanistic aspects [16] the conversion of CaO into $CaSO_4$ is far from complete: exhausted sorbent particles are therefore composed of unconverted calcium oxide and reacted calcium sulphate. This is related to the onset of significant diffusional resistances as a sulphated shell, characterized by low porosity, builds up around a largely unconverted porous core [17].

One of the main obstacles to a definitive success of FBC technology is represented by the great quantity and the poor quality of solid residues, compared to those of the ashes coming from

traditional pulverized coal plants. Therefore FBC waste disposal and utilization is quite difficult, and the identification of suitable application fields for such residues is of critical importance [18, 10]. The high amounts of FBC residues (which mainly contain coal ash and exhausted sorbent) are due to the need of an overstoichiometric sorbent feed, because of the incomplete sorbent sulphation. In the United States, more than 50% of the electric power is produced within coal plants, thus leading to the formation of more than 100 million tons per year of coal combustion by-products. A remarkable contribution to the generation of such residues is given by FBC plants: about 100kg of waste per coal ton are produced during a combustion process with *in situ* desulphurization, namely ~40% more than that generated in a pulverized coal plant [19]. Moreover the scarcity of quality FBC wastes is related to their peculiar chemical and mineralogical characteristics, *i.e.* the high free calcium oxide concentration and the poor amorphous phase content (due to the relatively low combustion temperatures). CaO can interact in landfill with atmospheric agents giving rise to expansive phenomena, loss of stability and subsoil alteration [20-24], while the reduced formation of a glassy state in the ashes lowers their pozzolanic activity and compromises their re-use in traditional fields of utilization such as cement and concrete industries.

4. EXPERIMENTAL

As main characterization techniques, X-Ray Fluorescence (XRF) and X-Ray Diffraction (XRD) analyses were employed. XRD analysis was also used for quantitative determinations on burnt mixes, in order to study the reacting system behaviour in terms of conversion and selectivity towards $C_4A_3\bar{S}$ and other useful phases.

Two FBC wastes, **A** (a sulpho-calcic fly ash) and **B** (a silico-aluminous fly ash), coming from industrial plants, were utilized as raw mix components. Furthermore, a solid waste (**C**) generated within a traditional coal-fired power plant as well as AR-grade $CaCO_3$, Al_2O_3 and $CaSO_4 \cdot 2H_2O$ were usefully employed as raw mix ingredients. Several combinations of the above-mentioned materials were heated in a laboratory electric oven for 2 hours at temperatures ranging from 1050°C to 1300°C.

5. RESULTS AND DISCUSSION

5.1 Proportioning of Raw Mixes

Table 1 and Figure 1 show the XRF and XRD data on samples **A**, **B** and **C**, respectively. From the characterization results it can be argued that:

- i) **A** shows a high amount of the sulpho-calcic fraction and a not negligible quantity of the silico-aluminous fraction. Traces of Fe_2O_3 (hematite) and $CaCO_3$ (calcite) were also detected by XRD analysis, according to the chemical composition data;
- ii) **B** has a low calcium and sulphur content as well as a high concentration of the silico-aluminous fraction. Iron content and loss on ignition were mostly associated with Fe_3O_4 (magnetite) and calcite;
- iii) **C** has the highest calcium content as well as sulpho-calcic and silico-aluminous fractions comprised between those contained in **A** and **B** samples. Traces of hematite and calcite were also detected by XRD analysis, according to the chemical composition data.

Three mixtures based on a single waste and two mixtures composed of a couple of wastes have been designed (Table 2). Mixtures **1** and **2** contain FBC fly ash **A**, $CaCO_3$ and Al_2O_3 ; mixture **3** contains FBC fly ash **B**, $CaCO_3$ and $CaSO_4 \cdot 2H_2O$; mixture **4** contains **A** and **B**; mixture **5** contains **B** and **C**. Compositions **1** and **3** were established with the purpose of converting all the sulphate into $C_4A_3\bar{S}$. Composition **2** was conceived for combining all the available sulphate and silica into $C_4A_3\bar{S}$ (as main component) and C_2S , respectively. Compositions **4** and **5** were aimed at obtaining

the maximum $C_4A_3\bar{S}$ concentration, allowing to avoid the use of external sources of lime, alumina and sulphate.

5.2 Burning of Raw Mixes

5.2.1 Mixture 1

The most interesting results were obtained at 1250°C and 1300°C. No significant differences were observed between the samples heated at these temperatures. The principal observations are the following:

i) the main reactive oxides (CaO, SiO₂, Al₂O₃, SO₃) are completely consumed;

ii) the main product is $C_4A_3\bar{S}$;

iii) among the minor phases there are $C_5S_2\bar{S}$ (calcium sulposilicate) and C_2AS (gehlenite).

Figure 2 shows the diffractogram for the sample heated at 1300°C.

5.2.2 Mixture 2

Again, the most interesting results were obtained at 1250°C and 1300°C. At both temperatures, the main products are, as planned, $C_4A_3\bar{S}$ and C_2S (larnite), respectively. Furthermore it can be noted (Figure 3) that the reagent oxides are fully converted, while $C_5S_2\bar{S}$ and C_2AS are present only in traces.

Figure 1. XRD analysis for *A*, *B* and *C* samples. A=anhydrite (CaSO_4), C=calcite (CaCO_3), H=hematite (Fe_2O_3), L=lime (CaO), M=magnetite (Fe_3O_4), Q=quartz (SiO_2).

5.2.3 Mixture 3

At temperatures higher than 1100°C melting phenomena occurred. At the temperatures of 1050°C and 1100°C the most important results were the following:

- CaO and Al_2O_3 are fully converted;
- SiO_2 and CaSO_4 are partially converted;
- the main products at 1050°C are $\text{C}_5\text{S}_2\bar{\text{S}}$ - C_2AS and $\text{C}_4\text{A}_3\bar{\text{S}}$ (respectively);
- the main products at 1100°C are $\text{C}_4\text{A}_3\bar{\text{S}}$ and $\text{C}_5\text{S}_2\bar{\text{S}}$ - C_2AS (respectively).

In Figure 4 are reported XRD analyses for the samples heated at 1050°C and 1100°C .

5.2.4 Mixture 4

At temperatures higher than 1150°C melting phenomena occurred. At 1100°C it was noted that:

- i) CaO is fully converted;
- ii) SiO₂, Al₂O₃ and CaSO₄ are partially converted;
- iii) the main products are C₅S₂ \bar{S} -C₂AS and C₄A₃ \bar{S} (respectively).

At 1150°C it was noted that:

- i) CaO and CaSO₄ are fully converted;
- ii) SiO₂ and Al₂O₃ are partially converted;
- iii) the main products are C₅S₂ \bar{S} -C₂AS, CAS₂ (anorthite) and C₄A₃ \bar{S} (respectively).

Figure 5 indicates the diffractogram for the sample burnt at 1150°C.

5.2.5 Mixture 5

At temperatures higher than 1150°C melting phenomena occurred. At 1100°C the principal findings are the following:

- i) CaO, SiO₂, Al₂O₃ and SO₃ are partially converted;
- ii) the main products are C₅S₂ \bar{S} and C₂AS;
- iii) C₄A₃ \bar{S} is present only in traces.

At 1150°C it was observed that:

- i) CaO, Al₂O₃ and CaSO₄ are fully converted;
- ii) SiO₂ is partially converted;
- iii) the main products are C₅S₂ \bar{S} -C₂AS, CAS₂ and C₄A₃ \bar{S} (respectively).

Figure 6 reports XRD results for the sample heated at 1150°C.

Figure 2. XRD analysis for mixture **I** burnt at 1300°C. *=calcium sulphoaluminate (C₄A₃ \bar{S}), # =calcium sulphosilicate-gehlenite (C₅S₂ \bar{S} -C₂AS, these phases can be present alone or together inasmuch as their strongest signals overlap).

Figure 3. XRD analysis for mixture 2 burnt at 1300°C. *=calcium sulphoaluminate ($C_4A_3\bar{S}$), §=larnite (C_2S), #=calcium sulphosilicate-gehlenite ($C_5S_2\bar{S}-C_2AS$).

Figure 4. XRD analysis for mixture 3 burnt at 1050°C and 1100°C. A=anhydrite ($CaSO_4$), Q=quartz (SiO_2), *=calcium sulphoaluminate ($C_4A_3\bar{S}$), #=calcium sulphosilicate-gehlenite ($C_5S_2\bar{S}-C_2AS$).

Figure 5. XRD analysis for mixture **4** burnt at 1150°C. AL=alumina (Al_2O_3), Q=quartz (SiO_2), *=calcium sulphoaluminate ($\text{C}_4\text{A}_3\bar{\text{S}}$), ^=anorthite (CAS_2), #=calcium sulposilicate-gehlenite ($\text{C}_5\text{S}_2\bar{\text{S}}-\text{C}_2\text{AS}$).

Figure 6. XRD analysis for mixture **5** burnt at 1150°C. Q=quartz (SiO_2), *=calcium sulphoaluminate ($\text{C}_4\text{A}_3\bar{\text{S}}$), ^=anorthite (CAS_2), #=calcium sulposilicate-gehlenite ($\text{C}_5\text{S}_2\bar{\text{S}}-\text{C}_2\text{AS}$).

5.3 Principal Considerations

The above-mentioned results indicate that mixtures based on fluidized bed combustion wastes are able to generate phases of interest for calcium sulphoaluminate cements. This aptitude mainly depends on the nature of the wastes employed and on the synthesis temperature. The best results have been obtained at the highest temperatures (1250°C and 1300°C), whereas the poor performance of some systems has to be related to limitations on the maximum temperature which can be reached without the occurrence of melting phenomena.

It is unlikely that a single FBC waste can give the amounts of CaO , Al_2O_3 , SO_3 , and SiO_2 required by the formation of significant $\text{C}_4\text{A}_3\bar{\text{S}}$ and C_2S contents. It seems very interesting to rely on other industrial wastes and by-products, instead of commercial raw materials, as external sources of the

needed oxides. The results shown by mixtures in which a FBC waste or another industrial waste was added to a given FBC ash were unsatisfactory. Combinations of several FBC wastes and other industrial by-products will be experienced in order to obtain high conversion and selectivity degrees towards $C_4A_3\bar{S}$ and C_2S .

6. CONCLUSIONS

Fluidized bed combustion ashes are mainly composed by SiO_2 , Al_2O_3 , CaO and SO_3 , have a poor pozzolanic behaviour and frequently contain high free lime amounts. Therefore, these wastes generally cannot be utilized in the manufacture of ordinary Portland and blended cements but may be of interest as raw materials for the synthesis of calcium sulfoaluminate-based cements.

It has been found that mixtures based on fluidized bed combustion ashes are able to generate $C_4A_3\bar{S}$ and C_2S , which are the main components of the calcium sulfoaluminate-belite cements. The nature of the employed wastes and the thermal treatment modalities can significantly affect the synthesis process.

In the near future the possibility of using different combinations of fluidized bed combustion ashes and other industrial wastes to achieve high conversion and degree of selectivity of $C_4A_3\bar{S}$ and C_2S will be explored.

SULFATE IN CEMENT AND CONCRETE - LET'S START AT THE BEGINNING

William G. Hime

Wiss, Janney, Elstner Associates, Inc., Northbrook, IL USA, E-mail: whime@wje.com

ABSTRACT

Until the end of the nineteenth century gypsum was not a deliberately introduced component of Portland cement. Then, from about 1900 to 1950, it was added at about 2% by weight as SO_3 , and now, 50 years later, it is often nearly twice that level. However, the usual understanding of the chemistry of Portland cement and concrete has been based on the lower SO_3 levels.

Regarding distress due to sulfate intrusion into concrete, the development of sulfate resistant cements was based on the understanding that “sulfate attack” involved the production of ettringite. Now the term “sulfate attack” is also used when gypsum is the reaction product, and even for all those chemical and physical reactions that occur when substances such as sodium sulfate, magnesium sulfate, and hydrogen sulfate (sulfuric acid) intrude into concrete. As a consequence, the world literature has become so confused that the consequences of the reactions between sulfate-containing chemicals and concrete are erroneously reported in much of the literature. Further, changes in the sulfate content of the cement over the years have significantly increased the sulfate resistance of concrete.

This paper seeks to clarify the influence of sulfate on the properties of Portland cement concrete, in a historical context, and also considers the author's experiences with internal sulfate attack and delayed ettringite formation.

1. INTRODUCTION

Definitions of Portland cement often include the phrase: “and calcium sulfate as an interground addition.” That phrase would not apply to Aspdin's invention or indeed to virtually any “Portland cement” produced during the nineteenth century.

Today's Portland cement often contains over 3% SO_3 by weight, and indeed an increasing number of manufacturers produce Type III cements with over 4% SO_3 – about the equivalent of 10% gypsum. The ramifications of this change have eluded most investigators, and are discussed herein.

2. HISTORY OF SULFATE IN PORTLAND CEMENT

2.1 The First 65 Years (1824-1889)

Impetus for the development of a hydraulic cement was provided by Smeaton in 1776 when he published his report showing that such a material required more than a lime system; siliceous or aluminous components, or both, were necessary [1].

Joseph Aspdin patented “Portland Cement” in 1824, but his son William said that his father had produced it as early as 1811. The patent failed to disclose either the raw material proportions or the need to heat the clinker to incipient fusion [2]. In fact, the historic evidence is that Aspdin's Portland cement was probably seldom similar to that which has been produced in the last eighty

years. Although Frost apparently was the first to make a plant for Portland cement production [3], Joseph and, independently, William Aspdin, both set up cement plants from 1826 to 1847 [4].

During this entire period there is no evidence that calcium sulfate, as plaster (hemihydrate) or gypsum, was intentionally added to the clinker. Aspdin and his sons James and William did add copper sulfate and other sulfates to the raw mix [5], very probably for no reason than as a subterfuge to confuse competitors. However, we have found copper slag in the fleur-de-lys at the top of the concrete wall around William Aspdin's home, Portland Hall, Gravesend, England [6], which is perhaps the oldest reinforced Portland cement concrete [7]. Some of the slag has the same fineness of the cement, and may have been a component of it rather than an admixture to the concrete.

William Aspdin did, at least at one plant, use thousands of tons of "alkali waste" as a patented raw material for Portland cement. This material contained calcium and alkali sulfates [8]. However, in attempts by others to use alkali wastes, "the amount of calcium sulfate present prevented the manufacture of a satisfactory cement" [9]. Indeed desulfurization processes were used to recover the sulfur, and to allow a "better chance of making a good cement" [10].

A question as to why the cement during this period of time did not set too quickly due to the rapid reaction of the tricalcium aluminate component with water has largely been unasked. One answer may be that the cement was ground too coarsely to expose much C_3A . Indeed, Portland cements of this period were far coarser than present-day cements that have 90-plus percent passing a 325 mesh screen. A fineness of 90% passing a 30 mesh screen was reported in 1879 [11].

A second possible answer to the setting question is that at that time vertical kilns were used to burn the raw materials. Thus sulfur oxides from the fuel circulated through the bed of raw materials. According to one report, "the atmosphere was always hot and sulphurous" [12]. Sulfate analyses during this period were apparently seldom made and were variously reported as "sulfuric acid" [13, 14], anhydrous sulfuric acid [15] "sulfuric anhydride" [16], "sulfate of lime" [17] and SO_3 . Reported analyses for sulfur ranged from "a trace" as sulfuric acid for Aspdin's cement (but the same London chemist also found 45% calcium phosphate! [14]), to 1% as sulfuric anhydride (SO_3) for an 1849 sample [18]. Analyses of concrete in 1851 [19] found 0.31% sulfuric anhydride.

Eckel [20] presented analyses of Portland cements from 1849 to 1873. The SO_3 contents for English Portland cements were about 1%; however, for a 1873 cement from Austria the value was 2.1%. Analyses of English cements in the 1880s and 1890s disclosed 0.5% to about 2% "sulfuric acid" [21]. Cummings [22] detailed the analyses of 53 cements, some of which were decades old, but likely dated from the late 1890's. Only six were analyzed for "sulfate of lime," and seven of those ranged from 0.3 to 1.0% as SO_3 . A "Gate of France Hydraulic Cement" contained 2% SO_3 .

The production of Portland cement in the United States didn't start until late in the century. Saylor, in 1871 in the United States patented a "natural cement" that was "in every respect equal to the Portland cement made in England," and indeed may have been Portland cement. The Portland cement industry in the U.S. had apparently begun. [23].

2.2 The Next 30 years (1890-1920)

Beginning just before 1890, several events led to enormous changes in the composition and manufacturing process of Portland cement. Among the mechanical changes were the introduction of better grinding mills and the rotary kiln. The former made the cement (the ground clinker) much faster reacting. Over 95 percent of the cement particles now passed a No. 50 sieve [24]. The latter, as patented by Crampton in 1877 and Ransome in 1885 [25], substantially decreased the sulfur content of the clinker since the gases did not significantly pass through the charge. As a result, the

setting of cement generally changed from slow to rapid [26]. The rotary kiln did not “take firm hold” in the U.K. until 1903 [27].

Just how the discovery of the set-control properties of calcium sulfate came about has not been well established, but obviously the problem demanded urgent research. In the United States the deNavarro family led innovation in the industry in the 1880's and 1890's; they built the first rotary kiln (24 ft long!), established the Keystone Company (later the Atlas Cement Company) and performed “numerous experiments...(that) would fill a book” [28]. Fortuitously, the deNavarro's brought in a French chemist, P.I. Giron, who had learned in France that when making “cement sidewalks” the time of set of the mortar could be materially retarded by adding plaster into the mix water. As a result, carloads of plaster were brought into the plant to add to the clinker. To befuddle competitors, those carloads were billed as “returned cement”[29].

Although plaster was found to be more effective, on a weight comparison basis, than gypsum, someone realized the materials were the same after addition of water, and gypsum was a lot cheaper. By the early 1900's, most Portland cement manufacturers worldwide added gypsum to the ground clinker, or ground the kiln clinker with the gypsum.

The first ASTM and British specifications for Portland cement were issued in 1904. For ASTM the specification was designated C 9-04. The British specification limited the SO_3 content to 2.5% (changed to 2.75% in 1907) [30], while the ASTM limit was 1.75% (increased to 2.0% in 1917).

This same period of time saw tremendous increases in production of Portland cement, in part because of the increased use of reinforced concrete. In 1890, the U.S. output was 335,000 barrels. This rose to one million barrels in 1895, 8½ million in 1900, 35 million in 1905, and 76½ million in 1910 [31]. European demand increased at a similar rate: Germany had three Portland cement works in 1854, 420 in 1882, and 1274 in 1894 [32].

2.3 The Next 30 years (1920-1950)

By 1920 Portland cement consisted of clinker interground with gypsum. In the same year, an ASTM Specification was adopted that represented an agreement “between all authorities in the United States” [33]. Interestingly ASTM C 9-21 as first published used a capital P for Portland. But as republished in 1924, the lower case was used, as it has been since then [34], and is so used herein. Further, the designation was changed from C 9 to C 150 in 1941 (C150-41). In 1941, due to increasing incidences of “sulfate attack,” American specifications now covered five types of cement, with Types II and V having limits on both C_3A and SO_3 , perhaps largely the result of studies by Tuthill [35]. Analyses by the Portland Cement Association [36], of several Portland cements from each of the five types, as reported by Bogue [37] and Eckel [38], disclosed that the SO_3 levels for each type of cement were generally less than 2%, and only Type III had an average level over 2%.

Interestingly, Anderegg in 1929 suggested that for the finer cements additional sulfate should be present to react with the aluminates and thus prevent the possibility of subsequent sulfate attack [39]. There is no evidence that subsequent increases in SO_3 content were made for that reason.

2.4 The Last 50 Years (1950-2000)

With greatly increased needs for low cost construction materials and for rapid procedures for building bigger and taller structures, the Portland cement industry began producing cements that provided substantially higher early strengths. To do this they increased the finenesses and the SO_3 contents of the cements, not only for Type III, but also for the other four types.

The most remarkable aspect of present-day Portland cements, at least for those produced in the U.S., is their SO_3 contents. In a survey by Gebhardt [40] of all of the Portland cements produced in this country during the mid-1990's, the average SO_3 contents of Types I, III and IV cements were above the numerical limits of the ASTM C 150 specification! (Gebhardt, however, had various classifications within each type) This interesting development occurred because the C 150 footnotes allow a cement to exceed the numerical limit if the cement passes a test to show that it will not cause deleterious expansion. Unfortunately, the test now used is unable to detect cements that can cause delayed ettringite formation.

3. THE EFFECTS OF SO_3 CONTENT CHANGES

3.1 Sulfate Minerals in Hydrated Cement

The literature is now in general agreement about the chemistry of sulfate in hydrated cement systems; ettringite ($\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$) is produced within minutes after addition of water. The calcium sulfate component reacts with tricalcium aluminate or its hydrates. When all the sulfate is combined as ettringite, then any excess C_3A will react with it to produce “monosulfate” (calcium monosulfoaluminate hydrate, $\text{C}_3\text{A} \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$).

Investigators throughout the twentieth century have suggested that most or all of the ettringite is replaced by monosulfate in days, months, or years, apparently not realizing that $\text{SO}_3/\text{C}_3\text{A}$ mortar ratios have increased over the century so that the ratio in many cements is now more than 1, meaning that some ettringite remains. And for some, the ratio is as high as 3, thus indicating that no monosulfate may ever be produced!

3.2 Sulfate Attack

Unfortunately, “sulfate attack” is now almost a meaningless phrase. Its meaning was simple back in the days when specifications began to recognize the need for sulfate-resistant cements, as created by limiting their C_3A contents. Sulfate from the environment reacted with monosulfate or calcium aluminate hydrates to destructively produce ettringite. No other sulfate-dependent chemistry was considered during most of the first half of the twentieth century.

From the discussion in the previous section, it is obvious that monosulfate and calcium aluminate hydrate levels in hydrated cement have been decreasing, and both may have reached 0% for some cements. Thus no “classical” sulfate attack is possible with many currently available cements (for simplicity, and because of conflicting literature, reactions of C_4AF are not considered herein).

During the twentieth century it gradually became popular for engineers to study sulfate attack by immersion of cylinders or prisms in sodium or magnesium sulfate solution. Studies by Miller and Manson [41] over several years, and by the Portland Cement Association (in Sacramento, California) over several decades [42, 43], investigated the effect of those sulfate solutions on concrete made with different types of cement, at various water-cement ratios, and with admixtures such as fly ash and slag. Virtually no chemical analyses or petrographic examinations of the deteriorating specimens were made.

During this period, and even back in the early 1900's, investigators found that sodium sulfate reacted with the calcium hydroxide product of cement hydration to produce gypsum. Some investigators reported that this reaction was destructive, and others reported that it was not. Some found that limiting the C_3S content was beneficial. Few, if any, called attention to the fact that if the intruding sulfate salt was gypsum, there was no reaction with calcium hydroxide. In fact, many papers discussed deleterious production of gypsum in concrete, loss of basicity, and decalcification of the calcium silicate hydrate phases, without considering that gypsum from the environment would cause none of these reactions.

It also was not until recently that Stark [44] reported that much or all of the above-ground distress to concrete prisms exposed to sodium sulfate solutions was due to “physical salt attack” or, as termed by this author and his colleagues [45], “salt hydration distress.” No reaction of the sulfate ion is involved. The distress mechanism is now being debated. Among the more prominent theories are pressure due to crystallization of sodium sulfate hydrate from saturated solution or expansion due to conversion from anhydrous sodium sulfate (thenardite) to the decahydrate (mirabilite). Mirabilite occupies about four times the volume of thenardite.

Astonishingly, Stark [44] had found that below ground portions of the Sacramento prisms were generally unaffected by the exposure to sulfate. It is discouraging, if not frightening, to consider the monetary consequences of misidentification of a physical phenomenon as a chemical one.

Returning to the change of sulfate levels in Portland cement over time, it is obvious that classical sulfate attack was very likely in the 1800’s, and then less and less likely as the cement sulfate levels increased. Although the destructive attack of sulfate on hydraulic cement systems was recognized as early as the 1700’s by Smeaton [45], sulfate attack was not proven until Candlot [46] and LeChatelier [47] late in the 19th century identified ettringite in deteriorating concrete, and LeChatalier demonstrated the destructive development of ettringite. Indeed identification of ettringite led to the development of the sulfate-resistant cements, all based on lower amounts of tricalcium aluminate. Unfortunately, Miller and Manson and the Portland Cement Association failed to check for ettringite during their massive studies.

The beginning of the twenty-first century finds many reports of studies of attack by magnesium sulfate and even hydrogen sulfate (sulfuric acid), with the investigators failing to recognize that the cation, not the sulfate anion, may have caused most or all of the damage [48]. Further, it is often not recognized that low C₃A contents will do nothing to prevent alkali sulfates from reacting with calcium hydroxide, and that physical salt attack is neither prevented nor lessened by use of Types II or V cements, nor by decreasing calcium hydroxide production by limiting C₃S content.

4. DELAYED ETTRINGITE FORMATION

In the 1980’s an internal sulfate attack phenomenon was reported by Heinz et al. [49]. Many other investigators soon reported studies of the phenomenon, the name of which has now been settled on as “delayed ettringite formation,” or DEF. The phenomenon involves the late development of ettringite. The generally recognized explanation is that the ettringite normally formed in concrete is destroyed, or is prevented from forming, by temperatures above about 60°C, due to either deliberate heat curing or to heat development caused by the casting of massive structures, or by exposure to the sun in hot, dry environments. Subsequent formation of ettringite in the hardened concrete, such as caused by exposure to water, results in expansion of the paste system, with consequent loss of prestress or bond of reinforcement, and cracking.

Other conditions may be necessary for such DEF, including “proper” cement composition. Generally unrecognized is the fact that higher temperatures are required for ettringite decomposition if the vapor pressure is higher.

This author has found that cements with high clinker sulfate, especially as caused by burning high-sulfur fuels, may lead to DEF even when the concrete is not exposed to high temperatures. Others have argued against this on the basis that the sulfate in such cements is water-soluble and will produce ettringite normally. Such arguments fail to consider that SO₃ gases in the kiln must alter the chemistry of the cement. For example, $3\text{CaO}\cdot\text{SiO}_2 + \text{SO}_3 \rightarrow 2\text{CaO}\cdot\text{SiO}_2 + \text{CaSO}_4$, and the sulfate is thus found in the slowly reacting belite phase. Further, most structures undergoing DEF are made at low w/c, where complete solubility of anhydrite is unlikely.

Finally, it is noted that the ettringite formation in this distress mechanism is often evidenced as a gel [50], identical in appearance to alkali silica reaction (ASR). Thus prior occurrences of DEF may have been unrecognized. Indeed, Copeland reported this possibility to one of our clients in 1976 [51], but his findings were received with skepticism, and were not published.

5. INTERNAL SULFATE ATTACK

This subject may be divided into two classifications: (1) deliberate and beneficial, or (2) unanticipated and harmful. However, in the author's opinion, the word "unanticipated" may occasionally be replaced by "foolish" or even "reckless."

In the first classification is the use of ettringite development in those cement formulations designed to produce "shrinkage compensated" or "expansive" concrete. There are two mechanisms for this. In the first, the cement usually consists in part of "anhydrous ettringite" ($C_4A_3\bar{S}$) plus an additional sulfate component. The development of ettringite continues after hardening but ceases before expansion cracking occurs. Such cement permits large expanses of joint-free concrete when used in slab construction, provided that sufficient steel is present in the slab to restrain concrete expansion.

Also in the first classification are formulations where controlled excesses of gypsum are present, but again expansion is limited in time and amount by the component proportions and the design of the reinforced concrete.

In the second classification are mixtures consisting primarily of plaster of Paris (calcium sulfate hemihydrate) but with several percent Portland cement, or largely of Portland cement but with substantial amounts of plaster. For the former, Portland cement is added to give both alkalinity, and thus some steel passivation, and added strength. Unfortunately, failures of both systems when used as post hole fillers, etc., have been myriad. Many of such proprietary products are an effort to reproduce a successful product whose trade secret is use of a zero- C_3A Portland cement, which cannot produce ettringite. No sulfate reaction occurs. The other producers do not recognize the need for the zero- C_3A Portland cement.

6. SUMMARY

For almost all of the 1800's gypsum was not added to Portland cement clinker. As a consequence, SO_3 levels were generally well below 1%. For the first half of the 1900s, and longer, gypsum was interground with the clinker to bring SO_3 levels to just under 2%. Now, at least in the U.S., SO_3 levels are frequently 3 to 4, or even 5 percent.

The effects of the higher SO_3 levels have been scarcely, if at all, recognized. They include:

- the common presence of ettringite in aged Portland cement concrete
- significantly less chance of "classical" sulfate attack, since there are far less amounts of hydrated aluminates and monosulfate to develop ettringite upon sulfate intrusion into the concrete
- greater chance of significant delayed ettringite formation

As a consequence, misdiagnoses of sulfate distress mechanisms are now rampant.

7. AUTHOR'S NOTE

In doing the literature research for this paper, I was enormously impressed by the literary and historical research abilities of the nineteenth and early twentieth century authors. Cogent and amusing phrases abound. The extensive use of photographs in Stanley's *Highlights in the History of Concrete* made that book a joy to read. Henry Reid's *The Science and Art of the Manufacture of Portland Cement* not only detailed Portland cement manufacture from raw material selection to testing of the final product, but also included anecdotes having nothing to do with the subject but fascinating in their own light.

Perhaps the most interesting book is John Smeaton's "A Narrative of the Building and a Description of the Construction of the Eddystone Lighthouse with Stone," as published in 1793. This book also caused my hilarious "mistranslation" of phrases in old English print (f-like letter for some s's) such as "that we might be in poffeffion of all the beft materials for water building within ourfelves: and though I own I have not fuccceeded with respect to the latter, fo far as my ardent wifhes led me to hope [52]."

This literature made my paper a labor of love. That labor was aided in great measure by our librarian, Ms. Penny Sympton, by Ms. Connie Field and Mr. Paul Tennis of the Portland Cement Association, and by Ms. Ellie Barkley, Editor of ASTM. Unfortunately, my inabilities with regard to the French and German language largely restricted my subject to English and American history.

Finally, I note that the bibliography published in 1952 by Miller, Manson and Chen [53] was of significant value. That bibliography demonstrates that papers titled "alkali attack" actually usually refer to sulfate salts, and that many experiments with "sea water" were actually with sulfate salts. Any search using the word "sulfate" would fail to locate these papers.

SULFATE IN CEMENT AND CONCRETE - LET'S START AT THE BEGINNING

William G. Hime

Wiss, Janney, Elstner Associates, Inc., Northbrook, IL USA, E-mail: whime@wje.com

Biographical Data

William Hime graduated from Heidelberg College (Ohio) in 1948 with majors in chemistry and mathematics. He then attended Northwestern University, completing all non-research Ph.D requirements for a major in Analytical Chemistry. He joined the Portland Cement Associate as a Research Chemist in 1951, serving in various capacities for 20 years.

In 1971 he and colleague Bernard Erlin formed Erlin, Hime Associates, a company primarily serving clients having construction materials problems. In 1984 that company was obtained by Wiss, Janney, Elstner Associates, then primarily a firm investigating similar problems through engineering.

Mr. Hime has published over 50 papers on analyses of cement and concrete, corrosion, cement burns and related matters. He is a member of ASTM and an Honorary Member of Committees C1 and C9. He is a Fellow of the American Concrete Institute.

He is an avid (but not accomplished) golfer, and collects caps from courses he has played throughout the world.

THE PORE FLUID IN PORTLAND CEMENT: ITS COMPOSITION AND ROLE

F. P. Glasser

Department of Chemistry, University of Aberdeen
Meston Walk, Old Aberdeen, AB24 3UE Scotland

ABSTRACT

Pore fluid forms an essential component of Portland cement formulations. Its chemistry is discussed: the main pH control arises from dissolved alkali, Na and K, effectively present as hydroxide. This causes calcium solubility to diminish with the result that in many commercial cements, calcium solubilities in pore fluid are comparable with those of Al and Si.

The redox potential (Eh) in cement pore fluids has been characterised: slag-rich blends have a low Eh. This is created and maintained by a vigorous sulfur chemistry: S^{2-} , S_x^{2-} , $S_2O_3^{2-}$ and SO_4^{2-} are present in the pore fluid.

Several models are described for the alkali distribution between aqueous and solid phases. The effectiveness of fly ash and silica fume in decreasing pore fluid alkalis is interpreted in terms of their impact on C-S-H composition.

It is suggested that pore fluid does not disappear even from low water: cement ratio “high performance” concretes: instead hydration ceases because of decreased water activity such that the critical humidity necessary to sustain hydration is no longer achieved.

1. INTRODUCTION

Portland cement is marketed and used as a fine powder typically having Blaine surface areas in the range 2500 – 5000 cm²/g. The mineralogy of the powder is complex: it consists of mainly “clinker” with other mineral admixtures. Portland clinker is a sintered product chemically high in CaOH, ca 65 - 70 wt%, and consisting of four phases: Ca₃SiO₅, Ca₂SiO₄, Ca₃Al₂O₆ and Ca₂(Fe,Al)₂O₅ (idealised formulae): additionally a little, ca 1 – 2%, free lime may persist. This clinker is interground with other minerals: principally gypsum, CaSO₄·2H₂O, which is used to control set times. In modern practise one or more supplementary cementing materials may be added. These include coal combustion fly ash, glassy iron blast furnace slag, natural or semi-synthetic pozzolanic materials, e.g., calcined clay, and limestone, CaCO₃.

The resulting mixed powder is used to bind coarser mineral aggregate; hydration is initiated by adding water. Traditionally pure or only slightly saline water is permitted although in certain applications, seawater has been allowed. However in modern practise, “water” may also include other soluble or dispersible substances added to achieve specific purposes: these include corrosion inhibitors, anti-freeze agents, chemicals to control bleed, foaming and air entrainment, accelerators, retarders and plasticisers. It follows that a range of inorganic and organic substances, the latter, often consisting of mixtures of substances, are added typically at levels up to 1 – 2% by weight.

The aqueous phase – which I will term ‘water’ despite its often complex constitution – serves two essential purposes. Upon mixing and for a few minutes or hours thereafter, it provides a freely-flowing semi-liquid mass which can be cast into formwork. Thereafter it continues to react with the cement powder forming a rigid mass. A complex series of reactions occur. Not surprisingly characterisation of these reactions, study of hydration mechanisms and of the resulting microstructures and of the relationship of these and mix formulation to engineering properties has provided an important stimulus to cement science as described in proceedings of previous Congresses. I make a number of points relevant to this presentation:

- Much of the added mix water becomes chemically bound into hydrates. While no absolute distinction between physically and chemically bound water is possible, all empirical and theoretical criteria agree that free water diminishes as hydration progresses. This water budget is important and will be discussed.
- As hydration progresses and solid paste hydrates self-assemble into an interconnected network, residual liquid water becomes increasingly confined to isolated pores: again no clear-cut distinction exists between mix water and pore water but final set, as determined by the Vicat test, may arbitrarily be taken as marking the transition between mix water and pore water.
- The free aqueous phase reacts with and dissolves cement components. Its physical and chemical properties: pH, Eh, ionic strength, conductivity, viscosity, etc., all undergo large changes as a consequence. These changes are continuous.
- Although concretes are normally formulated with more water than is required to hydrate the cement, thus leaving a permanent excess of pore water unless rigorously dried, modern “high performance” concretes are often formulated to low w/c ratios and, as a consequence, may undergo self desiccation. Self desiccation can still occur in the presence of pore fluid; this is discussed.

This review and discussion concentrates on internal chemistry; chemical fluxes such as diffusion of ions from the service environment into and out of cement paste have not been included. Nevertheless, many of the principles described here are applicable to service conditions, with appropriate modification in light of the development of concentration gradients within the aqueous phase and of accompanying mineralogical changes to the matrix.

The pore fluid of real cements was generally regarded as inaccessible to direct examination until Longuet and colleagues showed that pore fluid could be expressed from mature cement pastes using high hydrostatic pressure [1]. Since that time, numerous other investigators have expressed pore fluid: Taylor [2] references data from 212 superior analyses, defined as being accompanied by sufficient characterisation data for the cement and curing procedure. These data give new insights into the hydration process, many of which have yet to be incorporated into mainstream cement science. The purpose of this review is to highlight and correlate some of this work and discuss implications for concrete formulation and performance.

2. PORE FLUID CHARACTERISATION

2.1 Sampling

Most pore fluid collection has been done by uniaxial compression of a cylindrical sample. The yield of pore fluid is optimised if pressure is raised gradually and incrementally up to the maximum available pressure. Estimates of the efficiency of collection vary but it is unlikely that expression collects more than 50% of the total pore fluid. Doubts have been expressed that the compositions of the aqueous samples may be unrepresentative: that chemical potentials in thin films differ from those in bulk water. In support of this it has been claimed that systematic changes in pore fluid composition occur as a function of applied pressure although changes in concentration of some

substances, such as dissolved or dispersed superplasticisers, relate more directly to time, with selective removal of soluble low molecular weight fractions occurring [3]. However, the writer has not found significant pressure-related variation to occur. Instead, two other factors seem to be of greater importance: protection of pore fluid against reaction with air and the geometry of collection.

Pore fluid expression should if possible be done with a N₂ gas blanket atmosphere around the die and sample. Collection directly into a sealed drain coupled to a hypodermic syringe enables pore fluid to be removed by suction and free of contamination resulting from contact with air. The question of the impact of incremental pressure is much more complex than supposed. As is well known from industries requiring pressed products, e.g., tablets in the pharmaceutical industry, the pressure distribution in a uniaxial compression device is very unequal; friction between dies and along the sides generate high local pressures while the centre may remain at quite low pressure. Thus incremental increases in applied force do not necessarily achieve higher pressures in cement undergoing compression but instead to increase the volume fraction subject to sufficient pressure to express pore water.

Isostatic compression devices exist, for example multi-axial presses with tetrahedral or cubic geometry, but to the writer's knowledge have not been applied to pore fluid expression. Until this is done, the existence of compositional variations as a function of applied load must be regarded as not proven.

2.2 Chemical analysis

Analysis of expressed pore fluid can be made for pH, Eh and aqueous chemistry: Figure 1 shows the range of environments. As pore fluid is very atmosphere sensitive, the analytical emphasis is on rapid methods which minimise transfer and handling. The pH function is usually determined using a pH meter. Care should be taken to use an electrode that is insensitive to alkali and to calibrate the electrode. The Eh function is more difficult to determine; standard methods are only slow evolving. Ordinary Portland cements, are normally produced under oxidising conditions; they give a neutral to slightly oxidising redox potential (Eh), of +100 to +200mV at pH 12 – 13 relative to a standard hydrogen electrode. However, blast furnace slag cements blends, particularly if made with high (>40%) slag content can give very low Eh values, negative 250 to 400mV in the same pH range. Just as the application of pH concepts is unhelpful without specifying the nature and amount of pH buffering, if any, Eh measurements are most useful when the poisoning capacity – the equivalent of buffering - can also be defined. Portland cements lacks significant poisoning capacity, as a result of which its internal Eh is readily affected by electrochemically active additives, e.g., nitrites or other potential oxidising and reducing agents. Slag cements spontaneously develop an active internal chemistry involving sulfur. Slag hydration liberates sulfide, S²⁻, ions, which in the alkaline cement environment react with sulfate from Portland cement, giving rise to species such as thisosulfate, S₂O₃²⁻ [4 - 10]. While the sulfur speciations are not yet completely understood, it seems likely that the source of the low Eh and the greater poisoning capacity of slag cement arises from electrochemically active couples involving sulfur.

Figure 1. Range of Ph-Eh environments in alkaline cements. The units of Eh are volts, relative to a standard H_2 electrode, $1/2 \text{H}_2 + \text{H}^+ + \text{e}^-$ at 25°C , $\text{pH} = 0$ and $\text{PH}_2 = 1$ bar.
HAC = high alumina cement.

Thus the internal environment of cements can be explored and characterised using inert electrodes with which to measure Eh; platinum appears to be a better choice of electrode than glassy carbon, silver, titanium or palladium [4, 6]. As noted, no standard method for determining poisoning capacity yet exists. Angus and Glasser [4] suggested titration against standard Cr (VI) solution; the method is frequently used and the writer is not aware of adverse comment but considers that the method still requires further investigation before it can be accepted as a standard.

The dissolved inorganic components of pore fluid can be analysed by a combination of flame photometry (Na, K), atomic absorption (Mg, Fe, Ca, Al, Si) and ion chromatography (SO_4 , Cl, etc). Figure 1 summarises the pH-Eh regime in a range of commercial and experimental cements. As can be seen, large numerical variations exist in Eh. The variations in pH scale, from 11 to 14, do not at first sight look large. However from the definition of pH, $\text{pH} = -\log_{10}[\text{H}^+]$, and rewriting this as $\text{pOH} - \log_{10}[\text{OH}^-]$ as seems more appropriate for alkaline solutions, it can be seen from the form of the expression that a pH change of two units results in a hundred-fold change in hydroxide ion concentration. Organic constituents in pore fluid are best treated on the basis of molecular structure, choosing between mass spectroscopy, NMR, infrared, chromatography, fluorescence, perhaps with couplers, and classical C-H-N analysis; the latter requires selective recovery of the organics from the aqueous phase. Where high molecular weight organics occur, gel permeation chromatography, ultracentrifugation, light scattering and Raman spectroscopy may be applicable.

The labile nature of pore fluids has been mentioned. However, it is well known that pore fluids are liable to supersaturation: the same phenomena also occur in laboratory simulants. For example, if pore fluid is simulated using solid $\text{Ca}(\text{OH})_2$, it is comparatively easy to prepare supersaturated solutions containing up to $\sim 2\text{g/l}$ $\text{Ca}(\text{OH})_2$ at $20^\circ - 25^\circ\text{C}$. Such supersaturated solutions may appear clear but upon standing go cloudy and eventually precipitate $\text{Ca}(\text{OH})_2$. Similarly, pore fluids removed by extraction from cement may appear clear when fresh but subsequently go cloudy. Several explanations are possible: supersaturation is only one. For example, the solution may contain colloidal particles that undergo ripening with time. A very real possibility, despite care being taken, is contamination by carbon dioxide resulting in precipitation of CaCO_3 . It is often not certain which of these possibilities is applicable. In theory it should be possible to deal with the

presence of colloids by using ultrafiltration. Commercial filtration media are available which range in size to exclude even nm scale particles. However, these media may not be suitable for filtration of strongly alkaline solutions. Commercial filtration media down to $\sim 0.4\mu\text{m}$ are reasonably certain not to interact with cement pore fluids but the finer media, intended to retain colloids, are designed for filtration of near-neutral biological material and may interact with alkaline cement pore fluids: results obtained from commercial ultrafiltration schemes cannot be accepted uncritically. Fortunately, the presence of supersaturated solutions, precursor to colloids, seems to be confined to the early stages of hydration, characteristic of the first few hours or days of reaction. The writer is unaware of any evidence of the persistence of colloids in pore fluids of matured pastes even in the presence of cellulose simulants such as sacharinic acid [11] and superplasticisers [12].

For many analytical purposes, pore fluids are best acidified with standard acid; the acidified solutions have better keeping power than the original alkaline solution. Of course dilution factors need to be taken into account in any subsequent analyses and, moreover, care should be taken that acidification does not precipitate amorphous silica which may interfere with subsequent analytical determinations.

3. IMPACT OF PORE FLUID ON CONCRETE PROPERTIES

3.1 pH and cement paste mineral stability

The range of OH concentrations in cement pastes has two impacts on mineral stability. Firstly, as the ionic strength of the pore fluid increases – and in this respect all ions present in solution have to be included – the activity of water is diminished. This results in stabilisation of lower hydrates. For example in the $\text{CaSO}_4 - \text{H}_2\text{O}$ system, gypsum, the dihydrate, is stable across a broad range of temperatures. However, in solutions of high ionic strength as occur when soluble salts are added, hemihydrate and anhydrite are increasingly stabilised to lower temperatures. Secondly, as [OH] increases, ‘amphoteric’ ions such as aluminium are increasingly solubilised: the pattern of mineral stability, as established for hydrated Portland cement paste, is progressively altered. The high pH also affects calcium solubility, as will be discussed.

3.2 Ca(OH)_2 solubility

The solubility of Ca(OH)_2 is well known, ca 1.1 g/l at 25°C and is commonly regarded as controlling the high pH of pore fluid. A saturated solution of Ca(OH)_2 has a $\text{pH} \simeq 12.6$ at 25°C owing to ionisation of soluble Ca(OH)_2 . This occurs in stages:

The ionisation goes virtually to completion in a saturated solution: Ca(OH)^+ has a negligible concentration. However, analysis of the pore solution compositions of real cements known to contain free portlandite, Ca(OH)_2 , reveals a Ca solubility very much less, typically by more than an order of magnitude, than would be predicted from the known solubility of Ca(OH)_2 . A simple and nearly quantitative explanation of these differences is as follows: Alkali (Na,K) dissolves in pore fluid and its positive charge requires to be balanced by a corresponding negative charge. Since anions other than OH^- , e.g., aluminate, silicate, and sulfate, are relatively insoluble in the cement environment, alkalis are effectively present dissolved in pore fluid as their hydroxides. These impact on Ca(OH)_2 solubility as follows. If we write a solubility product, sp , for Ca(OH)_2 it follows that at low concentrations:

$$\text{Ksp} = [\text{Ca}] [\text{OH}]^2$$

activities should be substituted for molar concentrations, but since this is a simplified treatment, the more familiar molar units will be used. The literature value for $\text{Ksp} (\text{Ca(OH)}_2)$ is 4.21×10^{-5} ; at

equilibrium a saturated solution is thus $2.19 \times 10^{-2} \text{M}$ in Ca ions and $2 \times 2.19 \times 10^{-2}$ or $4.38 \times 10^{-2} \text{M}$ in hydroxide. However, if hydroxide is furnished from some external source, most probably from alkali hydroxides, Ca solubility must decrease in order to maintain K_{sp} . The extent of the decrease can be calculated from the above equation but a more precise calculation, taking into account changes in activity coefficients and changing ionic potential of the solution, is shown in Table 1. The solubility of calcium in the presence of NaOH initially decreases rapidly to $\sim 0.1 \text{M}$ but thereafter less rapidly. At 0.5M , a reasonable average concentration for cement pore fluid, Ca solubility is diminished relative to its solubility in initially pure water by a factor exceeding 20.

These solubility trends have several important consequences to the hydration process. Firstly, as alkali continues to be released and concentrates in a diminishing volume of pore water, $\text{Ca}(\text{OH})_2$ solubility continues to diminish. Secondly, the pH may rise above that of a saturated solution of $\text{Ca}(\text{OH})_2$ as NaOH and KOH concentrate and alkalis increasingly control pH. A further and important consequence is that the solubilities of other species, particularly those in anionic speciations such as $\text{Al}(\text{OH})_4^-$, increase with the result that solubilities of calcium, aluminium and silicon become more nearly equal. We are accustomed to thinking of calcium as the most soluble and most mobile species in hydrating cement. While this may be true of alkali-free simulants, it is not necessarily true for “real”, i.e., alkali-containing cements where solubilities are more nearly comparable. The exception to this is magnesium: magnesium solubility as $\text{Mg}(\text{OH})_2$ is orders of magnitude less than $\text{Ca}(\text{OH})_2$ in pure water. However the common ion effect still operates with the result that, like $\text{Ca}(\text{OH})_2$, its solubility diminishes even further in alkaline solution. Despite the small hydrated diameter of the Mg ion, its extremely low solubility renders it relatively immobile.

Table 1. Solubility of $\text{Ca}(\text{OH})_2$ in NaOH, 25°C^*

NaOH mM	$\text{Ca}(\text{OH})_2$ mM
0	21.91
10	18.60
20	15.72
40	11.26
60	8.32
80	6.42
100	5.16
200	2.49
300	1.63
400	1.20
500	0.95

* after Dow [13].

3.3 C-S-H Solubility

C-S-H refers to the principal bonding phase of Portland and blended Portland cement. The product, as encountered in cement and in certain laboratory preparations is nearly amorphous to X-ray powder diffraction and on that account, is termed “cement gel” or “C-S-H gel” although because of supposed similarities in structure to certain crystalline $\text{CaO-SiO}_2\text{-H}_2\text{O}$ minerals, it has also been termed “tobermorite gel” or “jennite gel”. I will continue to use the designation C-S-H. The range of C-S-H compositions encompasses a range of molar Ca/Si ratios, although agreement is poor about numerical extent of the values, perhaps 2.0 to 0.8. Portland cements have high Ca/Si ratios often in the range 2.6 – 3.0: consequently the upper limit of C-S-H compositions is of greatest interest to Portland cement. In hydrated laboratory preparations made by hydrating mixtures of $\text{Ca}(\text{OH})_2$ and silicic acid, my experience of combined electron microscopy with analysis and diffraction, coupled with X-ray diffraction and Franke extraction for free portlandite, is that the upper limit of homogeneity of C-S-H is in the range 1.7 to 1.8 at 25°C (expressed as Ca/Si molar

ratio), decreasing to ~ 1.5 in the course of prolonged curing at $55^\circ - 85^\circ\text{C}$ [14]. However, reports on hydrated Portland cement, reviewed by Taylor [15], claim higher ratio limits of 2.0. Whatever the 25°C limits, the solubility properties of mixtures of $\text{Ca}(\text{OH})_2$ and high ratio C-S-H are similar to those of $\text{Ca}(\text{OH})_2$ (silica excepted): Ca solubilities are in the order of 22mM and Si solubilities in the order of $1\mu\text{m}$. Thus the ratio of Ca:Si in solutions coexisting with lime-rich C-S-H, or with mixtures of $\text{Ca}(\text{OH})_2$ and C-S-H, is $\sim 22 \times 10^3$. This ratio dominates the behavior of laboratory simulants for Portland cement. However, investigators frequently use silica sources containing soluble alkali and, as a consequence, laboratory simulations supposed to be of carefully controlled chemistry, frequently fail to achieve their intended purpose.

The impact of alkalis on Ca and Si solubilities is shown in Figure 2: KOH behaves in an essentially identical manner to NaOH. The impact of alkalis is generally to reduce the solubility of Ca while enhancing the solubility of silicon. Figure 3 illustrates these impacts. As can be seen, the combined effects of the common ion (hydroxyl) and increasing pH – not shown, but increasing to nearly 14 at 0.8M NaOH – are to decrease calcium solubility while at the same time increasing silica solubility, with the result that at high Ca/Si ratios, aqueous concentrations of Ca and Si become approximately equal at 0.8M NaOH. Thus the order-of-magnitude differences in Ca and Si solubilities, inferred from data on the $\text{CaO-SiO}_2\text{-H}_2\text{O}$ system, are greatly reduced or even reversed at typical pore fluid molarities, in the range 0.1 – 1.0M. This conclusion must inevitably affect how we think about hydration processes in fresh cements. The mobility of species is a function of several factors, concentration being one, but with the result that species generally regarded as immobile on the basis of laboratory simulants, e.g., Al and Si, may be relatively mobile in pore waters whose alkalinity is conditioned by sodium and potassium.

Indeed, the solubility trends also affect how we model cement hydration processes. An often-used method to monitor hydration processes is the “chemical reactor” in which weighted amounts of cement or cement minerals are dispersed in water, typically at w/s ratios 5-50, while the stirred solution is monitored for pH, calcium and silicon contents, etc., as a function of time. The method works well for congruently-soluble substances although it may be less reliable for incongruently soluble substances. However, the seemingly good agreement obtained between, on the one hand, cement minerals, and on the other, real cements, results from the high dilution of alkalis which is achieved: real cement pastes formulated to much lower w/s ratios, *ca* 0.4 – 0.8, will behave quite differently than in the chemical reactor.

Figure 2. Relationship between solid $\text{CaO}:\text{SiO}_2$ ratio and aqueous composition: the vertical scale shows CaO concentrations (left-hand scale) and SiO_2 concentrations (right-hand scale) as a function of alkali (NaOH) molarity.

3.4 Solubility of Alkalis in Pore Fluid

Alkali releases into pore fluid are subject to a balance: some alkali remains sorbed in cement hydrates. Moreover, blending agents and aggregates are not totally inert and may (i) release alkali and (ii) by reacting with cement hydration products, alter their sorption characteristics. These factors jointly control the partition of alkali between solid and aqueous phases and require to be explored in light of recent knowledge. The rationale is, of course, to obtain a deeper understanding of the alkali-aggregate reaction (AAR). In AAR, susceptible siliceous aggregates are attacked by hydroxyl ions in the pore fluid. Their susceptibility increases rapidly as pH rises above the threshold conditioned by $\text{Ca}(\text{OH})_2$. However, not all the alkali is available to elevate pH.

A partition of alkalis occurs between the aqueous phase and cement solids. Of these solids, alkalis are virtually insoluble in both portlandite $\text{Ca}(\text{OH})_2$ and ettringite, leaving C-S-H and AFm phases as potential hosts. Of the potential hosts, C-S-H is much the most abundant in ordinary Portland cement where it comprises perhaps 70% by volume of the paste.

The general question of alkali partition between C-S-H and pore fluid has been approached in two ways. Taylor [19] collected pore fluid analysis from the literature, admitting data where cement alkalis were also reported. Sodium was treated separately from potassium. The results, after considerable recalculation and estimates of the total volume of residual pore fluid, were recast into semi-empirical equations which, starting from a cement analysis and w/c ratio, could be used to predict pore fluid alkali concentrations. Hong and Glasser [17, 18] took a somewhat different approach. Accepting that C-S-H was the principal sink for alkali, they prepared C-S-H gels of known C/S ratio and carefully homogenised the gels. A weighed amount of gel of known composition was mixed with a measured volume of aqueous solution having a known concentration of either NaOH or KOH. Aliquots of the aqueous phase were analysed periodically until a steady state was obtained: this generally required only a few days. The decrease in aqueous alkali concentration, coupled with other system parameters, enabled a distribution coefficient, R_d , to be calculated such that at constant temperature.

$$R_d = \frac{\text{Alkali in solid C-S-H, mM/g}}{\text{Alkali concentration in solution, mM/ml}}$$

Alkali-loaded gels were also used to determine desorption isotherms by dispersing the gel into initially pure water. It was concluded that sorption and desorption were not strictly reversible, although further tests of reversibility were recommended. But the ready release of alkali from “C-S-H” broadly supports the results of leach testing, which show sodium and potassium to be amongst the most weakly bound of the major components of cement. Concerning the sorption process, it was concluded that C-S-H and C-A-S-H gels were not alkali-saturated at (Na,K)OH aqueous concentrations in the range 0.2 – 0.3M: significant unused capacity remained. However, as pore fluid alkali concentrations exceeded about ~0.05 to 0.1M, sorption became less efficient as evidenced by a decrease in R_d . The introduction of Al into C-S-H made only a slight difference to alkali uptake at high Ca/Si ratios. But as the Ca/Si ratio decreased, Al had a progressively greater impact on increasing the numerical value of R_d : i.e., its introduction into C-S-H favoured alkali fractionation into the solid. This, it was suggested, helped explain the impact of fly ash on pore fluid alkalis concentrations and resolved the paradox, well recognised in the literature, that despite the often high (1 – 2wt%) alkali content of PFA’s, their inclusion in a blended cement reduced pore fluid alkalis. The explanation is that not only was more C-S-H produced in blends, but the Ca/Si ratio of C-S-H was reduced. This, coupled with enhanced alumina substitution in low Ca/Si ratio C-S-H, increased the number of silanol, Si-OH, sites as well as their mean acidity. Thus increase in the number of silanol sites and the strength of binding at these sites more than overcame the impact of additional alkali liberated from the fly ash: the net result was to reduce pore fluid alkalinity.

Subsequent to the publication of these papers, Van Eijk and Brouwers [20] have incorporated the alkali partition function into an overall model of pore fluid composition, which they proceeded to test. They found that the empirical approach by Taylor for sodium agreed well with Hong and Glasser's model, but that the fit for potassium was markedly better for Hong and Glasser's data.

The foregoing presentation has concentrated on intrinsic alkali contents, i.e., alkali released by the hydration of cement and cement blending agents. Indeed, specifications on the selection of cements for use with aggregates susceptible to alkali-aggregate reaction (AAR) are often based on cement alkali contents typically defined as Kg Na₂O equivalent per m³ of concrete. However, as Berube, *et al* have convincingly demonstrated, aggregates may also be a significant source of soluble alkali [21]. Berube, *et al* noted that some rock types, such as phonolites, were especially liable to alkali release but that even well-crystallised feldspar, especially potassic feldspars, as frequently occur in granitic rocks, could contribute as much or more alkali to pore fluid than commercial cements. Dow and Glasser [22] will also report that the impurity phases in semi-synthetic pozzolanic admixtures may release alkali. In this instance, the mica and feldspar impurities in kaolin were activated in the course of heating, essential to convert kaolin to metakaolin.

In summary, therefore, the alkalis in pore fluid arise spontaneously in the course of hydration. The alkalis partition between pore fluid and the solid phases: in ordinary Portland cement, C-S-H is the principal alkali-binding solid. Its capacity to bind alkali is dependent on (i) C/S ratio and (ii) extent of Al for Si substitution: both increase markedly the partition of alkali into the solid, other factors being equal. The kinetics of release from clinker are broadly understood. The cement itself contains alkali sulfates, which dissolve rapidly, as well as slower release sulfates, principally in the form of alkali in solid solution with clinker minerals, e.g., Na in tricalcium aluminate, potassium in belite. Depending on the balance between fast and slow release forms, alkali is liberated to pore fluid. The alkali is sorbed into C-S-H and, to a lesser extent, AFm. These phases equilibrate relatively rapidly with pore fluid, within hours or days, so pore fluid compositions change mainly in response to (i) changes in the volume of pore fluid, (ii) total alkali content and its fractional release rate and (iii) the alkali partition coefficient (R_d) into solid. The latter is of course composition dependent which helps explain the apparent paradox that coal combustion fly ash which, while often containing much more alkali than cement, nevertheless decreases pore fluid alkali contents: its contribution to increasing acidity of the C-S-H favours alkali partition into C-S-H and the effect is so marked as to outweigh the additional gain of alkali. However, not all fly ashes will necessarily achieve this favourable condition and there is a continuing need to refine and quantify the data. In this context, it should also be recalled that addition of alumina-rich phases, besides affecting C-S-H, also generates more AFm: preliminary indications are that AFm is also a strong sorber of alkali, especially potassium. Moreover the addition of reactive alumina-rich phases, besides affecting C-S-H, also generates more AFm.

4. WATER-DEFICIENT PASTES: "HIGH PERFORMANCE" CONCRETES

Much recent interest centres on high performance concretes. Formulations described in the literature have three characteristics: (i) they are formulated to low w/c ratio, usually <0.4, (ii) contain a high proportion of fines, e.g., specially ground, high surface area cement and other mineral admixtures and, (iii) they may need to be dosed with fairly high levels of superplasticisers to achieve workability. On account of the low w/c ratio, often less than that which is required completely to hydrate the clinker, even mature hardened pastes may contain much clinker: pores which are water filled in normal concretes either become empty, or fill with hydration product, or both. As a consequence the paste may self-desiccate with dimensional shrinkage. However, a special concern is the fate of dissolved components in pore fluid: as the aqueous phase depletes, concentrations of alkali presumably rise to levels not encountered in normal pastes: the internal

environment becomes hyperalkaline. We can at present only speculate on the consequences of developing hyperalkaline pore fluid in respect of initiating mineralogical reactions. Table 2 shows a tentative sequence of reactions. The effect of these reactions may vary in extent. For example, as sodium and potassium concentrate in residual pore fluid, its solubility for sulfate, aluminate and silicate increase. But because the volume of pore fluid is sharply diminished, the number of moles of sulfate, silicate and aluminate dissolved, relative to total moles in the solids, must be small. Thus the amount of a phase required to dissolve, e.g., of C-S-H to furnish sufficient silica to saturate the remaining aqueous phase, is small. Similarly, the total number of moles of sodium in pore fluid are unlikely to be sufficient to convert much of the AFm in the paste to U phase, probably $C_4A_{0.9}N_{0.5}S_{1.1}H_{16}$. However, dissolution of cement substance in residual pore water also lowers its activity and this may well exert the most important influence on late-stage hydration. It is well known that a critical humidity is needed to maintain cement hydration [15]. The reduced activity of “water” obtained by dissolution of cement substances is equivalent to reducing its relative humidity. Thus it is envisaged that water will not simply vanish in the course of hydration, but that hydration will effectively cease when the vapour pressure exerted by pore water - effectively converted to a concentrated salt solution - decreases to the minimum value necessary to sustain hydration. It is therefore opportune to revisit the Powers-Brownyard (P-B) model [33] of cement hydration to analyse in more detail mineral balances, including the amount of residual aqueous phase, occurring in the transition between regimes, one of excess water and the other, of water deficiency. Figure 3 shows a reconstruction of the P-B model. Note that evaporable water was found to persist even at low total water content, providing support for the contention that pore water will persist even in the presence of unreacted clinker, and that the coexistence of unhydrated clinker and pore “water” may actually be consistent with a steady state. In this view, the continuous changes in the activity function of water permits a smooth curve to be drawn, without the inflection point assumed in the P-B interpretation. We would, however, predict (i) that the portion of the curve to the right of the inflection point, i.e., at high w/c ratios, would be relatively independent of cement alkali content but that (ii) the exact shape and disposition of the curve to the left (i.e. its prolongation to low w/c ratios), would depend on cement alkali contents and (iii) that blending agents, e.g. slag, fly ash, will displace the position of the curve, depending on fraction reacted and composition of the blending agent.

Figure 3. The graph of w/c (ratio of evaporable water to cement) and w/c (total water/cement ratio), assuming no bleed water. Data points from [22] are omitted but a reinterpretation is suggested. The dot marks the point at which in the original, an abrupt change of slope occurs but which in the present study is suggested to lie at an arbitrary point within a short region in which the physiochemical characteristics of “water” undergo accelerated change.

Table 2. Chemical and Mineralogical Changes in Cement Paste undergoing self-desiccation.

Reaction	Comment
Enhancement of alkali content in residual pore fluid.	Increase in sulfate, silicate and aluminate concentrations in residual fluid: conversion of AFm to “U phase”.
Reduction of water content of hydrate phases.	Ettringite water decreases to $30\text{H}_2\text{O}$. Lower hydrates of AFm form. Self-desiccation of C-S-H occurs.
Precipitation	Direct precipitation of sodium aluminates, etc., as alkali concentrate and free water content approaches zero.

5. ADDITIONAL DISCUSSION AND CONCLUSIONS

The quantification of cement science has proved to be a slow process. Much work has been done in highlighting mineralogical changes in response to internal reactions (those initiated and conditioned by reaction with service environments are for the moment excluded). Yet the cement community, while freely using quantitative data and applying it to diverse problems such as heat treatment for accelerated curing, the selection of cements and aggregate to avoid alkali-aggregate reaction, and other important problems, has been reluctant to fund new initiatives, or even press a case for support to funding bodies such as national research councils, for basic science initiatives aimed at a fundamental understanding of the hydration process. Although some lines of research have reached a dead end, the new directions necessary to provide a scientific basis for improved cement properties are clear.

Quantification and modelling are seen as complementary: modelling is the tool whereby practical applications can be realised. While models are relatively well-developed, the weakness of their application is in the database: the wealth of validated data necessary to support and sustain calculations. By focussing on the internal chemistry, in this instance the aqueous phase, and relating to its practical examples, it is shown how many long-standing issues can be clarified, even if not resolved, at a stroke. For example, fractionation of alkalis between pore fluid and cement solids is conceptually presented as a series of partition functions, one for each pair of phases. The behaviour of a real cement pastes is the summation of the separate components multiplied by the mole fraction of each. Data are presently available only for C-S-H but, as it is the most abundant sorber of alkali, it enables a first generation model to be developed. To advance this model, additional data needs to be generated on the partition of alkali as a function of Al content - possibly also of the sulfate content in C-S-H - and the resulting impact on distribution coefficients. Thus the way ahead is broadly clear, even if much important detail remains to be quantified. The outcome, a quantitative model for the alkalinity function of Portland and blended Portland cement, would enable a more scientific basis to be established in respect of aggregate selection, particularly for alkali-susceptible aggregates. Progress need not always rely on “frontier” methods: as shown in my reinterpretation of the Powers-Brownyard model, even the application of simple and assessable techniques will enable progress to be made.

Cement science is thus seen as being at the verge of a new era with respect to durability - and performance related improvements not necessarily entailing additional costs. The rate of progress towards these goals lies in the lands of producers, consumers and stakeholders.

ABSTRACT

Hydration of fly ash blended Portland cement was allowed to take place at 20 and 60°C in the presence of sulphonated melamine formaldehyde condensate (SMF) and sulphonated naphthalene formaldehyde condensate (SNF) superplasticizers. Hydration properties varied considerably with temperature and superplasticizer. Compressive strength was highest in the presence of SMF at 60°C.

1. INTRODUCTION

Many industrial materials considered essential for supporting a better quality of life consume large amounts of energy for their production. Ordinary Portland cement (OPC) is used widely as a building material and its manufacture consumes large quantities of energy. In India, the cost of energy accounts for >40% of the total cost of cement manufacture. The cost to manufacture cement is expected to increase because of increasing demands for energy. Scientists are attempting to prepare OPC and other binding materials at lower cost by using agricultural and industrial wastes during clinkerization and by making blended cements. These measures decrease the cost of production, conserve mineral resources and protect the environment by beneficial disposal of wastes. Blended cements are usually blends of Portland cement clinker with other finely ground materials (also known as mineral admixtures) that take part in the hydration reactions and thereby make a substantial contribution to the hydration products. A large number of blended cements using a variety of waste materials have been studied¹⁻⁷. One of the most important blending components is fly ash that is obtained from thermal power plants using pulverized coal. Incorporation of fly ash in Portland cement concrete is common practice now, due to technological, economic and environmental benefits. It reduces the water requirement, rise in temperature and bleeding and improves the workability and strength development. These properties are further changed in presence of superplasticizers^{8,9} and with temperatures¹⁰. In this paper hydration of OPC – Fly ash blended cement in presence of SMF and SNF at 20 and 60°C has been studied.

2. EXPERIMENTAL

2.1 Materials

Ordinary Portland cement (Prism) was used for detailed hydration studies. The oxide and mineralogical compositions of the cement are given in Table 1 and 2 respectively. The Blaine surface area was 2.82 m²/g. The chemical composition of fly ash is given in table 3.

Sulphonated melamine formaldehyde condensate (SMF) and sulphonated naphthalene formaldehyde condensate (SNF) have been used as the superplasticizers.

Superplasticizers SMF and SNF of concentration 1.0 wt. % with reference to fly ash blended Portland cement was used for the hydration studies. The blended cement with 20 wt % fly ash is referred to as blended cement and all the experiments were done with this cement.

Table 1. Oxide composition of Portland cement

Oxide	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	TiO ₂	PbO	ZnO	MnO	P ₂ O ₅	SO ₃
Composition wt%	19.75	4.84	3.26	62.66	4.19	0.54	0.06	0.44	0.77	0.09	0.15	0.03	2.13

Composition wt%	59.06	24.34	7.59	1.40	0.97	0.43	1.42	1.85	1.79	1.15

2.2 Methods

2.2.1 Preparation of Blended Cements

OPC and FA were mixed in different proportions and homogenized. OPC was replaced by 5.0, 10.0, 15.0, 20.0, 25.0 and 30.0 wt. % FA and then stored in polythene bags.

2.2.2 Setting Time

Initial and final setting times were determined with the help of a vicat apparatus at room temperature.

2.2.3 Preparation of Hydrated Samples

Blended cement with 20 wt % FA was mixed with and without 1.0 wt % SMF and SNF separately with a W/S = 0.5 at 20 and 60 °C. Hydration was allowed to occur at different intervals of time and then stopped with the help of isopropyl alcohol and ether. The hydrated samples were then dried at 105 °C and stored in polythene bags for analysis.

2.2.4 Combined Water Content (W_n)

One gram of the hydrated blended cements was heated in ceramic crucibles at 1000 °C for one hour and from the weight loss the combined water contents were determined.

2.2.5 Free Calcium Hydroxide Content

One gram of the hydrated samples was refluxed for one hour in presence of 40 ml isopropyl alcohol: acetoacetic ester (20:3). The filtrate was then titrated against 0.1 N HCl in order to determine free calcium hydroxide content¹¹.

2.2.6 Electrical Conductivity Measurements

The electrical conductivities of the blended cement pastes in the absence and presence of 1.0 wt % SMF and SNF (W/S = 1.0) at 20 and 60 °C were determined with the help of a digital conductivity meter. In each experiment 10 g blended cement was taken. The measurements were made at 20 and 60 °C for about 3 hours.

2.3 Study of Adsorption of Superplasticizers

In order to study the adsorption of superplasticizers spectral studies were made. First the u.v. spectra of water solution (0.05 wt %) of SMF and SNF were recorded and the λ_{\max} values were determined at 220 and 285 nm respectively. One gram of blended anhydrous blended cement and hydrated for 24 h in the absence of superplasticizer solution (0.05 wt %) was shaken for 5 minutes and then filtered. The optical density at λ_{\max} was then determined. One gram of anhydrous blended cement was shaken with 10cc water for 5 minutes and then filtered. The optical density of this filtrate was determined at 220 and 285 nm. In order to determine the extent of adsorption these values were subtracted from the optical density values determined in the presence of superplasticizers. These experiments were carried out at 20 and 60 °C.

2.4 Compressive Strength Measurements

Blended cement was mixed with 1.0 wt % SMF and SNF (W/S = 0.32) and the pastes were filled in different moulds to form cubes (8 x 8 x 8 cm³). These cubes were taken out of the moulds after 48 hours and submerged in clean water at 20 and 60 °C until taken out just prior to measurement. Compressive strengths were measured by breaking the cubes with the help of a compressive strength testing machine (AIMIL India. Each observation is an average of three observations.

2.5 Results and Discussion

Setting times of fly ash blended Portland cements of different composition in presence of 1.0 wt. % SMF and SNF were determined. It was found that both initial and final setting times increased with the increase of Fly ash but the increase was more pronounced when OPC was replaced by 20.0 wt. % Fly Ash. Thus this concentration of fly ash was considered as the optimum limit for making the blended cement.

The variations of combined water content (W_n) of the hydrated blended cement in the presence of superplasticizers at 20 and 60 °C are given in Figure 1. The values increased with hydration time and temperature indicating that the degree of hydration of the blended cement increased with time and the increase was more at higher temperatures. From the figure it is also clear that in the presence of SMF the extent of hydration is higher than in the presence of SNF.

Figure 1. Variation of Combined Water Content (W_n %) in the presence of wt. % Superplasticizer at 20 and 60 °C

The variation of free calcium hydroxide content with time is shown in Figure 2. The values increased up to 7 days of hydration at both the temperatures and then decreased. The results show that up to 7 days of hydration, free calcium hydroxide liberated either could not react or reacts very slowly with fly ash. But after this the pozzolanic reaction enhanced and the values decreased because of consumption of free calcium hydroxide. Both liberation and pozzolanic reaction of Ca(OH)_2 increased with the increase of temperature. The consumption of Ca(OH)_2 in the presence of SMF after 7 days is higher than in the presence of SNF indicating that at 60°C , SMF enhances the pozzolanic reactions more than SNF.

The variation of electrical conductivities with time at a particular temperature was almost constant up to 3 hours (the time of measurement) in the presence of both SMF and SNF. However, the values were slightly higher at 60°C as compared to those at 20°C and also the values were slightly higher in the presence of SNF. It appears that the superplasticizers are adsorbed at the surface of cement and hinders the dissolution of ions in the solution responsible for conduction. Also SMF might be adsorbed more as compared to SNF.

Figure 2. Variation of Free Ca(OH)_2 Content in the presence of 1.0 wt. % Superplasticizer at 20 and 60°C

The percent adsorptions of the superplasticizers on the surface of blended cement hydrated for 24 hours are given in Table 4. SMF is adsorbed more than SNF and the extent of adsorption is higher at lower temperatures.

Table 4. Extent of adsorption of SMF and SNF on the surface of blended cement hydrated for 24 h at 20 and 60°C

Superplasticizers	Percent adsorption	
	20°C	60°C
SMF	45	38
SNF	41	36

The superplasticizers can affect the process of hydration by interacting at the surface of hydrated blended cement in a number of ways¹². These include reduction of the surface tension of water, electrostatic repulsion between particles, lubricating film between cement particles, inhibition of surface hydration of cement, steric hindrance in particle-particle contact and change in the

morphology of hydration products. Both physical and chemical interactions may be involved, but it is difficult to differentiate. However, low adsorption at higher temperature is in favour of physical adsorption.

The variations of compressive strength with hydration time in the presence of SMF and SNF are shown in Figure. 3. The values increased with time and temperature. The compressive strength values are higher in the presence of SMF as compared to those in the presence of SNF. According to Mor and Mehta¹³ the higher compressive strength is due to lower amounts of large capillary pores present in the presence of superplasticizer.

Figure 3. Variation of Compressive Strength in the presence of 1.0 wt. % Superplasticizer at 20 and 60°C

3. CONCLUSIONS

The results have shown that:

1. The hydration of fly ash blended Portland cement is more in the presence of SMF at 60°C.
2. The adsorption of SMF on the surface of hydrated blended cement is more as compared to that of SNF and the extent of adsorption is higher at 20°C.
3. SMF accelerates the pozzolanic reactivity of FA at 60°C.
4. Compressive strength is highest in the presence of SMF at 60°C.

It is concluded that SMF is a better superplasticizer as compared to SNF in accelerating the hydration of fly ash blended Portland cement especially at higher temperatures.

ABSTRACT

This paper highlights the use of frequency domain electrical measurements for the investigation of PFA as a replacement material in OPC based mortar. Impedance data were acquired in the frequency range 1 Hz up to 10 MHz on mortar samples containing PFA from three different sources as well as plain OPC. The results corroborate and extend previous findings, confirming that the introduction of PFA produces a unique electrical signature when the data are viewed in complex-plane format. Analysis of the impedance and de-embedded conductivity and dielectric constant show that this PFA-effect results from a polarisation mechanism operating largely between 1 kHz and 100 kHz, which is superimposed on the electrical response of the plain OPC. The exact characteristic of the PFA-effect is shown to be determined by the type of PFA present. These findings suggest that electrical measurements could provide the means for the detection and characterisation of PFA in cementitious materials for quality control purposes.

1. INTRODUCTION AND THEORY

The utilisation of replacement materials such as pulverised fuel ash (PFAⁱ) has assumed an important role in the design of durable cementitious systems and extensive use continues to be made of these quality-enhancing by-products. However, design for, and prediction of, durability and performance are rendered irrelevant if quality is not monitored satisfactorily at all stages during production, and there is considerable on-going debate on the problem of non-compliance with product conformity standards. In the case of PFA the need for a simple-to-apply characterisation technique is of major importance, not merely because of its widespread use but because the amount and quality of PFA in the binder has a decisive effect on its performance. This paper highlights the use of the electrical response as the basis of a test method in this field and builds on previously reported work [1][2][3].

Impedance spectroscopy (ISⁱⁱ) is now a developing technique in the characterisation of cementitious systemsⁱⁱⁱ. IS involves monitoring the electrical response (usually current flow in amps) of a material as a function of the strength (in volts) and frequency (f , in hertz) of an applied sinusoidal electric field. The ratio of voltage to current, inclusive of the phase difference, is a frequency dependent complex parameter called impedance:

ⁱ PFA is also known as fly ash in European Standards and in many countries. Fly ash may also refer to non-coal ashes such as incinerator ash. These might have significantly different properties that don't offer the same advantages as PFA from coal.

ⁱⁱ sometimes known as IMMITTANCE spectroscopy, a catchall term covering a range of related electrical parameters such as impedance, admittance, relative permittivity, dielectric modulus, complex conductivity and complex resistivity.

ⁱⁱⁱ see, for example, *Advances in Cement Research*, Vol. 10, No. 4, Oct 1998 – complete issue.

$$Z(\omega) = Z'(\omega) - jZ''(\omega) \quad \dots(1)$$

where, Z' is the resistive component and Z'' the reactive component of impedance (both ohms), ω ($=2\pi*f$) is the angular frequency (radian/sec) and j is the complex operator ($\equiv\sqrt{-1}$).

In aqueous, heterogeneous, non-magnetic materials such as cement paste, mortar or concrete the underlying mechanisms responsible for electrical behaviour are strongly correlated to the physical and chemical properties of the individual material components, and the way in which they are combined. This correlation is manifested in the frequency domain as dispersive behaviour characterised by frequencies of relaxation above which the *dielectric constant* ($\epsilon'_r(\omega)$) falls, and the *conductivity* ($\sigma(\omega)$ Siemens/m) rises (the respective polarisation of bound charges and conduction of free charges within the material determine these intrinsic electrical parameters). The impedance is related to the dielectric constant and the conductivity in accordance with the expression:

$$Z(\omega) = ((\sigma + j\omega\epsilon'_r\epsilon_0)k)^{-1} \quad (2)$$

where, ϵ_0 is the permittivity of free space ($=8.854\times 10^{-12}$ Farads/m), and k (m) is the cell constant, a factor determined by the sample holder and electrode system. Equation (2) is only valid at frequencies where the signal wavelength is significantly larger than the electrode dimensions.

Different materials, and different stages of material development, may therefore be identified using electrical measurements, provided these are obtained across a wide enough range of frequencies, making IS a potentially powerful diagnostic technique. Several other advantages may be afforded by the use of IS: the technique is non-destructive and non-invasive; samples need not be restricted to cement pastes as mortars and concretes can be easily studied; the acquisition of data is relatively simple, and continuous monitoring can be carried out under normal pressures and temperatures.

In this paper we report on the use of IS within the frequency range $\approx 1\text{Hz}$ - 10MHz as a characterisation technique in the study of PFA binders, particularly in the early stages of hydration. IS is used to:

- investigate the complex immittance spectra of individual PFA's as a possible characterisation signature
- provide frequency spectra for the detection of PFA in concrete

2. EXPERIMENTAL WORK

2.1. Impedance Measurements

A Solartron 1260 frequency response analyser (FRA) was used to obtain electrical impedance data on mortar samples containing PFA. A 100 milli-volt energising signal was employed, and resultant current was monitored at 20 points per decade of frequency increase, giving a total of 141 points for the investigated 1Hz to 10 MHz range. Control of the FRA was by means of Solartron Z60 software run on a Hewlett Packard HP486/66 personal computer. Cuboid shaped samples were moulded in rigid Perspex cells of nominal internal dimensions $50\times 50\times 50$ mm. Attached to two internal opposite faces were square (50×50 mm) 3 mm thick stainless steel electrodes. Electrical connection was facilitated by threaded stainless steel rods which were passed through the cell walls and welded to the back of the electrodes. Connection to the FRA was effected by individually screened coaxial cables of length 0.4 m.

At frequencies higher than ≈ 100 kHz the impedance of the leads can have a masking effect on the required impedance of the measurement cells. The acquired data was therefore subsequently processed to calibrate out this effect. The process involved the prior acquisition of data on three known impedances (a short circuit, an open circuit and a capacitor-resistor network containing precision components) at each frequency point [3]. The algorithm used to achieve this was developed in-house and run as a routine in Mathcad.

Impedance data thus acquired represent the electrical properties of the specific samples (including electrochemical interaction with the electrodes). In order to consider the *intrinsic* electrical properties of the materials under test, independently of sample dimensions, the parameters dielectric constant, ϵ_r' , and conductivity, σ , were de-embedded from the measured impedance in accordance with equation (2). The cell constant, k , for the parallel plate electrode system used is calculated from the area of the plates divided by the distance between them, or it can be obtained from measurements on materials of known electrical properties. For the present arrangement k has a value of 0.0565.

2.2. Materials, Samples and Curing

Ordinary portland cement (OPC) was used as the main binder in the mortar samples. PFA samples of part 1 quality [6] from several UK sources were investigated, and the results for three are presented here. These are Longannet Power Station in Scotland (PFAL), FerryBridge C Power Station in W. Yorkshire (PFAF), and Eggborough Power Station in E. Yorkshire (PFAE). The chemical analysis for each binder material is given in Table 1. PFA fineness is quoted as the percentage retained on a 45-micron sieve. Four mortars were fabricated, one using a pure OPC binder, and three others with OPC partially replaced by each PFA at a level of 33% by mass. The aggregate used for the mortars was a uniformly fine-grained Leyton-Buzzard sand. All four mortar samples had a sand:binder mass ratio of 3:1 and a water/binder ratio of 0.5.

Table 1. Chemical and physical properties of cementitious materials

	OPC	PFAL	PFAF	PFAE
Fineness (on 45 μm)	-	8%	9.5%	13.5%
Specific Gravity (g/ml)	3.15	2.09	2.1	2.1
% component				
SiO ₂	20.68	51.0	50.5	44.3
Al ₂ O ₃	4.83	34.7	24.7	24.7
Fe ₂ O ₃	3.17	4.6	7.4	9.2
CaO	63.95	3.4	2.6	5.9
MgO	2.53	1.4	1.5	1.9
SO ₃	2.80	0.7	0.8	0.69
TiO ₂	-	1.6	1.0	1.4
K ₂ O	0.54	1.0	3.0	1.7
Na ₂ O	0.08	0.2	0.8	0.6
LOI	1.90	5.5	5.3	1.9

Prior to gauging all materials were thoroughly mixed by shaking together in a closed plastic storage bottle. Water was added to the dry blend in a ceramic bowl and hand mixed for about eight minutes. Samples were compacted in the measurement cells in layers using mild vibration and hand tamping. Following compaction, the tops of the measurement cells were covered with Perspex lids. In the case of the mortar samples the first swept frequency measurements were then taken (≈ 10 minutes) and the samples subsequently stored in the humid environment of a small plant propagator. The mortars were removed from the chamber prior to each subsequent measurement sweep (at 30 min, 60 min, 120 min, 240 min and 1-3 day).

3. RESULTS AND DISCUSSION

3.1. Impedance Measurements

Figure 1 displays impedance data obtained immediately after gauging (≈ 10 minutes) in complex plane format for the four mortar samples (plain OPC plus one each containing PFAF, PFAE and PFAL). Data are presented from ≈ 20 Hz up to 1 MHz. For freshly gauged material the impedance values (particularly the reactive component) are not measured reliably at frequencies higher than this. This appears to be due to the relatively high conductivity of the pore water, but the full reasons are not clear.

Indicated on the plot for plain OPC is the “cut-off” frequency (70 kHz). This is the point of convolution of the bulk material and electrode polarisation responses, above which the electrode effects become much less significant and below which the reactance of the sample material is considered to be less significant [4][5]. This feature has been previously noted by many workers and, because the reactance is at a minimum, is used to obtain an accurate approximation to the DC resistance of the sample (in this case 51.29 ohms at 70 kHz).

Figure 1. Impedance of Mortars at 10 min

It is clear from Figure 1 that each of the PFA mortars is quite distinct from the plain OPC case in that a plateau or shallow-arc region appears above the apparent cut-off frequency of the electrode effects. This confirms previous findings [3] (although these had been confined to PFA from Longannet power station) and suggests, together with results from other UK PFA samples (not presented here), that the “PFA-effect” is likely to be found in classified material from any similar coal burning power station. This general effect is *not* detected when other replacement materials (e.g. blast furnace slag, meta-kaolin, and micro-silica) are used [1][2]. There are, however, detectable differences between the three PFA samples. PFAL shows the most distinct arc-like plateau region and in this respect is closely followed by PFAF. PFAE lies closest to PFAF on the graph, indicating similar resistance, but the plateau region is not so prominent or obviously arc shaped.

The frequencies at which two of the key features of the PFA-effect occur are indicated on the plot for PFAF. The point at which the reactance reaches a minimum at the apparent upper end of the electrode arc occurs at 3.16 kHz, and the point at which the PFA-effect reactance is at a maximum is at 30 kHz.

Impedance plots for OPC and PFAF at approximately 3 days (73 hours) after gauging are displayed in Figure 2. This is the period during which the OPC component of the binders has begun hardening, but before the main reactions of the PFA have begun. These plots are presented to illustrate the persistence of the PFA-effect subsequent to the setting of the OPC. The data in this case are presented from 5 Hz up to 1 MHz. Again, the OPC cut-off and PFA-effect frequencies are indicated, with the addition of a second local reactance minimum at 126 kHz on the PFAF plot.

Figure 2. Impedance of Mortars at ≈ 3 Day

It can be seen in both Figure 1 and Figure 2 that the resistance of the PFAF mortar is about 10-20 percent higher than that of the OPC mortar. This is due to the partial replacement of the OPC, which is the major contributor of ions to the mix water. For an aqueous ionic conductor it is the ionic concentration which determines the level of electrochemical activity at the surface of the electrodes (electrode polarisation), and it can be generally observed that the higher the conductivity (i.e. ionic content) the higher the frequency to which such effects persist. The higher resistance of the PFA mortar can therefore be expected to promote a lowering of the cut-off frequency of the electrode polarisation, and it was previously assumed that the cut-off frequency for PFA binders was located at the extreme right hand end of the PFA-effect [3]. However, it is now thought that this point occurs at too low a frequency in comparison to those on the respective OPC plots. This suggests that the presence of the PFA is introducing a phenomenon that is significant at frequencies below and above the convolution point of the electrode and bulk material impedance arcs produced by a plain OPC binder. Obtaining an estimate for the DC resistance of the PFA mortars from their respective impedance plots is therefore not a simple matter as it is for plain OPC.

To explore this further, impedance data over the same frequency range were acquired from two modified “mortar” samples from which the OPC was removed. The first of these contained sand, PFAL, and sodium chloride solution at ≈ 0.1 M concentration (6g/litre). The purpose of adding the salt to the mix water was to compensate for the loss of ionic conduction caused by the removal of the OPC. The mix proportions were 200 grams of sand to 33 grams of PFAL and 40 millilitres of salt solution. The second sample had identical mix proportions but the PFA was replaced by glass spheres of diameter 30-50 μm . The purpose of the glass spheres was to produce a material that was physically (i.e. morphologically) identical to the sample containing PFAL but which was essentially inert in regard to its polarisation properties, while at the same time having similar chemical and conductive properties. The results, from 7 Hz to 10 MHz, are presented in Figure 3.

Figure 3. Synthesised PFA-Effect

The plot for the sample containing the sand and glass spheres can be seen to have a similar characteristic to that of the plain OPC with a sharply defined convolution point at 44.67 kHz. The sand and PFAL plot has a definite PFA-effect characteristic and has a slightly lower resistance. This is probably due to the low-level presence of ions dissolved from the PFA, but the lower density of the PFA might also be a determining factor. The frequency of the reactance minimum at the right hand side of the PFA-effect (708 Hz) is certainly too low to be the point of electrode polarisation cut-off. Interestingly, however, the frequency at which the shallow arc of the plateau region reaches its peak reactance (44.67 kHz) corresponds to the cut-off frequency of the plot for the glass spheres. Given that the materials are of comparable resistance and are morphologically very similar it seems reasonable to take this value as the cut-off frequency of the electrode polarisation effects. When this is applied to the plots for PFAF mortar in Figures 1 and 2, the electrode effect cut-off frequencies are 30 MHz and 14 kHz respectively, and these values accord well with those obtained from the associated plots for OPC mortar.

3.2. Conductivity and Dielectric Constant

Using equation 2, conductivity and dielectric constant data were de-embedded from the impedance measurements obtained at 10 minutes after gauging (Figure 1). These data are presented in Figures 4 and 5, and they give a clearer view of the conductive-dispersive [7] behaviour of the mortars.

In Figure 4 the low frequency masking of the measurements caused by electrode polarisation is clearly seen, particularly below 100 Hz. At frequencies above 1 kHz the increased slope on the plots for the PFA mortars is evidence of the presence of dispersion due to dielectric relaxation. By contrast the OPC plot is levelling out towards the electrode effect cut-off frequency of 70 kHz. The dispersive effect is most pronounced in the case of PFAL, which, although having the lowest conductivity, also has the most distinctive impedance PFA-effect.

Figure 4. Conductivity of Mortars at 10 min

The PFAF mortar displays a similar dispersion characteristic to the PFAL and because it appears to have a higher DC conductivity the frequency dependent conductivity actually exceeds that of the OPC at 1 MHz. This is despite having a lower ionic concentration than the plain OPC. The PFAE mortar shows the least pronounced dispersion characteristic, which accords with its less distinct impedance PFA-effect.

In Figure 5 the large enhancement of the dielectric constant of the PFA mortars over that of the plain OPC is evident between 1 kHz and 1 MHz. It is clear from this graph that the mechanism responsible for this effect is operating above and below the cut-off frequency of the electrode polarisation effects, confirming what was surmised above from the impedance data. The principal relaxation frequency of the polarisation mechanism appears to lie in the range 10 to 100 kHz. Again, the relative differences between the PFA mortars are visible, with PFAL showing the most pronounced dielectric enhancement and PFAE the most dispersed.

3.3. Material and Electrical Properties

It can be seen in Table 1 that OPC and PFA have similar chemical composition but that the main oxides are present in very different amounts, and this is known to account for the major differences in mineralogy between the two. There is also a considerable difference in the morphology of OPC and PFA particles. Although the particles are of similar average dimensions, OPC has a greater spread of particle size and the grains themselves are jagged and non-uniform in shape. PFA particles, by contrast, tend to be more uniformly sized and mostly consist of smooth glassy spheres, some of which are hollow. We have previously hypothesised that the major difference in morphology between these two materials is what promotes the large enhancement of dielectric constant evident when OPC is partially replaced by PFA, the smooth glassy spheres of the PFA lending themselves to the setting up of a highly polarisable electrochemical double layer on the particle surfaces [3].

Figure 5. Dielectric Constant of Mortars at 10 min

The reasons for the differences observed between the electrical properties of the PFA samples are not yet clear but examination of Table 1 allows the following observations:

PFAL and PFAF, which show the most distinct PFA-effect, have:

- higher silica content than PFAE (51.0% and 50.5% compared to 44.3%)
- higher carbon content (LOI) than PFAE (5.5% and 5.3% compared to 1.9%)
- lower lime (CaO) content than PFAE (3.4% and 2.6% compared to 5.9%)
- lower fineness than PFAE (8% and 9.5% compared to 13.5%)

PFAF and PFAE, which are generally more conductive than PFAL, have:

- lower alumina content than PFAL (both 24.7% compared to 34.7%)
- higher potassium oxide (K₂O) content than PFAL (3.0% and 1.7% compared to 1.0%)
- higher sodium oxide (Na₂O) content than PFAL (0.8% and 0.6% compared to 0.2%)

With regard to the observation that the PFA-effect is less well defined in the case of PFAE (see Figure 1) it is possible that the CaO content plays a part in this. Previous measurements (unpublished) with unclassified high lime (type C) PFA from North America have shown no evidence of the PFA-effect, but the reasons for this are not yet fully known. Work is continuing to widen the range of PFA sources accessed and the types of PFA examined.

4. CONCLUSIONS

Impedance data over the frequency range 1 Hz to 1 MHz have been acquired on freshly mixed mortar samples containing a plain OPC binder and three blended binders where 33% of the OPC was replaced by PFA from three different UK sources. The results show that the presence of each of the PFA's alters the electrical signature of the mortars (from that of the plain OPC) and introduces a plateau region in the complex impedance plot, confirming previous findings that were limited to PFA from one source. This effect is shown to persist after the setting of the OPC.

The PFA-effect is shown to be caused by the presence of a frequency dependent polarisation mechanism that greatly enhances the dielectric constant and conductivity of the mortar in the range 1 kHz to 1 MHz. The exact characteristic of the PFA-effect is also shown to depend on the type of PFA used and its mineralogical composition.

While work is continuing on PFA from a wider range of sources, these preliminary findings demonstrate the feasibility of using electrical measurements for detecting the presence of PFA in cementitious material, and also the possibility of distinguishing between PFA from different sources.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the financial support of the U.K. Engineering and Physical Sciences Research Council (grant GR/N16365). We are also grateful to Dr Lindon K. A. Sear of the U.K. Quality Ash Association for arranging the supply of PFA samples from a number of UK power stations, and to Mr Bill Armstrong of ScotAsh Limited for the supply of PFA from Longannet power station.

ABSTRACT

In Ultra High Performance Matrices (UHPM) mix design focuses on improving homogeneity, compactness, reactivity of the fine powders, and the microstructure of the cementitious matrix. Therefore, UHPM do not contain any coarse aggregate. Finely crushed quartz is also added to correct the granular distribution as well as to decrease the potential Ca/Si ratio of the C-S-H when the matrix is cured at high temperature.

The main purpose of this study was to see if UHPM could be made using less Portland cement and materials more reactive than crushed quartz such as fly ashes or blast-furnace slag. The consequences of these substitutions on the characteristics of fresh and hardened mortars were studied. Compressive strength was measured before and after hot-water curing at 90°C. For example, with slag, it was possible to reach a compressive strength of about 180 MPa with a replacement rate of 60 percent of Portland cement.

Slag matrices samples were also analysed using Nuclear Magnetic Resonance (NMR). ²⁹Si probe was used to identify and quantify all the phases produced during the hydration process. It was found that the Q₂/Q₁ ratio increased with the slag content, which means an increase of the average length of the C-S-H chain.

1. INTRODUCTION

Concrete is usually considered a low-tech commodity product despite the fact that many engineered concretes have been developed recently. The use of very efficient admixtures and silica fume, as well as the elaboration of new manufacturing processes, has resulted in an improvement of the mechanical properties of concrete. From the pioneering work of Brunauer and his colleagues [1] to the Reactive Powder Concrete (RPC) or Ductal[®] concept [2], very impressive compressive strengths have been achieved. These important mechanical and durability performances are mainly due to the high compactness and improved microstructure of this material made generally of sand, cement and silica fume. Designers could design lighter, more aesthetic structures, pushing back in this manner the frontiers of the imagination. In 1997, the first structure was built with an ultra high performance matrix in Sherbrooke [3].

One of the major difficulties when using UHPM concerns workability, which sometimes makes its casting difficult. Furthermore, because of the large amount of fine and ultrafine particles, high heat

emission can be measured during hydration. Although many researchers have worked for years on UHPM, up to now studies have basically been concerned with the optimisation of superplasticizer dosage [4] and not the nature of the "raw" materials used. In this paper the influence of the nature of several supplementary cementitious materials such as blast-furnace slag or fly ashes on the properties of fresh and hardened matrices have been studied. ^{29}Si nuclear magnetic resonance (NMR) has been used to investigate the microstructure of UHPM and better understand its evolution with the slag content.

2. EXPERIMENTAL

2.1 Materials

The physical data and oxide composition of the different powders used for the design of UHPM are given in Tables 1 and 2.

Table 1. Physical data of the cementitious materials used

	Type 20M cement	Slag	Limestone filler	Siliceous filler	Fly ash	Silica fume
Specific gravity	3.33	3.03	2.82	2.75	2.46	2.42
Blaine surface (m^2/kg)	380	630	510	850	850	-
Surface BET (m^2/kg)	-	-	-	-	-	21 500

Table 2. Oxide composition of the cementitious materials

	Type 20M cement	Slag	Limestone filler	Siliceous filler	Fly ash	Silica fume
SiO_2	23.1	35.5	3.5	93.3	73.2	95.9
Al_2O_3	3.6	10.8	1.0	0.7	19.7	0.6
Fe_2O_3	4.7	1.4	0.6	0.3	1.1	0.2
CaO	61.5	41.4	51.6	4.4	2.9	0.1
Na_2O	0.1	0.2	0.1	0.1	0.1	0.1
K_2O	0.6	0.3	0.1	0.1	0.6	0.9
MgO	2.4	8.1	0.7	0.2	0.4	0.6
SO_3 total	2.3	2.2	-	-	-	0.3
Loss on ignition	0.95	0.7	42.0	0.6	0.7	1.4

A Type 20M cement was used for all the mechanical tests. This low-heat cement has a C_2S content higher than most of the cements available in North America and a low C_3A -content: consequently, it displays a very low reactivity and allows workability gains. European slag was also used which was essentially glassy but had a small amount of crystallized merwinite due to its high MgO content. The fly ash came from Australia. Its X-ray diffractogram showed the presence of quartz and mullite with some traces of haematite. The limestone and siliceous fillers were local.

2.2 Processing methods and NMR experiments

The matrices were designed from a reference made essentially of cement and silica fume for its hydraulic part with a W/C mass ratio of 0.19, a polysulphonate-based superplasticizer at a dosage of 1.65% and a sand volume content of 38%. Then the cement was progressively substituted with a supplementary cementitious material X, the substitution rate varying $\text{X}/(\text{X}+\text{C})$ from 10 to 80%.

At the end of mixing, flow was measured according to ASTM Standard C 230 [5]. Afterwards, 50-mm cubes were cast and placed immediately in lime-saturated water at a temperature of 20°C for 48 hours. The cubes were then submitted to hot-water curing at 90°C for 48 hours. Compressive strength tests were performed at 48 hours, 91 days and after hot water curing according to ASTM Standard C 109/C 109M [6] with a load rate of 1110 N/s.

^{29}Si NMR experiments were performed on samples made with a Type 20M cement which didn't come from the same lot as the one used for the mechanical tests. However, their oxide composition and specific gravity were similar. The hydration of all the matrices was stopped with the acetone-ether method before testing.

The Magic Angle Spinning (MAS) single pulse spectra were obtained on a 11.7-Tesla Bruker ASX500 spectrometer with a cross-polarization probe for 7-mm zirconium oxide rotors at 7 kHz. ^{29}Si chemicals shifts are given relative to tetramethylsilane (TMS) at 0 ppm.

3. RESULTS

3.1 Macroscopic properties of UHPM

3.1.1 Flow

Figure 1 shows the flow evolution as a function of the replacement rate of cement. It can be seen that the higher the content of slag or limestone filler, the higher the flow. A maximum flow of 110% was reached for a replacement rate of 60%. After this point, if more slag or limestone filler is added, the flow decreases.

The siliceous filler has an identical behaviour but the flow maximum is given for a content of only 30%. Afterwards, the matrix rheology worsens rapidly: the flow of a mix containing 80% of siliceous filler is half that of the reference.

Figure 1. Flow evolution as a function of the supplementary cementitious materials content

As far as the fly ash is concerned, it induces a different rheological behaviour, and this in spite of its higher Blaine surface area. Indeed, the flow increases continuously with the fly ash content.

The supplementary cementitious materials used in this study have various surface states which explain the differences observed in the rheology of the fresh mortars [7]. In the case of the siliceous filler, cement is substituted by angular particles negatively charged, which are likely to absorb more superplasticizer or water molecules. Conversely, for the same Blaine surface area, the replacement of cement by fly ash, essentially made up of spherical particles of glassy material, results in an

improvement in the matrix rheology. In addition, the granular packing effect must be taken into account.

3.1.2 Compressive strength

The evolution of the compressive strength of UHPM at 48 hours, 91 days cured in lime saturated water at 20°C and after hot-water curing, is illustrated in Figures 2 and 3. Three 50-mm cubes were tested for each mix. Each experimental point is the average of three series of experiments done from three mixes prepared randomly.

Figure 2. Compressive strength evolution as a function of the supplementary cementitious materials content

Figure 3. Compressive strength evolution as a function of the supplementary cementitious materials content

Whatever the supplementary cementitious material used, the compressive strength at 48 hours decreases linearly with the replacement rate of cement, the least important negative slope being measured for the slag matrix. This evolution could be explained by considerations of kinetics order. Indeed, in all the mixes studied, the hydration reaction developed during the first 48 hours depends mainly on cement. In that way, the slope can be seen as a measure of the physical (*filler effect*) and chemical activity of the supplementary cementitious material used, the origin ordinate being only characteristic of the initial mix {cement + silica fume}.

Each compressive strength curve at 91 days or after curing exhibits a maximum and can be expressed by second-order polynomials. Statistical considerations of variance lead us to consider that there is no significant difference for the mixes with a substitution rate between 0 and 30%. Except for slag, strength curves decrease linearly for higher replacement contents, which reflect the hydraulicity of the mineral additive.

Finally, the evolution of the compressive strength of the slag matrix differs from that of the other cementitious materials. Indeed, whereas for the filler or the fly ash the difference between the 91-day compressive strength and the one obtained after hot water curing tend to disappear with the substitution rate, it seems to remain in the case of slag.

Compressive strength can also be expressed as a function of the W/C ratio. This variable change is illustrated for example for slag in Figure 4.

Figure 4. Compressive strength evolution as a function of the W/C ratio

It is possible to superimpose on the 48-hour compressive strength curves using the following equation:

$$y = A \times (x+1)^p \quad \text{with} \quad x = \rho_c \frac{W}{C} \quad (1)$$

Expression and regression coefficients are given in Table 3 for each type of substituting material.

Table 3. Equations of the fit curves for the 48-hour compressive strength

Complementary cementitious material	Curve fit	Regression coefficient (R ²)
Slag	$y=3.488(x+1)^{-5.148}$	0.9909
Limestone filler	$y=1.707(x+1)^{-6.469}$	0.9862
Siliceous filler	$y=2.101(x+1)^{-6.073}$	0.9891
Fly ash	$y=1.351(x+1)^{-6.912}$	0.9912

These expressions can be linked to the generalized Feret formula,

$$R = R^* \left(1 + \frac{E}{C} \right)^v \quad (2)$$

where the coefficient R^* is a constant representing the compressive strength corrected by the initial porosity of the matrix. A hierarchical organization of the supplementary cementitious materials similar to the one previously obtained appears: the use of blast-furnace slag seems to give the matrix with the lowest porosity.

The exponent v depends on the nature of the mix (cement paste, mortar or concrete). A previous study [8] indicates that it varies from 5 to 6 for cement pastes. In ours, the values of v are between 5 and 7, which may indicate that the homogeneity of our matrices are close to the one made from a cement paste. This observation is consistent with the UHPM mix-design concept in which the choice and content of each powder aim to obtain the best homogeneity.

This model can hardly be applied to the 91-day compressive strength curves or those obtained after hot water curing because of the simultaneous reaction of the supplementary cementitious materials and the silica fume.

3.2 Microstructure of UHPM

²⁹Si NMR experiments were performed to follow the evolution of the C-S-H polymerization degree as a function of the slag content. This method allows a quantitative observation of the silicon chemical environment provided the relaxation of all silicate species, except the siliceous sand, is respected. The ²⁹Si spectra are displayed in Figures 5 to 7. Each peak corresponds to a given chemical environment of silicon nuclei according to the Engelhardt and Michel chemical shift table for silicates [9]. The cement presents Q₀ species at −71.0 ppm. In accordance with previous work on synthesized C-S-H [10] or similar materials [11], we could sort the C-S-H with Q₁ and Q₂ species at −80.2 and −85.0 ppm respectively. The silica fume and quartz sand present Q₄ species at −111.0 and −107.2 ppm respectively.

The emergence of a peak at −74.0 ppm was noticed, which corresponds to one of the slag phases. Therefore, in order to calculate the C-S-H Q₂/Q₁ ratio, very short (500 ms) pulses were also used for the high slag content mixes. In this way, the slag signal could be drastically diminished and it was possible to properly quantify the C-S-H phase. The results are displayed in Table 4.

Table 4. C-S-H Q_2/Q_1 ratio of UHPM for different slag content

		Slag content (wt%)				
		0	20	40	60	80
C-S-H Q_2/Q_1 ratio	48 hours	1.07	1.08	1.02	0.99	0.93
	91 days	1.43	1.47	1.32	1.17	1.02
	Hot curing	1.81	1.99	2.09	2.47	2.83

At 48 hours, the C-S-H Q_2/Q_1 ratio decreases insignificantly with the slag content. A similar tendency is observed for the 91-day matrices, the variation of the polymerization degree being linked with the slight activity of slag and silica fume. Hot-water curing has a different effect on the matrices, the C-S-H Q_2/Q_1 ratio increasing with the slag content, which may be linked to the higher substitution of silicon by aluminium as noticed in ^{27}Al NMR experiments [12].

Figure 5. ^{29}Si NMR spectra of UHPM at 48 hours as a function of the slag content

Figure 6. ^{29}Si NMR spectra of UHPM at 91 days as a function of the slag content

Figure 7. ^{29}Si NMR spectra of UHPM after hot-water curing as a function of the slag content

Table 5 allows us to compare the quantities of silica fume remaining in the paste.

Table 5. Relative amount of silica fume in UHPM for different slag content

		Slag content (wt%)				
		0	20	40	60	80
Relative amount of silica fume (%)	Initial	50.1	47.4	45.1	42.9	41.0
	48 hours	46.5	44.7	42.5	39.7	-
	91 days	22.5	26.5	27.6	30.8	40.2
	Hot curing	14.2	12.3	16.9	17.6	-

After 48 hours, the same amount of silica fume was used whatever the slag content, which is mainly due to its slow kinetics of hydration. If the values at 91 days are compared, it seems that the higher the slag content, the less the silica fume has reacted. As expected, at ambient temperature, the slag activation is preponderant on that of the silica fume. Silica fume is mainly consumed during the hot water curing, even for low-cement content. In that case, silica fume should react with the C-S-H resulting from the hydration of slag and cement in order to form secondary C-S-H of lower C/S ratio.

Hot water curing has another effect on the matrices. Indeed, the existence of a large peak around -90.3 ppm has been observed, which can be related to Q_3 species, and whose intensity increases with the slag content. This may reveal the presence of an aluminium and magnesium-rich silica gel [13].

4. CONCLUSION

This paper presents the impact of different types of cementitious materials on the properties of fresh and hardened ultra high performance matrices. Thus, except for the siliceous filler, the supplementary cementitious materials used improved the rheology of the mixes, which is mainly due to their surface state. As far as compressive strength is concerned, slag appears to be the most promising mineral additive. Aside from 48-hour compressive strength values higher than those obtained for the other supplementary materials, 175-MPa compressive strength can be reached after hot-water curing for a replacement rate of 60 percent of Portland cement. The difference between the long-term compressive strength and those obtained after hot-water curing indicates that the latter has more than a kinetic effect on the hydration of the matrices. Therefore, in addition to a refining of the capillary network, thermal curing modifies the nature of C-S-H.

Moreover, the microstructure of mortars containing different slag contents was investigated by ^{29}Si NMR experiments. It appears that cement substitution at 48 hours and 91 days results in a decrease of the polymerization degree of the C-S-H. Hot-water curing has the opposite effect: thus, the average chain length seems to increase with the slag content. This phenomenon, backed up by some ^{27}Al NMR experiments, is to be linked to a higher substitution of silicon by aluminium.

ABSTRACT

This study concerns the durability of *oil well cementing*. During this process, a cement slurry (water/cement ratio=0.44 usually) is pumped down the steel casing of the well up the annular space between the casing and the surrounding rock to support and to protect it. The setting conditions in terms of pressure and temperature in the well are therefore expected to be severe (up to 1 kbar and 250°C). Here we report the hydration of the main component of cement: synthetic tricalcium silicate Ca_3SiO_2 , often called C_3S . Silicates hydrates are first elaborated in high temperature and pressure cell and then studied by various characterisation methods (^{29}Si - and ^1H -NMR, XRD, DTA-TG and SEM) to complete phase diagram (P,T) of the calcium silicate hydrates. To correlate macroscopic behaviour and physico-chemical properties of hydration products, mechanical tests are performed. C-S-H-phases are seen to disappear beyond 160°C and 0.4 kbar and to give crystalline phases such as α - and β -polymorphs of C_2SH , whose mechanical resistance is not so efficient.

1. INTRODUCTION

The aim of this study is to understand C_3S hydration under severe temperature and pressure conditions. Indeed, this hydration is well known at ambient temperature and pressure and leads to the formation of two phases: Portlandite and C-S-H. Portlandite is a crystalline phase with chemical formula $\text{Ca}(\text{OH})_2$, also called CH in the conventional notation of the cement and concrete industry [1]. C-S-H are not stoichiometric and poorly crystallised phases, which bring its adhesion properties to cement. The question is to know if these poorly crystallised phases are still stable under high pressure and temperature setting conditions and if the phases formed under such severe conditions (T up to 250°C and P up to 1 kbar) are still efficient binders. From oil and gas companies point of view, the disappearance of mechanical resistance of cement at high pressures and temperature is critical: it can lead to a loss of integrity of cemented annular and consequently can induce hydrocarbons production stops.

Two types of high-pressure cell have been used during this study. The aim was to reveal different hydration kinetics. The structural results are presented for the oldest samples hydrated at different temperature and pressure with the high-pressure cell (hydration period of 28 days). Indeed, the pressure parameter is found to increase the hydration kinetics. A pseudo-equilibrium is assumed to be reached. Each sample (P, T hydrated) has been analysed by various methods. First, the

crystalline phases have been detected by XRD. Then, a thermal analysis was performed in order to confirm the XRD results and quantify the different phases. In addition, (scanning electron microscopy) SEM was used to observe the morphology of the hydrated tricalcium silicate. At last, ^{29}Si then ^1H -NMR were used to confirm these results, to probe poorly crystallised phases, which may appear, and to achieve the quantification of the calcium silicate hydrates mixture. In order to correlate the macroscopic behavior and physico-chemical properties of the products, mechanical compression tests were performed.

2. EXPERIMENTAL

2.1 Sample elaboration

Synthetic C_3S (triclinic T1 structure) has been used for this study. Its quality has been verified by XRD, which showed a small amount of CaO (1,1%) and C_2S (less than 1 %, also revealed by NMR technique). In order to reproduce the conditions of a deep oil well (up to 1 kbar and 250°C), synthetic C_3S was mixed at room temperature with a water / cement (W/C) ratio of 0.44, which is a standard consistency requirement of class G cement. Distilled water was used.

In the first pressure cell (called LP - low pressure cell - in the following), a Teflon® pot filled up with this cement paste was placed in distilled water. Oil was the pressure transmitting fluid and the pressure was limited to 0.5 kbar. The pressure was increased before the external heating was switched on. Stable pressure and temperature conditions were reached after three hours. Different periods of hydration, up to two months, have been performed in order to reach a pseudo-equilibrium for the products formed.

The second high-pressure cell could reach the desired temperature and pressure in only 30 minutes. This second cell (called HP in the following) has been built for this particular work and allowed to attain pressures up to 1 kbar, and to study different hydration kinetics than with the first cell (LP). The body of the cell is a steel cylinder of diameter 80 mm and length 205 mm. The cell is sealed by a « Bridgman unsupported seal ». During the experiments, the cell is oriented vertically. The pressure inlet is at the bottom of the cell. A thermocouple through the mushroom plug permits to measure and regulate the temperature. Here, a Teflon® pot filled up with this cement paste is also used and placed in the middle of the cell (figure 1). Argon gas was the pressure transmitting fluid. The low pressure (~ 200 bar) was first applied, then the heating was switched on, simultaneously regulating the pressure.

Figure 1. High-pressure cell (HP)

2.2 Structural analyses

After the hydration has been stopped by quenching and fast decreasing of pressure, the samples were crushed and analysed by various methods. First the crystalline phases were detected by powder XRD on a Philips PW 1820 diffractometer. The diffraction patterns were recorded from $2\Theta = 10^\circ$ to 80° with a step of 0.03° and 4 s accumulation time per step.

Then, the thermal analysis was performed, with a thermobalance TAG24 SETARAM, to confirm the XRD results and quantify Portlandite (CaOH_2). After being exactly weighed, the powdered sample was submitted to a increase in temperature ranging from 20°C up to 1050°C at a rate of $10^\circ\text{C}/\text{min}$. The weight loss was recorded simultaneously.

In addition, SEM and energy dispersive X-ray spectrometer (SEM-EDX), were used to observe the morphology of the hydrated tricalcium silicate. Secondary electron images of fractures and qualitative X-ray analyses were performed on a JEOL 6300F field emission electron microscope equipped with an IMIX PGT EDS spectrometer. The sample was covered by a thin metallic layer of platinum to increase the poor conductivity of the observed fracture. The observation was carried out in vacuum (4.10^{-6} Torr) and under 15kV acceleration voltage.

Finally, ^{29}Si and ^1H -NMR were used to confirm the previous results and to probe amorphous or poorly crystallized phases possibly present with a structure based on SiO_4 chains with variable length [2].

The sample with ^{29}Si isotopic natural abundance (4.7%) was investigated using an ASX 300 Bruker spectrometer at a resonance frequency of 59.6 MHz. The pulse sequences used - MAS Single Pulse and ^1H - ^{29}Si CPMAS (Cross-Polarization at Magic Angle Spinning) - are well known in solid-state NMR studies [3,4]. The resolution is optimised with the signal of Q_8M_8 $[\text{Si}(\text{CH}_3)_3]_8\text{Si}_8\text{O}_{20}$, which was used as reference for the chemical shift measurement. The calibration gives the biggest peak at 11.6 ppm. MAS Single Pulse and CPMAS experiments were performed with the following parameters: a $\pi/2$ pulse length of 3.3 μs and spinning frequency of 5 kHz. A Single Pulse experiment was carried out with a recycle delay of 150 s and 500 scans of accumulation. The C-S-H relaxation - $T_1=30$ s - was respected, to allow for C-S-H [1] present in hydrated samples. A number of scans equal to 10000, a recycle delay of 5 s and a contact time ranging from 1 to 10 ms were used in the CPMAS experiments. With these CPMAS experiments the dynamics of polarization of each phase is clearly evidenced in agreement with previous work [5]. Therefore, CPMAS experiments are a valuable tool to distinguish hydrate phases in a mixture and are technically easier than 2D-NMR measurements. Moreover NMR experiments allow us to confirm the previous measurements by thermal analysis.

^1H NMR experiments were performed on an ASX 300 Bruker spectrometer at a resonance frequency of 300 MHz on a sample with ^1H isotopic natural abundance ($\sim 100\%$). The pulse sequence used - CRAMPS (Combined Rotation And Multi Pulse Spectroscopy) [6] - again well known in solid-state ^1H -NMR studies [7,8]. It permits screening of the homonuclear proton-proton dipolar interaction, which broadens the peaks in MAS ^1H -NMR experiments. Resolution and calibration are adjusted with the signal of adamantane $\text{C}_{10}\text{H}_{16}$, with a peak at 1.7 ppm.

Previous work has shown the efficiency of this method (using thermal analysis, XRD, SEM, ^{29}Si and ^1H -NMR) to determine the relative amount of each phase [9].

2.3 Macroscopic tests

The macroscopic tests consisted of the determination of the samples' compressive strength and Young's modulus E .

The samples' geometry was cylindrical with average height of 5 cm and diameter of 2.5 cm. Only for samples hydrated at the highest temperature and pressure (200°C and 0.6 kbar), compression tests were performed at the Institut Français du Pétrole. A preloading was applied then the loading was achieved with a 0.05 mm/min rate. The deformation of the sample was then recorded versus the loading intensity.

3. RESULTS

3.1 Structural analyses

3.1.1 High pressure and temperature silicate hydrates

C_3S hydration is well known at ambient temperature and pressure [1]. Two phases are formed: Portlandite $Ca(OH)_2$ and a poorly crystallised and not-stoichiometric phase: C-S-H. Previous works show that in addition to these two phases, other silicate hydrates (table 1) may appear under non-ambient temperature and pressure [1,10,11].

Name	Compound
Portlandite	$Ca(OH)_2$
C-S-H	$Ca_3(OH)_4H_4Si_2O_7$ (in the case $Ca/Si=1.5$)
Jaffeite (TSCH)	$Ca_6(Si_2O_7)(OH)_6$
Hillebrandite (β - C_2SH)	$Ca_2(SiO_3)(OH)_2$
α - C_2SH	$Ca_2(SiO_3)(OH)_2$

Table 1. P and T silicate hydrates

In order to characterise mixtures of different phases, 1H and ^{29}Si -NMR experiments were performed on pure phases (Portlandite, C-S-H, α - C_2SH , β - C_2SH), elaborated by N. Lequeux at the ESPCI. Table 2 gives characterisation parameters for these phases.

Name	^{29}Si -NMR chemical shift (ppm)	1H -NMR chemical shift (ppm)
Portlandite	-	1.4 ± 0.4
C-S-H	-79.5 and -85.8 ± 0.4	5.1 ± 0.5
Jaffeite (TSCH)	-82.9 ± 0.4	-0.2 ± 0.4
Hillebrandite (β - C_2SH)	-77.8 and -86.0 ± 0.4	0.7 and 2.0 ± 0.4
α - C_2SH	-72.3 ± 0.4	2.5 ± 0.4

Table 2. Silicate hydrates ^{29}Si - and 1H -NMR chemical shifts (ppm)

With the chemical shifts determined on pure phases, NMR-spectra were easier to analyse even in the case of a phases mixture. Hydration with two different kinetics have been carried out to simulate the oil well conditions.

3.1.2 Hydration kinetics

Table 3 gives the description of the two pressure cells used to perform C_3S hydration [9,12].

Name	P. max (kbar)	T. max ($^{\circ}C$)	Internal vol. (cm^3)	increasing T period (h)	decreasing T period (h)
LP	0.5	$350^{\circ}C$	800	5	6
HP	1	$250^{\circ}C$	65	0.5	4

Table 4. Characteristics of the two high-pressure cells used in our experiments

During the oil well cementing, cement paste is rapidly (half an hour typically) in contact with a T and P tank, the conditions in cell HP are closer to those found in practice (excepted for off-shore cementing). Nevertheless, the use of both devices permits us to show the importance of the kinetics

in such non-equilibrium processes (for samples hydrated during short periods). As a comparison, figure 2 gives the amounts of hillebrandite (β -C₂SH) and jaffeite (TCSH) for two samples of C₃S hydrated during 15 days.

Figure 2. Amounts of hillebrandite (β -C₂SH) and jaffeite for two samples of C₃S hydrated 15 days

Jaffeite appears as the more stable phase, even if its activation barrier is higher than that of hillebrandite. It becomes obvious that the nucleation-growth process is highly dependent on the rate of temperature increase (slowly or fast). Furthermore, previous work has shown the acceleration role of pressure on silicates hydration [5,13]. For this reason, we have chosen to present hydration results for samples elaborated with cell HP for the longest hydration time (28 days).

3.1.3 Results

Different conditions of pressure and temperature were applied (table 5).

Temperature (°C)	120	160	160	200	200	200
Pressure (kbar)	0.4	0.07	0.4	0.07	0.4	0.6

Table 5. Temperature and pressure conditions of hydration (28 days)

In particular the quantitative results obtained by ²⁹Si- and ¹H-NMR will be presented and discussed for one sample: C₃S hydrated at 200°C under 600 bar for 28 days.

3.1.3a ²⁹Si- and ¹H-NMR

X-Ray powder diffraction allowed us to find the highly crystallized phases present in these samples, in agreement with the technical literature (JCPDS data). Thermal analysis confirms the trends observed by X-ray diffraction studies. The phases detected by these methods are the following: jaffeite mainly, hillebrandite, portlandite and α -C₂SH.

Finally, ²⁹Si and ¹H NMR experiments allow us to validate the previous results. The ²⁹Si and ¹H spectra are shown in figures 3 (²⁹Si) and 4 (¹H). In figure 3, a ²⁹Si Single Pulse spectra is represented. Three main peaks are observed at around -72.5 ± 0.4 ppm (Q⁰ entities, signal reinforced by short contact times in CPMAS experiments), -83.0 ± 0.4 ppm (Q² entities) and -86.0 ± 0.4 ppm (Q² entities). The Qⁿ entities are SiO₄ tetrahedra linked to n other tetrahedra, according to Michel and Engelhardt's chemical shift table [2]. The second peak identifies jaffeite [5]. The other phases are hillebrandite (peak at -86.0 ± 0.4 ppm) and α -C₂SH (-72.5 ± 0.4 ppm). Chemical shifts for the three phases are in agreement with the literature [9,10].

Figure 3. ^{29}Si Single Pulse spectra of C_3S hydrated 28 days at 200°C under 0.6 kbar.

Finally, ^1H -NMR experiments were performed to confirm the presence of these phases according to Heidemann's chemical shift table [8]. CRAMPS spectra (figure 4) can clearly be analyzed and is quantitative. Four peaks are found: at 4.9 ± 0.4 ppm (relative to free water in the sample due to porous volume water saturation), at $2.4 \text{ ppm} \pm 0.4 \text{ ppm}$ (relative to $\alpha\text{-C}_2\text{SH}$), at 1.6 ± 0.4 ppm (characteristic of hillebrandite), and at -0.2 ± 0.4 ppm (characteristic of jaffeite). We notice that the little amount of portlandite does not appear very clearly in CRAMPS spectra (certainly indistinguishable of the hillebrandite peak).

Figure 4. : ^1H -NMR CRAMPS spectra of C_3S hydrated 28 days at 200°C under 0.6 kbar.

All the methods used in this work are in good agreement and give following amounts of each phase: jaffeite mainly ($68 \pm 4 \%$), hillebrandite ($11 \pm 4 \%$), portlandite ($10 \pm 4 \%$), $\alpha\text{-C}_2\text{SH}$ ($11 \pm 4 \%$).

In comparison to results found at 200°C under 0.07 and 0.4 kbar, an equilibrium emerges between α - and β -polymorphs of C_2SH . The α - to β - C_2SH reaction seems to be enhanced at high temperature, which is consistent with Taylor's work [1], and the reverse reaction appears predominant at high pressure. The P/T-relation between α - and β -polymorphs of C_2SH has been pointed out, $\beta\text{-C}_2\text{SH}$ formation will be considered more in details now, using SEM observations.

3.1.3b SEM observations

Previous work has shown the structural similarity between C-S-H and β -C₂SH [14]. Indeed, if we consider table 2, we can notice the extremely close chemical shift values for both phases by ²⁹Si-NMR, in particular for the tetrahedra at the middle of SiO₄ chains. Furthermore, this resemblance can be observed microscopically. A continuous phase (figure 5) is observed, which is most likely to be hillebrandite, in agreement with the electron dispersive X-ray analysis. This morphology is close to the C-S-H morphology, a sea-urchin with numerous disordered needles (figure 6).

Figure 5. SEM image of secondary electrons (x 3500) of the C₃S hydrated sample (w/c=0.44) at 200°C under 0.6 bar during 28 days

Figure 6. SEM image of secondary electrons (x 7500) of the C₃S hydrated sample (w/c=0.44) at 120°C under 0.4 bar during 7 days

This morphology likeness has already been reported [11] and in addition, the possibility to find C-S-H phases with a Ca/Si ratio about 1.7 (close to the Hillebrandite Ca/Si=2 ratio) at high temperature has been pointed out previously [1,11].

3.1.3c Quantitative results

Using the various techniques used, the quantitative evolution of each phase as a function of temperature and pressure has been determined.

Figure 7. Phases fraction (%) formed during 28 days hydration of C_3S versus temperature and pressure

The C-S-H disappearing is revealed till 200°C and low pressure (0.07 kbar). This phase could react with portlandite and give β - C_2SH , as shown previously. Moreover, we noticed the competition between the thermodynamic (jaffeite) and kinetic (β - C_2SH) product of the high temperature and pressure C_3S hydration, which suggests the two following ways of jaffeite formation: CH and C-S-H or CH and β - C_2SH .

In addition the equilibrium between α - and β - C_2SH polymorphs has been pointed out in this work. The α - C_2SH seems to be enhanced at high pressure, and β - C_2SH seems predominant at high temperature.

3.2 Mechanical behaviour

The tested samples were hydrated at 200°C and 0.6 kbar during 2 to 28 days. The results are summarized in table 4.

Hydration duration (days)	Young's modulus (MPa)
2	$7900 \pm 3 \%$
4	$7200 \pm 4 \%$
6	$4800 \pm 4 \%$
14	$6700 \pm 2 \%$
28	$10800 \pm 6 \%$

Table 4. Young's moduli of Ca_3SiO_5 hydrated at 200°C and 0.6 kbar during 2 to 28 days

Measured Young's moduli are comparable to ones determined in a previous work on Ca_3SiO_5 studies with ultrasonic experiments [15]. But obviously the Young's Modulus continuously

decreases during the first 6 days and the hydrated Ca_3SiO_5 is then the more elastic. This hydration period corresponds to the highest $\alpha\text{-C}_2\text{SH}$ amount but these results have to be completed with porosity measurements. Rapidly the Young's modulus value increases and attains the same value as the modulus of Ca_3SiO_5 paste hydrated at room temperature and ambient pressure.

4. CONCLUSIONS

The NMR results are in fair agreement with the XRD, SEM and DTA data. Some methods are relevant to investigate crystalline phases (XRD, SEM and NMR) but NMR is very useful even in the case of poorly crystallized phases, such as C-S-H. Using chemical shift measurements on pure phases, NMR-spectra were easier to analyse even in the case of a phases mixture. This tool permits us to identify and to quantify hydrates of silicates by the use and comparison between various techniques. Two different hydration kinetics have been evidenced to simulate the oil well conditions. We have chosen to present hydration results for samples concentrated with the HP cell for the longest hydration period (28 days) because of the role of pressure in the activation on silicate hydration.

The existence of C-S-H was shown up to 200°C and low pressure (0.07 kbar). This phase may react with portlandite and give $\beta\text{-C}_2\text{SH}$ (comparable morphology, structure and Ca/Si ratio). Jaffeite is the most stable phase at $\text{C/S}=3$ but $\beta\text{-C}_2\text{SH}$ formation is faster. Moreover, the competition between the thermodynamic (jaffeite) and kinetic product ($\beta\text{-C}_2\text{SH}$) suggests two ways of jaffeite formation: CH and C-S-H or CH and $\beta\text{-C}_2\text{SH}$. In addition the equilibrium between $\alpha\text{-}$ and $\beta\text{-C}_2\text{SH}$ polymorphs has been pointed out in this work. The $\alpha\text{-C}_2\text{SH}$ seems to be enhanced at high pressure, and $\beta\text{-C}_2\text{SH}$ seems predominant at high temperature.

The Young's modulus of hydrated Ca_3SiO_5 at 200°C and 0.6 kbar for a period of between 2 and 28 days decreases during the first 6 days which corresponds to the highest $\alpha\text{-C}_2\text{SH}$ quantity. Nonetheless, correlation between these two observations cannot be made. Some work in this direction is under progress. In a second step, this Young's modulus value increases and becomes the same value as found in Ca_3SiO_5 paste hydrated at room temperature and ambient pressure.

There is the question whether the crystalline phases formed under the most severe conditions ($200^\circ\text{C} - 0.6$ kbar) could play the role of a binder, because the usual glue C-S-H, formed during the first hours of setting, has disappeared and a phase with poor mechanical performance appears: the layered structure known as $\alpha\text{-C}_2\text{SH}$.

ACKNOWLEDGMENTS

The authors want to thank the Institut Français du Pétrole for supporting this work. The authors are grateful to Ciments Français-Italcementi CTG for the tricalcium silicate synthesis, to Bernadette REBOURS for her help with the XRD-experiments, to Elisabeth ROSENBERG for the SEM-observations and to Nicolas LEQUEUX for access to the pure synthetic phases.

ACADEMIC BACKGROUND

- 1998 - 2001: Ph.D Thesis at the University Paris VI in collaboration with the French Petroleum Institute (IFP), the City of Paris Industrial Physics and Chemistry Higher Educational Institute (ESPCI) and the Physics of Condensed Matter Laboratory (PMC-Paris VI). Ph.D title: Structural study of cement silicate phases hydrated at high pressure and temperature. Thesis examination: 23 October 2001, Ph.D Supervisor H. Zanni (ESPCI) and C. Noik (IFP). Referees K. Scrivener (Swiss Federal Institute of Technology Lausanne) and D. Petit (Polytechnic Engineer-Institution Palaiseau). Obtained with honours, my Ph.D thesis has been proposed for the IFP Ph-D reward.
- 1995-1998: Materials Science Degree (“DEA”), and “Licence” and “Maîtrise” degrees in physical chemistry (Paris VI). Obtained with honours.

EXPERIENCE

- Since Sept. 2001: Full time assistant lecturer at PMC laboratory (192 hours teaching). Study of amorphous ice (HDA and LDA) in the group of Dr S. Klotz. During this year, I have observed structural HDA variation up to 3 GPa at 100 K, LDA-HDA transition (0,3 GPa) and crystal-amorphous transitions by neutron diffraction (ISIS neutron spallation source, Rutherford Appleton Laboratory, UK). In order to understand the role of phonons in the pressure-induced amorphisation of ice I_h (ordinary ice), I made the first measurements of the phonons dependence of TA modes by inelastic neutron scattering on single crystal at 130 K to 0.5 GPa (LLB, Saclay). This work, which will be completed by additional measurements later this year, will be presented at the IUCr meeting in Geneva. In parallel, I have determined elastic constants at AgGaSe₂ by ultrasonic method under pressure.
- 1998-2001: Ph.D thesis: Synthesis and hydration of the main component of cement (Ca₃SiO₅) under high pressure and temperature to simulate deep oil well conditions. During my Ph.D thesis, I have studied hydrated cement samples by various characterisation methods (²⁹Si- and ¹H-NMR, XRD, DTA-TG and SEM) to complete phase diagram (P,T) of the calcium silicate hydrates. I have established a systematic method (now in use at the IFP on the real oil well cements formulation) to characterise quantitatively silicate phases mixtures in comparison with studies on pure phases (characterised with the same techniques during my Ph.D thesis). To correlate macroscopic behaviour and physical-

chemistry properties of hydration products, mechanical tests and ultrasonic measurements have been performed too. Jaffeite has been found to be the most stable phase at these conditions. To simulate the hydration of real cement, hydration of C_3S with ground quartz with / without superplasticizers was performed. In those cases, new phases appear: mainly kilchoanite, and xonotlite. A large amount of $\square-C_2SH$ is also produced. Compression tests were done to correlate the macroscopic behavior and physico-chemical properties of the products. With superplasticizers, samples porosity was found to be lower and the 28-days aged samples recover the Young modulus they had at the early stage of hydration.

ABSTRACT

Nuclear Magnetic Resonance (NMR) is a relevant technique for the investigation of disorganized or poorly crystallized systems. Indeed, in these materials where long-range crystalline order vanishes, traditional methods like X-ray diffraction are inefficient.

²⁹Si MAS NMR studies gave important structural and quantitative information about silicate and aluminate phases in anhydrous and hydrated cement. NMR strengthened many ideas concerning the hydration of the major component of clinker, tricalcium silicate (C₃S), and the C-S-H structure. Other studies were also realized to complete the phase diagram of C-S-H under high temperature and pressure.

Finally, NMR happened to be very useful to study high or ultra high performance concretes so that we could probe their microporosity. Being sensitive to water confined protons dynamics in pores, the measurement of their relaxation time allowed us to obtain an estimation of the average pore sizes. The results exhibited a fractal surface with an average dimension of 2.6, which confirmed previous works done by nitrogen adsorption-desorption isotherms.

1. INTRODUCTION

The techniques normally used, such as XRD, TDA or SEM, do not enable us to reach a sufficiently small scale to entirely understand the structure of cementing materials. Nuclear magnetic spectroscopy and spin relaxation have shown themselves to be particularly interesting techniques to reach nanoscopic scales and therefore understand the structure of various hydrates. Moreover, their non-invasive character allows us to monitor the evolution of hydration as well as the formation of the porous system.

2. FEW WORDS ON NMR PRINCIPLES

Atomic nuclei, as well as the fundamental particles that constitute them, possess a spin moment of their own, called **I**. If **I** ≠ **0**, the result will be the simultaneous existence of a magnetic moment **μ**, co-linear with **I** and of the same direction. The orientation of nuclear spins is random except in the presence of an external magnetic field **B**₀. They then tend to align either in a parallel or antiparallel fashion to this field following the Boltzmann statistic with a precession movement, known as the Larmor precession, at the following frequency:

$$\omega_0 = \frac{\gamma}{2\pi} B_0 \quad (1)$$

where γ is the magnetogyric ratio which is characteristic of the nucleus under study. This spin arrangement results at the macroscopic scale in a magnetization \mathbf{M} that must be measured (Fig. 1.1).

Figure 1. Single Pulse Experiment in NMR

NMR experiments consist of exciting the system using a transversal radiofrequency field \mathbf{B}_1 . When its frequency ω_1 is close to that of the precession of all spins under consideration, the magnetization is reversed, which unbalances the system from a thermodynamic point of view. Practically, the \mathbf{B}_1 field is applied for a predetermined period to reverse magnetization on the transversal plane (Fig. 1.2). Once excitation stops, the spins, influenced only by the principal field, tend to return to the state of equilibrium with a free precession movement around the \mathbf{B}_0 axis, whose frequency ω depends on the interactions on the nucleus (Fig. 1.3). The signal obtained, after Fourier transform processing, produces a central peak at ω whose integrated intensity is proportional, under certain conditions, to the number of excited spins (Fig. 2).

Figure 2. NMR spectrum produced by Fourier transform processing

Aside from the Zeeman effect resulting from the action of the principal magnetic field, the nuclear spins undergo various interactions through which the investigator can obtain information on the material. In the systems that interest us, there are mainly bipolar and quadrupolar interactions, and especially, chemical displacement. This last interaction expresses the effect of the chemical environment around a nucleus on its frequency peak.

Silicates possess a structure based on the silicon tetrahedron SiO_4^{4-} , that can link itself with the help of oxygen atoms present at its peaks with one, two, three or four other tetrahedrons. The creation of

a bridging oxygen modifies the electronic environment as well as the magnetic field affecting the silicon nucleus, which results in a shift of its peak on the spectrum. Researchers such as Engelhardt have established a classification of these chemical shifts as a function of the degree of connectivity of silicon tetrahedron (Fig. 3) [1].

Figure 3. Chemical shift domains of ^{29}Si in solids and corresponding Q^n species connectivity [1]

The degree of sensitivity of NMR allows one to discriminate, on a given concrete spectrum, the peaks relative to cement from those of C-S-H or quartz sand and silica fume.

3. NMR OF ^{29}Si APPLIED TO SILICATES

Over twenty years ago, researchers initiated the study of cement hydration using NMR analysis of silicon and aluminium. Following in the footsteps of these pioneers, an ever increasing number of research teams are working on this research theme. This technique helped us to better understand the chemical species that develop within cementing materials, thus helping us to better understand phenomena such as the setting of cement.

3.1 Hydration kinetics and the stability of silicate phases

The study of the hydration reaction of cement and C_3S using NMR was initiated by Grimmer and Lippmaa [2, 3]. By following hydration using single pulse experiment with magic angle spinning, they brought out the appearance of Q^1 species after 6 hours of hydration, and then of Q^2 species after 14 hours of hydration.

These results were confirmed a few years later on samples obtained by hydrating C_3S enriched in ^{29}Si [4]. Their spectra, obtained by cross-polarization during and after the dormant period at room temperature, showed that the polymerisation process began within the first hour of hydration with the creation of $Q_0\text{H}$ species, which correspond to a protonation of silicate ions at the surface of C_3S particles [5, 6]. These hydrated monomeric entities continue to be present as long as there is anhydrous C_3S (Fig. 5). In the same way, Q^1 and Q^2 species relative to C-S-H are created during the induction period. These appear long before oversaturation in calcium and the precipitation of portlandite, which is in agreement with the proposals concerning reaction mechanisms [7].

Figure 4. ^{29}Si NMR spectra of hydrated C_3S obtained by single-pulse experiment (a) and cross-polarisation (b) [6]

Some research has been done to identify and quantify the silicate phases resulting from the hydration of C_3S between 60 and 120°C [8]. Figure 5 shows the single pulse with magic angle spinning of samples at 14 days of age. The 60 °C spectra shows that the Q^1 peak at the end of the silicate chains is far superior to that of Q^2 from the middle of the chains, which shows that the silicate chains are still relatively short, as they would be at room temperature. On the other hand, for the sample hydrated at 120 °C, the Q^2 peak dominates which is related to the lengthening of the C-S-H. Moreover, the Q^0 peak, representing C_3S , has disappeared, which indicates that the hydration reaction is complete. Aside from accelerating the hydration reaction, an increase in temperature results in an increase of the mean length of silicate chains in C-S-H [9].

The literature tells us that such a lengthening of silicate chains occurs also during the carbonation of samples, the modification of the pH level of solutions during preparation of synthetic CSH and/or the addition of silica fume.

3.2 Pozzolanicity of silica fume

The addition of silica fume accelerates the process of hydration of clinker at room temperature, without necessarily affecting the induction period [10]. A study carried out during the first 24 hours on a mix of C_3S containing 20 % of finely ground silica fume showed the rapid evolution of Q^1 and Q^2 peaks relative to C-S-H [11]. According to its authors, the acceleration of C_3S hydration would depend mainly on the specific surface of microsilica. However, silica fume would have a tendency to delay the kinetics of cement in the long term, in particular for low water/binder ratios [12]. Moreover, silica fume increases the quantity of C-S-H through its reaction with portlandite. These also represent a high degree of polymerisation as shown in figure 6.

Figure 5. Evolution of the ^{29}Si NMR spectra of C-S-H as a function of the hydration temperature [8]

Figure 6. Contribution of the pozzolanic reaction to the C-S-H structure (according to Samuel Philippot's work).

4. PROTON RELAXATION AND POROSITY

The spin relaxation of protons offers a new alternative to the study of cement-based materials. Indeed, as hydration progresses, the confinement of water molecules in the cementitious matrix will modify relaxation rate. From several existing models, it is then possible to obtain a physical quantity such as the specific surface area or the microporosity of the material.

Measurements of relaxation rate $1/T_1$ as a function of frequency provide information on the dynamics of protons in pores. The relaxation model most often encountered in cement-based materials is the biphasic fast exchange model [13]. This model can separate contributions of bulk protons ($1/T_{1,bulk}$) from those of surface protons ($1/T_{1,surf}$). In this model, the longitudinal relaxation rate can be written, for a pore of S surface and V volume, as:

$$\frac{1}{T_1} = \frac{1}{T_{1,bulk}} + \frac{eS}{V} \frac{1}{T_{1,surf}} \quad (2)$$

where e is the thickness of the surface layer. Recent experiments in relaxometry with variable magnetic fields on water confined in microporous silica glass containing paramagnetic impurities on the pore surface showed diffusive behaviour different from surface and bulk water molecules [14]. Similar phenomena have been observed in macroporous systems [15].

Previous studies [16] have shown that this model could be used in the case of discrete distribution of pore sizes. In that case, the relaxation process is no longer exponential, but exhibits three or four well-defined values for T_1 . This was observed by Samuel Phillipot in his thesis on reactive powder concretes. He developed relaxation experiments to follow the evolution of more or less confined bulk water and water at the surface of particles. The first experiments correspond to measurements of T_1 carried out by inversion-recovery sequence on a Bruker ASX300 at 7,1 T (300 MHz). The second ones correspond to T_1 measurements to follow surface protons. Magnetization recovery curves were then analysed and fine-tuned using the least square method and the reverse Laplace transform. In both cases, this decomposition brings out many relaxation times corresponding to different pore sizes.

Figure 7 shows the evolution of T_1 distribution as a function of hydration time for a Ductal[®]-type concrete hydrated for 20 hours. At the beginning of this experiment, the first peak appears for high values of T_1 associated to weakly-confined water. As hydration progresses, this peak moves to lower values, which is characteristic of the confinement degree of water, and two more peaks appear. A more detailed study based on an extension of Eq. (2), has linked each peak to a pore size. The peak intensity representing the respective proportion of these pores in the overall distribution. For example, this results in the presence of protons between anhydrous grains and not within the C-S-H. On the contrary, as shown in figure 8, after several weeks, the $T_{1,i}$ distribution is reversed. This is normal for $T_{1\rho}$ measurements. $T_{1\rho}$ distribution characterizes the porosity refinement towards small-sized pores. This phenomenon is due to anhydrous grains that lead mainly to C-S-H whose porosity is caused first by dry granular stacking, followed by clogging of the porosity.

By considering the fast biphasic exchange model, the relaxation times of $T_{1,i}$ can be related to the pore size. Indeed, the longitudinal relaxation time $T_{1,i}$ is proportional to the corresponding pore mean radius $\langle R \rangle_i$ [17]

$$\langle R \rangle_i = \kappa T_{1,i} \quad (3)$$

where the proportionality factor K depends on different known or measurable parameters (for example, paramagnetic spin density measurable by Electronic Paramagnetic Resonance). By using this relation, Korb *et al.* obtained four pore radii for a Ductal[®] of 8 months of age cured at 20°C :

$$\langle R \rangle_i = 0.7 \text{ nm} ; \langle R \rangle_i = 2.9 \text{ nm} ; \langle R \rangle_i = 8.9 \text{ nm} ; \langle R \rangle_i = 28.0 \text{ nm}.$$

Figure 7. Evolution of T_1 distribution obtained with CONTIN (at 300 MHz) as a function of hydration time (according to Samuel Philippot's work)

Figure 8. Evolution of T_{1p} distribution obtained with CONTIN (à 17.8 kHz) as a function of hydration time (according to Samuel Philippot's research)

If the highest pore diameter values are in agreement with the dimensions of C-S-H crystallites [18] measured by other techniques, the smallest pores can be attributed to the C-S-H interlayer space. The limit of the resolution of other techniques cannot give a reliable measure of it. The other sizes obtained are related to the C-S-H inter-crystallite porosity, and stacking defects and gaps. It should

be noted, however, that there does not seem to be any well-defined border between these different porous modes.

The non-invasive character of NMR techniques benefits NMR as opposed to other techniques. As well, the relatively short length of experiments also allows an in-situ follow-up of concrete hydration at early ages. Finally, this method seems to be the only one giving information on the C-S-H inter-crystallite porosity.

This technique has been applied to other RPC in which the nature and content of silica fume varied. Figure 9 shows the $T_{1,i}$ distribution of protons in percentage (300 MHz) as a function of the $T_{1,i}$ for different UHPC mix-designs [19].

Figure 9. Logarithmic plot of the fraction of proton magnetization as a function of the relaxation time $T_{1,i}$ for UHPC designs. The dotted lines are the best fits obtained with a power law. (from [19])

The order of magnitude of 10 observed in the $T_{1,i}$ is due to frequency scale change. Indeed, the previous curves were obtained at 17.8 kHz while these were obtained at 300 MHz. In accordance to the results, five values are obtained for $T_{1,i}$ at similar ages. In fact, this figure represents the distribution of various “Contin” peaks *associated* with the various T_1 . This evidence a power law of 3 to 4 orders of magnitude between the amount of surface protons and the average pore size. This phenomenon is to be related to the expression of total specific surface area $S_{\text{total}}(i)$ for each pore category $\langle R \rangle_i$ represented by:

$$S_{\text{total}}(i) \propto \langle R \rangle_i^{2-D_f} \quad (4)$$

where D_f is the fractal dimension of the porous network surface ($2 \leq D_f \leq 3$). This parameter has a value of about 2.6 depending on the mix design, in agreement with those obtained by other techniques [20-23].

The fractal dimension increases significantly from 2.58 to 2.65 with the densification of the matrix by silica fume, a phenomenon which can be correlated to a higher specific surface area and so, potentially, to a higher quantity of hydrates. This observation was corroborated by ^{29}Si NMR experiments. The measurement of the fraction of proton magnetization as a function of T_1 gives us information about texture, i.e. the spatial organization of the material at middle scales, between the nano and mesoporosity [19].

5. CONCLUSION

Nuclear Magnetic Resonance (NMR) is particularly well-adapted to analyze amorphous or poorly crystallised systems. Therefore, it is of great use in the study of construction materials such as cement.

^{29}Si NMR has led to a better understanding of the kinetics of hydration of anhydrous silicates present in clinker. The presence of Q0H monomer species agrees with the reaction mechanisms commonly accepted today. It has also allowed us to better understand the architecture of C-S-H. The research conducted on synthetic C-S-H enriched with ^{29}Si and ^{43}Ca has emphasized the existence of two Q^2 species in C-S-H.

Also, measurements of the relaxation time of protons present in the pores of cementitious matrices provide information on their size distribution. These obey the scaling law on three or four orders of magnitude characteristic of a surface fractal. As well, NMR of protons allows the visualization of the distribution of water or voids in a porous material/system.

The application of magnetic imaging techniques (MRI), already used in porous systems, should bring a better understanding of the structuring mechanisms of cementitious materials during their hydration.

ABSTRACT

In industrialized countries concrete products represent a significant market segment for cement. Requirements as to the characteristics of these products do not only refer to their strength and durability, but also to aesthetic aspects. In this sense, brown discolorations are a quality problem, the reasons for which Heidelberg Cement intensively examined by means of a research project.

The occurrence of brown discoloration, however, is connected to the existence of iron dissolved in the pore solution. Here, an essential contribution is made by clinker mineralization, the alkali content of the pore solution, the Fe (II)-content of cement and additives as well as by the grinding and concrete additives used.

The transport of this solution to the concrete surface is considerably influenced by concrete structure. Therefore, a dense structure must be striven for in order to effectively avoid brown discolorations. This can be achieved by the use of appropriate inter-grinding materials, such as slag, optimized particle-size composition and sufficient hydration of the concrete.

1. MARKET REQUIREMENTS AS TO CEMENTS USED FOR CONCRETE PRODUCTS

In Germany, 48 million tons of concrete products (paving units, pipes, etc.) are produced and sold every year. That means, with more than 15 % of cement used by this sector, the production of concrete products represents a considerable market segment for cement sales in Germany. Also in neighboring European and other developed countries, the share of cement used in this field of application is comparably high.

The specific production process involving highly automated processing of low-slump concrete together with product expectations of end users results thereby in a very specific requirement profile for the binders used. To enable optimized production with regard to economic and process-related aspects, the cement has to show appropriate processing characteristics. Hardening time must be sufficient for processing during standard operations, but also in the case of manufacturing-technical malfunctions. At the same time, the concrete must be sufficiently plastic enough to guarantee appropriate compaction during machine processing. For further treatment, that means piling and taping, a high early strength of the products is an absolute necessity. To achieve durable usage

properties, compliance with the corresponding standard requirements is necessary (for example DIN 18501 [1] and draft DIN EN 1338 [2]). That means that a corresponding final strength has to be achieved as well as sufficient resistance to abrasion and frost-thaw corrosion, for example.

Besides these production and usage characteristics, the aesthetic requirements of the end users as to pavement blocks, for example, are gaining more and more importance. The use of concrete products as design elements, for example in gardening and landscape architecture, results in the demand for high and even brilliance of color as well as high resistance to efflorescence and discoloration.

2. DISCOLORATION – CURRENT STATUS

While production and usage properties are reliably achieved by adjusting the corresponding processing and hardening characteristics of cements used for concrete products, sometimes problems arise with efflorescence and discoloration. One reason for complaints are brown discolorations, which can appear at different times after production. Due to the repair work necessary (for example re-installing), these complaints can cause considerable financial loss in addition to the associated loss of reputation.

Figure 1. Brown discoloration

In the literature soluble iron compounds are basically identified as major triggers of brown discoloration, among others in the “VDZ-Mitteilungen” No. 80 [3] and No. 98 [4] as well as in Engelbrechtsen [5] and Häring [6]. If these are dissolved and come to the surface together with the alkali- and calcium-hydroxide-rich pore solution, they oxidize into trivalent iron compounds in the carbonized lime layer and thus cause yellowish to brownish discoloration. Besides others the ferritic clinker phase C_4AF [6], elemental iron originating from grinding abrasion [3], [6], fly ash [5], [8], slag [3] or other concrete admixtures as well as iron-containing aggregates [5], [6] are identified as sources of the iron. Variables influencing the solubility of iron are on one hand represented by the share of bivalent iron, but above all by the alkalinity of the pore solution [6] as well as the grinding aids [4] and concrete admixtures [5] used.

Furthermore, various authors deal with the crystalline structure of concrete, which is responsible for an increased material circulation and thus an increased tendency towards brown discoloration. Correspondingly, according to a study conducted by the FMPA Baden-Württemberg [9], a high capillary porosity is of essential significance for the occurrence of these discolorations. This porosity can considerably be increased by a reduced hydration of cement, resulting from drying-out

too abruptly. A too low cement proportion in coincidence with a high proportion of fine inert materials can also cause an unfavorable shifting in pore size distribution (Häring [7]). The degree of carbonation is also named as a factor having an impact on the potential for discoloration [6].

In summary, it can be stated that relevant literature mentions a multitude of influencing variables without making it possible to derive an assessment of their importance.

3. VARIABLES INFLUENCING THE FORMATION OF BROWN DISCOLORATIONS

Against this background a project was set up in the Heidelberg Cement Technology Center. It was the objective of this project to find possibilities to limit the reasons for the formation of brown discolorations. Proceeding from the results obtained, the cement specific impacts should be eliminated as far as possible and user consulting services tailored to occurring problems should be offered.

The development of an appropriate lab test method for determination of the material potential for discoloration was the first basic step. For this test a porous special mortar is produced, which subsequently hardens in an airtight PE-bag. After hardening the PE-bag is cut several times. Through these openings the pore solution included in the mortar evaporates. Afterwards the dissolved salts remain as white to gray efflorescence at the cuts. Via chromatometry (LAB-system according to CIE) of the discolored as well as of the neighboring non-discolored areas of the cement mortar and subsequent subtraction of the values, the discoloration can be described quantitatively. Decisive for the degree of efflorescence is on one hand the difference of the brightness values ΔL^* as well as of the yellow value Δb^* of the (brown) discoloration.

Figure 2. PE-bag test

The suitability of this test method was proven in numerous comparative tests on semi-industrially produced pavement blocks. There it was revealed that binding agents with Δb^* values below 0.3 show no discoloration potential. For Δb^* values between 0.3 and 0.6, slight discolorations can occasionally appear under extreme storing conditions, which result in low hydration levels. This tendency towards brown discoloration continues to increase with rising Δb^* , so that we can talk of a significant discoloration potential for values above approximately 1.0.

The simple test method enabled the analysis of hundreds of samples. Conditions of clinker production and origin, inter-grinding materials and additives, grinding aids and concrete admixtures varied in the course of the test series. In this test method examinations of 31 production clinker

types of one plant and thereof produced lab cements revealed besides others the following correlations as to the yellow value Δb^* :

<u>Parameter</u>	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	K ₂ O	Na ₂ O
<u>Correlation coefficient</u>	0.46	0.23	-0.11	-0.51	0.75	0.44

<u>Parameter</u>	CaO _{fr}	KSt	C ₃ S	C ₂ S	C ₃ A	C ₄ AF
<u>Correlation coefficient</u>	0.84	0.16	-0.81	0.79	0.18	-0.11

The example of this clinker shows the obvious dependence of discoloration tendency on the alkali content and above all on the included proportion of free lime (CaO_{fr}) as well as of alite (C₃S) and belite (C₂S). Supplementary tests with admixtures of quick lime disproved a significant impact of free lime. The latter is rather to be seen as indicator for sufficient mineralization of the clinker. In a similar way clinker and cement types from different plants, different inter-grinding materials and additives were examined. Thus, it could be proven that clinker containing increased amounts of bivalent iron ($\text{FeO} \geq 0.04 \%$) due to reducing burning conditions showed a noticeably higher tendency towards discoloration during the quick test. From the very low absolute FeO-contents in industrial clinker, which lie within traceable limits, mathematical correlations, however, cannot be derived.

From the multitude of individual data the following essential material variables influencing discoloration can be derived with sufficient statistical verification:

- composition of the pore solution regarding alkalinity and Fe^{2+} content
- clinker mineralization – a relatively low C₃S content increases the risk of discoloration
- content of soluble iron compounds in inter-grinding materials and additives
- grinding aids / concrete admixtures, which stimulate the solubility of iron

The material potential is of course not the only factor decisive for the development of brown discoloration. Circulation processes resulting from the pore structure have at least the same impact on their formation. The structure of the hardened cement paste (and of the whole concrete texture), determine the capillarity of the concrete, whereby especially the degree of hydration plays a major role. The impact of this variable was questioned in numerous semi-industrial tests on pavements followed by considerably differing storing conditions and additional tests via mercury intrusion porosimetry. In the course of this testing the substantial impact of curing and storing conditions on the tendency towards brown discolorations could be proven.

The more unfavorable hydration was due to quick drying-out or cold storing, the higher was the potential for discoloration. In contrast, when storing samples at 30°C, for example, and high air humidity they showed a significantly lower discoloration ratio. The semi-industrial block-making machine did not allow for sufficient variation of compression energy, so that influences resulting from that variable have remained unobserved up to now. Nevertheless, the results available allow conclusions to be drawn on how to minimize the danger of brown discolorations.

4. CEMENTS FOR CONCRETE PRODUCTS

Quality assurance in the production of cements for concrete products already starts with the burnout of clinker. A sufficient mineralization degree of the clinker must be taken care of and, at the same time, burning conditions leading to increased formation of bivalent iron are to be avoided.

During the examination, cements containing a high proportion of slag proved to be very favorable. By inter-grinding slag, alkalinity as well as the content of soluble iron is considerably reduced. The impact of the inter-grinding of different amounts of slag on the material's discoloration potential can be seen from figure 3.

Figure 3. Diagram Δb^* -value vs. slag content

The use of slag also results in a more dense structure, so that circulation processes are reduced. However, slag cannot be used unlimitedly due to the accompanying reduction of early strength. That means each plant has to find out individually the appropriate balance between required early strength on one hand and security against discoloration on the other hand. Additionally, grinding aids, which can cause increased solubility of iron, should be avoided.

Besides the traditional test methods included in the tight production control processes additional examinations (for example Fe(II)-content, test for brown discoloration) are useful to guarantee the desired product characteristics. By observing the above-mentioned principles, cement can be produced which is especially suitable for the production of concrete products.

Unfortunately, even such a type of cement does not completely exclude the risk of brown discoloration in case several unfavorable factors accumulate in the production process of concrete products. Therefore, the manufacturers are recommended to comply with some important principles. When selecting aggregates (especially fine additives and fillers) the content of (in alkaline medium) soluble iron must be observed. Thereby it must be considered that partly this solubility can substantially be increased by concrete admixtures [5]; in case of doubt corresponding examinations should be conducted.

Besides the selection of materials to be used in the production of concrete products, also the development of a dense concrete structure must be paid attention to in order to largely eliminate corresponding circulation processes. For this, a sufficient proportion of reactive cement is required in relation to the inert materials, which only contribute a little to developing a dense concrete. Above all, however, appropriate hydration of the cement must be assured, which means concrete products have to be protected against drying too rapidly.

By complying with the abovementioned parameters, the production of high-quality, durable and aesthetically satisfying concrete products is definitely possible.

ABSTRACT

There exists a strong interaction between the hydration of CA and of C₃S at room temperature. C₃S hydration is strongly delayed by the presence of aluminate ions issued from CA dissolution. On the other hand, CA hydration is progressively accelerated as calcium and hydroxide ions are released by C₃S dissolution. This leads to a complex CA hydration mechanism which displays two kinetic steps. The behavior of CA-C₃S mixtures is very similar to that of HAC-OPC mixtures due to a very close interaction mechanism which indicates that C₃S poisoning by aluminate ions persists even if different hydrates are found by the reaction of gypsum on calcium aluminates.

1. INTRODUCTION

Calcium aluminate cement (HAC) is often used as set accelerator for Portland cement (OPC). It is known that the setting time of calcium aluminate cement and Portland cement mixtures passes through a minimum for weight compositions between 20/80% and 50/50% [1-2]. As a consequence it is difficult to predict the exact composition that will induce the more rapid setting from a Portland cement to another one. The main reason is an imperfect understanding of the hydration behaviour of calcium aluminate cement and Portland cement mixtures. The purpose of this study is to provide new data by investigating well defined systems constituted by pure phases. The CA-C₃S system was first studied because it appears to be the simplest system relevant to HAC-OPC system as the setting time of pastes made by CA-C₃S mixtures also passes by a minimum (Figure 1).

Figure 1: setting time of CA-C₃S mixtures (% in weight) obtained on pastes (W/C=0.4)

2. EXPERIMENTAL

Pure CA and C₃S were laboratory made and the purity was checked by XRD analysis. The mixtures were prepared by mixing the two powders several hours. The proportions in the mixtures are given in weight percent. The fineness was about for 350m²/kg.

Hydration was followed by isothermal calorimetry on paste having a W/C ratio of 1. The heat flow (Φ) is related to the rate (V) and the enthalpy (ΔH) of all reactions that occur simultaneously:

$$\Phi = \sum_j V_j \Delta H_j \quad (1)$$

Both the rate and the enthalpy are temperature dependant so the experiments were realized in isothermal condition at 20°C. The enthalpy of reaction is generally quite different between dissolution and precipitation; most of the heat generated during hydration of cement phases is due to the dissolution of the anhydrous phases whereas precipitation from the ions contained in the aqueous phase produced a small amount of heat or even can consume some heat (endothermic reaction).

Electrical conductimetry experiments were also performed on stirred suspensions in a thermoregulated vessel called a chemical reactor (W/C=10). During these experiments, it was possible to recover part of the suspension at different hydration times in order to analyze the aqueous phase composition by ICP-AES and the solids by XRD, DTA and SEM. The electrical conductivity of a solution (Λ) depends on the concentration and the ionic species. One can write in a general way:

$$\Lambda = \sum_i \lambda_i \cdot \gamma_i \cdot C_i \quad (2)$$

λ_i is the equivalent ionic conductivity of ion i and $\gamma_i \cdot C_i$ corresponds to the activity of ion i. These values depend on temperature so the vessel is thermoregulated at 20°C but also stirred in order to reduce, as far as possible, concentration gradients between the surface of solids and the bulk of the solution. As a general rule, electrical conductivity increases with an increase of the ionic concentrations of the solution. Thus periods with an increase in the electrical conductivity correspond to periods where all or part of the ions generated by the dissolution of the solids are stocked in the aqueous phase: precipitation rate lower than dissolution rate and/or some ions are not used in the precipitated solid. On the contrary, a decrease of the electrical conductivity can be associated with a period of strong precipitation of solids. However, some variations of the electrical conductivity can also be induced by the replacement of an ion by another one: λ_i can vary strongly from an ion to the other one.

3. RESULTS AND DISCUSSION

The calorimetric and conductimetric results are presented in order to follow the evolution when an increasing content of C₃S is added to CA (Figures 2 to 4). As the experiments are made with different water to cement ratios, the time is not directly comparable between calorimetric and conductimetric experiments.

Figure 2: Plots of the rate of heat development and of the electrical conductivity versus hydration time for CA and a mixture containing 80%CA-20%C₃S

Figure 3: Plots of the rate of heat development and of the electrical conductivity versus hydration time for 60%CA-40%C₃S and 40%CA-60%C₃S

Figure 4: Plots of the rate of heat development and of the electrical conductivity versus hydration time for 20%CA-80%C₃S and C₃S

First of all, the mechanism of hydration of the two end members, CA and C₃S, has to be briefly described. CA hydration is composed of an initial period during which ions are accumulated in the aqueous phase (rise of electrical conductivity). This is associated with a short period of dissolution of CA (initial exothermic peak). Then an induction period is observed (very little heat flow and plateau of electrical conductivity). This period is due to the time needed to nucleate the first hydrates and especially AH₃ [3]. Once critical nuclei have been produced, growth occurs and a period of very rapid precipitation is observed (drop of electrical conductivity). This period is associated with a strong increase of the dissolution rate of CA (second exothermic peak). Then the reaction rate is reduced by the occurrence of several mechanisms such as the covering of CA grains by hydrates and the progressive return to the equilibrium state.

C₃S hydration contains similar periods but their length and time of occurrence are different [4]. The initial dissolution period (initial exothermic peak) is very short as C-S-H(β) is rapidly precipitated. Then a period of slow reaction rate is observed: period of low heat flow and of an increase in the electrical conductivity. This period corresponds to an induction time in order to nucleate C-S-H(γ) and CH. Once growth occurs (drop of electrical conductivity), a strong increase of C₃S dissolution is observed (second exothermic peak). Finally the reaction rate is reduced.

First it appears that the mechanism of hydration of CA-C₃S mixtures is more complex than the simple addition of CA and C₃S hydration: the heat flow curve can display three exothermic peaks in addition to the initial one (20%CA-80%C₃S) whereas only two exothermic peaks were expected.

When passing from pure CA to a mixture containing 80%CA and 20%C₃S (Figure 2), it appears that the period of induction observed during CA hydration, decreases. Only one exothermic peak is observed after the induction period whereas the electrical conductivity shows an additional increase then drop at longer time. For the 60%CA-40%C₃S mixture, the previous trends are amplified and a small second exothermic peak appears (Figure 3). This last exothermic is well observed in the 40%CA-60%C₃S mixture (Figure 3) which also displays a drastic change in the electrical conductivity: the late part of the curve resembles the curve obtained with C₃S (shape and value higher than 9 mS/cm). It can be also noticed that the previously observed rapid drop then increase of the electrical conductivity is still observed (t=1500 minutes) even if less intense. Moreover the plateau in the basal part of the second exothermic peak seems to indicate that a third exothermic peak is present. This last point is confirmed by the mixture 20%-80%C₃S (Figure 4).

From these experiments, it seems that after the initial exothermic peak, the first exothermic peak is associated with CA hydration: as a consequence the rate of CA hydration is accelerated whereas the rate of C₃S hydration is reduced. Complementary experiments have been carried out in order to attribute to C₃S or to CA, the second and the third exothermic peaks.

The analysis of the solids by XRD and of the composition of the aqueous phase, has been performed for mixtures 60%CA-40%C₃S and 40%CA-60%C₃S that delimit an important change in behavior as reported by the electrical conductivity. The evolution of the ([Ca], [Al]) concentration during the hydration, also called the kinetic path, is very similar for the two mixtures¹ (Figures 5 and 6). An initial increase of both [Ca] and [Al] is observed like for pure CA, then both concentrations decrease with a shape which is specific to the following of the maximum supersaturation curve with respect to C₂AH₈, also called curve I [5]. A similar kinetic path was observed previously with mixtures ranging from C₁₂A₇ to C₃A [6]. Here the lime enrichment of the aqueous phase due to the hydration of C₃S, has a similar effect to the increase of the C/A ratio in C₁₂A₇ or C₃A compared to CA. The higher C₃S contents of the 40%CA-60%C₃S mixture, enable it to reach higher final [Ca] concentration whereas [Al] remains very low: the aqueous phase can become supersaturated with respect to CH and typical features of C₃S hydration are then observed; values of electrical conductivity higher than 7 mS/cm.

As a consequence the hydration process passes progressively from a mechanism close to CA, then to C₁₂A₇ and finally to C₃A and C₃A-CH. This progressive change in the hydration process is at the basis of the minimum setting time when the initial hydration mechanism resembles C₃A (average amounts of C₃S) as C₃A rate of hydration is faster than C₃A-CH, C₁₂A₇ and than CA.

The important changes that are observed in the aqueous phase can be correlated with the evolution of the solids precipitated from the aqueous phase. During the first exothermic peak, both [Ca] and [Al] are high and the hydrates usually precipitated during CA and C₁₂A₇ hydration are found : CAH₁₀, C₂AH₈, AH₃ (amorphous and crystalline). If C-S-H is present, the amount is too low to be detected with our experimental techniques. Then once [Al] concentration remains lower than 1 mmol/l, C₃S hydration tends to accelerate. As a consequence [Ca] increases and all silicate ions liberated by C₃S dissolution are consumed as [Si] remains lower than 20 μmol/l. These changes in the composition of the aqueous phase, induce some modification of the previously formed hydrated which are no longer stable in these conditions. Globally C₂AH₈, CAH₁₀ and AH₃ are dissolved and C₂ASH₈, hydrogarnet (C₃AS_xH_{6-2x}) and C-S-H are precipitated.

¹ [Si] concentration remains lower than 20μmol/l and is not considered here in a first approach.

If $[Ca]$ concentration is high enough, CH forms and C_2ASH_8 should disappear and be transformed into hydrogarnet in these conditions. When equilibrium is reached, the $CaO-Al_2O_3-SiO_2-H_2O$ phase diagram [7] indicates that the solids formed will evolve as a function of the amount of C_3S added between the following invariant points :

- $AH_3-C_2ASH_8-C-S-H$ - aq. phase
- $C-S-H$ -hydrogarnet- C_2ASH_8 -aq. phase
- $C-S-H$ -hydrogarnet-CH-aq. phase

Figure 5: Plots of the rate of heat development versus hydration time for 60%CA-40% C_3S and of the kinetic path (evolution of the $[Ca]$, $[Al]$ concentrations during hydration)

C-S-H and CH are observed at the end of the hydration of 40%CA-60% C_3S mixture (Figure 6). Thus the third exothermic peak could be attributed to C_3S hydration. This is confirmed by the 20%CA-80% C_3S mixture (Figure 7); CA is completely consumed after the second exothermic peak while it remains about 80% of C_3S . Then in the presence of C_3S , CA hydration is composed of two exothermic peaks which indicate a more complex hydration mechanism ; CA hydration is firstly accelerated (first exothermic peak) and then delayed (second exothermic peak). Several hypotheses could be made to explain these two kinetic steps. The initial hydrates, C_2AH_8 , CAH_{10} , AH_3 , are covering the surface of CA particles. This could create a barrier layer and impede further CA hydration while C_3S hydration can become more efficient as the aluminate ion concentration is considerably reduced due to the slowing down of CA hydration. A part of the silicate ions released by C_3S dissolution is used in order to convert the primary hydrates into C_2ASH_8 and hydrogarnets. This may reduce the efficiency of the barrier layer and enable the restart of CA hydration. It can be also considered that an induction period is observed due to difficulties of nucleation of C_2ASH_8 and/or hydrogarnets. This last hypothesis is more flexible and more general. It also accounts for the known difficulties of forming C_3AH_6 or C_2ASH_8 directly from an aqueous phase at 20°C.

Figure 6: Plots of the rate of heat development versus hydration time for 60%CA-40%C₃S and of the kinetic path (evolution of the ([Ca],[Al]) concentrations during hydration)

Figure 7: Plots of the rate of heat development versus hydration time for 20%CA-80%C₃S and of the relative percentage of CA and C₃S determined by XRD

Finally the fact that during CA hydration, the $[Al]$ concentration can be much higher compared to C_3A hydration, is an indirect proof of the retardation of C_3S in the presence of aluminate ions. This was assumed by De Jong et al. [8] when these authors studied C_3A - C_3S mixtures and also by Cottin [9]. Aluminate ions retardation can be easily evidenced by hydrating C_3S in a aqueous phase saturated with respect to CA obtained by the filtration of a CA suspension hydrated about 5 hours: $[Al]$ close to 37mmol/l (Figure 8). If the same aqueous phase is diluted by 2, the retardation is less important (Figure 8). The origin of the poisoning of C_3S by aluminate ions is still unclear, but from our experiments it seems that at the beginning of hydration C_3S is able to dissolve and that silicate ions are mostly incorporated in C_2ASH_8 and hydrogarnet. Thus the poisoning effect of aluminate ions would be more effective on C-S-H nuclei than on C_3S dissolution.

Figure 8: Electrical conductivity recorder during the hydration of C_3S ($W/C=20$) in saturated or half saturated solution with respect to CA

4. CONCLUSIONS

The hydration mechanism of CA- C_3S mixtures is initially governed by CA hydration : the reaction rate of C_3S is considerably reduced when the aluminate ion concentration in the aqueous phase exceeds 2 mmol/l during the early hydration. This can be associated with the poisoning of C-S-H nuclei by aluminate ions.

With an increasing quantity of C_3S added, CA behaves as $C_{12}A_7$, then as C_3A and finally as C_3A-CH due to greater amounts of calcium and hydroxide ions released by C_3S dissolution. The hydration of CA is accelerated by the presence of C_3S , which is in agreement with the hydration of HAC-OPC mixtures. However CA hydration is decomposed in two kinetic steps which are closely related to the consumption of CA depending on the nucleation and growth rates of the hydrates.

A comparable evolution of the rate of heat development versus hydration time was also previously observed in OPC/HAC mixtures. In this latter system, the main difference concerns the hydrates that are formed with aluminate ion: ettringite and calcium monosulfoaluminate instead of C_2AH_8 , C_2ASH_8 and hydrogarnets in CA- C_3S system. But C_3S poisoning still exists as CA-gypsum mixtures can also lead to the accumulation of large quantities of aluminate ions at the beginning of hydration [10].

Denis Damidot received his B.Sc., M.Sc., and PhD. in physico-chemistry from Burgundy University, France. His thesis research was based on the study of C₃S hydration. Then he obtained an European Community research grant and worked as a post doc fellow at the Department of Chemistry of the University of Aberdeen, Scotland, on the calculation of phase diagrams used to estimate the durability of cement based materials. He joined the Central Research Laboratory of Lafarge in 1993 and worked for 6 years on special cements and on durability. He is currently Professor in the Civil Engineering Department of Ecole Normale Supérieure, in Cachan (suburb of Paris), France. He carries out research on the relationships between the microstructure and the macroscopic properties and on durability of cement based materials.

EFFECT OF GYPSUM ON CA AND C₁₂A₇ HYDRATION AT ROOM TEMPERATURE

ABSTRACT

Gypsum has a strong influence on CA hydration that is initially accelerated due to the rapid precipitation of ettringite. However it appears to remain an induction period governed by the rate of AH₃ nucleation, before a period of rapid reaction rate. As a consequence, admixtures usually used to accelerate or retard CA hydration, have similar effects in the presence of gypsum. During the last period, CA and gypsum can be completely consumed, but also calcium monosulfoaluminate can be formed in the place of ettringite, depending on the gypsum/CA molar ratio of the mixture studied. The effect of gypsum on C₁₂A₇ is similar to the one observed with CA.

1. INTRODUCTION

The effect of gypsum has been studied mostly on the hydration of C₃S and of C₃A due to its relevance to portland cement hydration [1-10]. The hydration of C₃A in the presence of gypsum, displays several periods and usually ettringite formed at the hydration beginning, is transformed into calcium monosulfoaluminate depending on the gypsum/C₃A molar ratio. However all the authors do not agree on the explanation of the mechanism involved in these periods. To the contrary, a systematic study of the effect of gypsum on CA and C₁₂A₇ hydration does not exist despite its importance in mixtures containing OPC and HAC. An initial study on mixtures of Ciment Fondu Lafarge and calcium sulphate [11] reported the formation of calcium monosulfoaluminate and/or ettringite depending on the amount of calcium sulphate, instead of the usual calcium aluminate hydrates. Thus some similarities with C₃A-gypsum hydration should exist even if the aqueous phase composition is richer in [Ca] and poorer in [Al] during C₃A hydration compared to the hydration of CA and of C₁₂A₇.

2. EXPERIMENTAL

Pure CA and C₁₂A₇ were laboratory made and the purity was checked by XRD analysis. Mixtures of different ratios of CA (or C₁₂A₇) and gypsum (given in weight percent) were prepared by mixing defined amounts of CA (or C₁₂A₇) and gypsum in order to have a lack (under-stoichiometric mixtures) then an excess (over-stoichiometric mixtures) of gypsum with regard to the following equations (Table 1) :

The hydration of these mixtures was followed by isothermal calorimetry at 20°C with a water to solid ratio (W/S) of 0.6 (paste). The hydration was also investigated in stirred and diluted suspensions (W/S=10) by recording the electrical conductivity at 20°C. During these experiments, it was possible to recover part of the suspension at different hydration times in order to analyze the aqueous phase composition by ICP-AES and the solids by XRD, DTA and SEM.

Table 1. Composition of the mixtures studied

Mixture Number	CA weight %	C ₁₂ A ₇ weight %	Gypsum weight %	Gypsum / CA molar	Gypsum / C ₁₂ A ₇ molar	Type of mixture
1	90		10	0,10		Under-stoichio.
2	80		20	0,23		Under-stoichio.
3	70		30	0,39		Under-stoichio.
4	50		50	0,92		Under-stoichio.
5	48		52	1,00		Stoichiometric
6	45		55	1,12		Over-stoichio.
7	42		58	1,27		Over-stoichio.
8		70	30		3,45	Under-stoichio.
9		30	70		18,80	Over-stoichio.

3. RESULTS

The calorimetric experiments indicate that the hydration of CA is markedly modified by the addition of gypsum (figure 1). Compared to CA, the initial exothermic peak is stronger but the main difference concerns the major heat release that always appears earlier and is composed of two peaks. However, there still exists a period of low heat flow between the initial exothermic peak and the major heat release but here, contrary to CA, the heat flow is not nil and indicates a moderate reaction rate. Globally the presence of gypsum accelerates CA hydration.

Figure 1. Plots of the rate of heat development versus hydration time for CA-gypsum pastes (W/C=0.6)

It is interesting to note that the heat flow curves are similar for all mixtures up to 400 minutes. Thus the hydration mechanism is similar up to that time. Then the second exothermic of the major heat release appears sooner and is more intense for the mixtures that are poorer in gypsum. However this peak is also observed for the over-stoichiometric mixture and thus it cannot be associated with changes in the hydration mechanism due to the total consumption of gypsum.

The analysis by XRD of the solids collected during the hydration of the stoichiometric mixture (N°5) indicates the following trends:

- a small quantity of ettringite is observed before the major heat release. Then the ettringite quantity is strongly increased during the two next exothermic peaks whereas both CA and gypsum amounts decrease markedly,
- the hydration is not completed at the end of the second exothermic peak.

For mixture N°1 (under-stoichiometric), gypsum is no longer detected by XRD at the end of the first exothermic peak during the major heat release. A decrease in the quantity of CA and of ettringite is observed during the second exothermic peak. A small quantity of calcium monosulfoaluminate is also detected at this time.

The evolution of electrical conductivity obtained on mixtures hydrated in diluted and stirred suspension brings additional information (figure 2).

Figure 2. Plots of the electrical conductivity versus hydration time for CA-gypsum pastes (W/C=10)

There are three types of curves for the electrical conductivity which correspond to under-stoichiometric (N°1 to 4), stoichiometric (N° 5) and over-stoichiometric mixtures (N°6), respectively. All the mixtures produce the same conductimetric curve from the beginning of hydration until 220 minutes; a similar observation has been made on paste during calorimetric experiments, but over a different period of time due to the different W/C. The differentiation of the conductimetric curves indicates that the hydration mechanism evolves with an increasing amount of gypsum. Globally gypsum accelerates markedly the hydration of CA in diluted suspension as observed previously in paste by calorimetry.

At the beginning of hydration the conductivity increases more rapidly than during the hydration of CA: the rate of gypsum dissolution is then faster than the rate of CA dissolution. The period of increase of the electrical conductivity, is rapidly finished as the maximum conductivity is obtained after 15 minutes. Then the conductivity decreases and presents a small drop at about 220 minutes. During this period, the small decrease of the electrical conductivity is expected to be associated with a moderated precipitation of hydrates from the ions accumulated in the aqueous phase.

The shape of the electrical conductivity curve at the beginning of the hydration of CA in the presence of gypsum, is very similar to that observed for $C_{12}A_7$ hydrated in water (Figure 4.). This confirms the hypothesis of a rapid precipitation of hydrates in small quantities, followed by an induction period and then an acceleration of both dissolution and precipitation rates [12]. However this last period is more complex in the case of CA-gypsum mixtures. The electrical conductivity falls rapidly for under-stoichiometric mixtures (1,2 and 3), then increases quasi vertically and finally decreases again. This kind of pattern is common and indicates a strong competition between precipitation of the hydrates (decrease of electrical conductivity) and dissolution of the anhydrous solids (increase of conductivity). It is observed for CA hydrated in water (Figure 1) but its intensity is greater in the presence of gypsum. The last under-stoichiometric mixture (N°4) displays the same characteristics, but over a longer period of time indicating a slower kinetics. The stoichiometric mixture (N°5) does not present an increase of the electrical conductivity after the first drop, whereas the over-stoichiometric mixture (N°6) only shows a slight decrease of the electrical conductivity followed by a plateau.

Finally the electrical conductivity remains almost constant but at different values indicating different compositions of the aqueous phase. The analysis of the aqueous phase (Table 2) evidences the presence of:

- calcium and aluminate ions for under-stoichiometric mixtures whereas sulfate ions are under the limit of detection (25 $\mu\text{mol/l}$),
- calcium, aluminate, and sulfate ions for the stoichiometric mixture,
- calcium and sulfate ions for the over-stoichiometric mixture whereas aluminate ions are under the limit of detection (50 $\mu\text{mol/l}$). The concentrations of calcium and sulfate found, 15.63 and 15.6 mmol/l respectively, indicate that the aqueous phase is in equilibrium with the remaining gypsum.

Table 2. Composition of the aqueous phase at the end of the suspension experiments

Mixture number	[Ca] mmol/l	[Al] mmol/l	[SO ₄] mmol/l
1	6,52	9,14	< DL
2	5,96	7,50	< DL
3	5,71	8,32	< DL
4	4,88	3,62	< DL
5	9,50	3,62	4,69
6	15,63	< DL	15,60

The analysis of solids recovered with the analyzed aqueous phase, has been made by XRD. CA has been completely consumed and also gypsum except in the case of the over-stoichiometric mixture. Calcium monosulfoaluminate and ettringite are the main hydrates which are present. AH_3 is mainly in a not very well crystallized state and is better detected by DTA.

If we consider the composition of the aqueous phase and the identified solids, it appears that both under-stoichiometric and over-stoichiometric mixtures are not far from the equilibrium states even if those can be metastable. Indeed, if the aqueous phase in equilibrium with the hydrates found experimentally is calculated at 25°C, the compositions are comparable to those obtained experimentally :

- under-stoichiometric mixtures contain, AH_3 (gel form)- calcium monosulphoaluminate - ettringite in equilibrium with the aqueous phase. The composition calculated at this invariant point is $[\text{Ca}] = 5.06 \text{ mM/l}$, $[\text{Al}] = 2.30 \text{ mM/l}$, $[\text{SO}_4] = 0.006 \text{ mM/l}$ and $\text{pH}=11.81$.
- over-stoichiometric mixtures contain, AH_3 (gel form) -ettringite - gypsum in equilibrium with the aqueous phase. The composition calculated at this invariant point is $[\text{Ca}] = 15.3 \text{ mM/l}$, $[\text{Al}] = 0.03 \text{ mM/l}$, $[\text{SO}_4] = 15.2 \text{ mM/l}$ and $\text{pH}= 9.92$.

The stoichiometric mixture that contains AH_3 (gel form) and ettringite, leads to aqueous phase compositions between these of the under and over-stoichiometric mixtures.

The semi-quantitative amounts of ettringite and calcium monosulfoaluminate produced at the end of the hydration of the different mixtures are presented in figure 3. Both calcium monosulfoaluminate and ettringite pass through a maximum but for different gypsum amounts. The maximum quantity of calcium monosulfoaluminate is observed for mixture having 20% by weight of gypsum whereas the maximum of ettringite is found for the stoichiometric mixture.

Figure 3. Semi quantitative amounts of ettringite and calcium monosulfoaluminate formed at the end of the conductimetric experiments

The main trends induced by the presence of gypsum on CA hydration are also found for C_{12}A_7 (figure 4). The hydration rate is increased at the hydration beginning as the electrical conductivity decreases rapidly till the beginning and all mixtures follow the same curve. Then under-stoichiometric mixtures present a period of very rapid drop and rise of the electrical conductivity, followed by a slower decrease, whereas over-stoichiometric mixtures just displays a slow decrease of the electrical conductivity.

Figure 4. Plots of the electrical conductivity versus hydration time for $C_{12}A_7$ -gypsum pastes ($W/C=10$)

4. DISCUSSION

The addition of gypsum to CA modifies strongly the hydration mechanism:

- ettringite and/or calcium monosulfoaluminate and AH_3 are formed,
- the overall kinetics is accelerated.

Globally the increase of the hydration rate is firstly due to a reduction of the induction period governed by the nucleation-growth of the hydrates. Contrary to CA, small amounts of ettringite and of AH_3 are precipitated till the beginning of this period. As a consequence, this period is shorter than during CA hydration where no hydrates are precipitated till the beginning of this period. With this respect, the beginning of the hydration of CA-gypsum mixtures resembles to $C_{12}A_7$ hydration in water. Consequently the addition of gypsum to $C_{12}A_7$, has a less intense effect on the beginning of $C_{12}A_7$ hydration ; ettringite is formed in place of C_2AH_8 . However the quantity of AH_3 formed by the hydration of $C_{12}A_7$ in the presence of gypsum (eq. 2) is 3 times than that formed by $C_{12}A_7$ hydrated in water (eq. 3) :

This explains the higher reaction rate during the induction period for $C_{12}A_7$ hydrated in the presence of gypsum compared to water hydration. Indeed, the reaction rate during the induction period is higher with higher amounts of AH_3 precipitated as these act as seeds.

In order to investigate further the control of the induction period by the rate of nucleation of AH_3 , CA-gypsum mixtures have been hydrated in the presence of additives that are known to favor or reduce the nucleation rate of AH_3 . First, lithium ions which accelerate AH_3 nucleation [13] have been added in the form of Li_2CO_3 . As expected, the induction period observed at the beginning of CA-gypsum mixtures is all the more decreased with increasing Li_2CO_3 amounts (Figure 5); it even disappears if the amount of Li_2CO_3 is high enough (0,05 % by weight in our experiments). On the other hand, the duration of the major heat release is globally not modified even if the intensity of

the last peak is reduced with respect to the reference mix. As a consequence, it seems that lithium ions have no influence on the nucleation of both ettringite and calcium monosulfoaluminate.

Figure 5. Plots of the rate of heat development versus hydration time for mixture N°7 hydrated in the presence of Li_2CO_3 ($\text{W/C}=0.6$)

Second, citrate ions that retard AH_3 nucleation [13], have been added in the form of trisodium citrate. The presence of citrate ions induces a longer induction period during the hydration of CA-gypsum mixture (Figure 6). Also it seems that citrate ions have an influence on the nucleation rate of the other hydrates as the major heat release appears over a longer period and is less intense.

Another important feature is the mechanism involved during the major heat release that contains two exothermic peaks. This indicates two periods of intense dissolution of CA and it appears that CA is more rapidly consumed when calcium monosulfaluminate forms. However these two periods are always observed even in the case of over-stoichiometric mixtures where only ettringite is formed in all periods. Thus it is not possible to just consider that;

- the reduction of the rate between the two exothermic peaks is due to the formation of an hydrate layer of ettringite,
- the starting up of the hydration is due to the partial or complete transformation of this hydrate layer.

The reaction rate is also governed by the consumption of CA which in this period mainly depends on the growth of the previously formed hydrate nuclei. During the first exothermic peak of the major heat release, nucleation and growth of both ettringite and AH_3 induce a strong consumption of CA.

Figure 6. Plots of the rate of heat development versus hydration time for mixture N°7 hydrated in the presence of trisodium citrate (W/C=0.6)

Then depending on the gypsum content different mechanism can occur. For over-stoichiometric mixtures, the ettringite crystals are growing (no more nucleation) from an aqueous phase which has a low pH (about 10 close to the invariant point gypsum-ettringite-AH₃); in these conditions big ettringite crystals are grown (longer than 10 μm) from the ettringite nuclei and smaller crystals dissolve to form bigger one (Ostwald ripening). CA consumption rate is moderate so the second exothermic peak is large and averagely intense. For under-stoichiometric mixtures, the pH is higher (about 12 close to the invariant point calcium monosulfoaluminate-ettringite-gypsum). In these latter conditions, the average crystal size of ettringite is smaller and as a consequence the growth of ettringite crystal is less than in overstoichiometric mixtures but nuclei are more numerous. However an additional nucleation and growth process, that of calcium monosulfoaluminate, appears when the sulfate ions concentration is close to 10 μmol/l. As a result, CA consumption is strongly increased in order to nucleate and growth calcium monosulfoaluminate crystals directly from sulfate ions contained in solution that may come from gypsum or ettringite dissolution. In this latter case, some supplementary AH₃ is produced (eq. 4) ;

Thus the second exothermic peak lasts over a shorter period and is more intense for under-stoichiometric mixtures.

The presence of two exothermic peaks during the major heat release was also observed for C₃A - gypsum mixtures. Like CA-gypsum mixtures, the appearance of the second exothermic peak and its intensity vary with the content of gypsum; it appears sooner and is more intense with lower gypsum contents. In the same manner, ettringite is partly or completely transformed in calcium monosulfoaluminate for under-stoichiometric mixtures. It has been often hypothesized that the acceleration of the reaction rate during the second exothermic peak observed in C₃A-gypsum mixtures, corresponds to the destruction of an hydrate layer formed by ettringite during the early hydration thanks to the transformation of ettringite in calcium monosulfoaluminate. This may only be part of the answer, if we consider the previously reported experiments on CA-gypsum and the

similarities with $C_{12}A_7$ -gypsum and C_3A -gypsum systems: it seems possible to consider the influence of nucleation and growth rates on CA, $C_{12}A_7$ or C_3A dissolution rate in order to explain the general mechanism involved during the hydration of these mixtures. The presence of CH added to C_3A -gypsum system in order to reach the high pH region of the $CaO-Al_2O_3-CaSO_4-H_2O$ phase diagram should not change markedly the hydration mechanism even if the variation of pH between under and over-stoichiometric mixtures is very weak (pH =12,52 at invariant point CH-ettringite-gypsum and 12,49 at invariant point CH-ettringite-monosulfoaluminate). This last point needs to be experimentally confirmed such as the action of C_3S and these systems, knowing that the release of aluminate ions by CA, $C_{12}A_7$ or C_3A hydration in the presence or not of gypsum will retard C_3S hydration as demonstrated in the study of CA- C_3S system [14].

5. CONCLUSIONS

The hydration mechanism of CA - gypsum mixtures can be described by three periods :

- a) an initial period during which :
 - gypsum dissolves rapidly to reach the gypsum solubility,
 - CA dissolves moderately and small quantities of ettringite and AH_3 are formed
- b) an induction period controlled by the nucleation and growth of AH_3 during which small amounts of ettringite and AH_3 (gel form) are precipitated. The duration of this period is independent on the quantity of gypsum in the mixtures.
- c) a period of massive precipitation of the hydrates during which most of CA and gypsum are consumed in order to form :
 - calcium monosulfoaluminate, ettringite and AH_3 for under-stoichiometric mixtures,
 - ettringite and AH_3 for stoichiometric and over-stoichiometric mixtures.

As in the hydration of C_3A -gypsum mixtures, the hydration rate in this last period, is divided in two exothermic peaks and is more rapid for under-stoichiometric mixtures for which ettringite is partially or completely transformed into calcium monosulfoaluminate. Thus, a hypothesis similar to that made for C_3A -gypsum mixtures, such as the formation and then the destruction of a protective layer, could be used to explain the appearance of these two peaks. From our point of view, it seems that an alternative explanation can be made by considering the consumption of CA that mainly depends on the nucleation and growth of the hydrates.

Finally it appears that the effect of gypsum on $C_{12}A_7$ is similar to the one observed with CA.

Denis Damidot received his B.Sc., M.Sc., and PhD. in physico-chemistry from Burgundy University, France. His thesis research was based on the study of C₃S hydration. Then he obtained an European Community research grant and worked as a post doc fellow at the Department of Chemistry of the University of Aberdeen, Scotland, on the calculation of phase diagrams used in order to estimate the durability of cement based materials. He joined the Central Research Laboratory of Lafarge in 1993 and worked for 6 years on special cements and on durability. He is currently Professor in the Civil Engineering Department of Ecole Normale Supérieure, in Cachan (suburb of Paris), France. He carries out research on the relationships between the microstructure and the macroscopic properties and on durability of cement based materials.

EFFECT OF SUPERPLASTICIZER TYPE ON THE FLUIDITY RETENTION OF PORTLAND CEMENT MORTARS AS A FUNCTION OF THE C₃A LEVEL AND THE NATURE OF ADDED CALCIUM SULFATES

ABSTRACT

Within the frame of concrete technology improvement, high performance properties such as high fluidity has been in great demand over the last few years.

Therefore, a number of new superplasticizers (SP) have been developed and among them, polycarboxylate-type superplasticizers (PCP) have become more widely used.

In this study, the effect of a common Polynaphtalene Sulfonate-type SP and of 2 PCP-type SP's as a function of the nature of the added calcium sulfates (gypsum, hemihydrate, anhydrite) and C₃A content (2 levels) in Portland cement has been compared through the fluidity behavior of mortars over a period of 90 minutes. Concurrently, SP adsorption rate has been monitored in the mortars over the same period of time. The mortars have been designed at a W/C of 0.5 and SP's have been introduced by a slight delayed addition. The results indicate that, for the high C₃A level, the initial fluidity increases as a function of calcium sulfates' solubility rate regardless of the type of SP. Concurrently, it is also observed that fluidity retention depends strongly on both calcium sulfates and SP type. In particular, the fluidity retention in the presence of PCP-type SP seems to be very sensitive to the nature of the added calcium sulfates. Those effects are less pronounced when the C₃A level is moderate.

1. INTRODUCTION

High performance properties such as high strength, high durability but also high fluidity and have been in great demand in the concrete technology over the last few years. Therefore, advanced superplasticizers (SP) have been developed to exhibit high dispersibility at small dosages and retention of dispersing effect for a long period of time. Among this new generation of SP's, the polycarboxylate-based superplasticizers (PCP) have recently become popular [1-4]. A characteristic of this type of SP is that its chemical structure has the potential to be modified because it is composed of several components and it is a polymer. Electrical repulsion is the proposed mechanism of dispersion of polynaphtalene-sulfonate (PNS) and polymelamine-sulfonate (PMS) [1,2,5,6,7,8]. With PCP-based SP's, cement particles are supposed to be dispersed due to two factors: low electric repulsion caused by adsorption of negative ions of the carboxylic group in the chemical structure onto the surface of cement particles and more importantly, the steric effect by adsorption of the polymer [1,2,4,6].

SP's interact strongly with the various components of cements and influence cement hydration reactions. There are numerous studies on the interactions of common sulfonates-related SP with different cement types. A literature review [1,2,5-15] indicate that, in the presence of SP's such as PNS and PMS, the fluidity of concrete can be affected by the chemical nature of clinker (mainly C_3A and soluble alkalis content), the cement fineness, the amount and nature of added calcium sulfates, the SP dosage and its addition method, the chemical nature and molecular weight of the SP and the sulfonation degree of the SP. Initial dispersibility is related to SP adsorption capacity that appears to be governed by the initial ettringite formation that plays an important role on the rheological properties of cements [10-15]. Adsorption of the SP has been shown to modify the size, morphology and kinetics of ettringite formation [16-18].

The dispersibility retention appears to be strongly governed by the ionic strength of the pore solution and marginally by the ettringite formation [14,15].

It has been pointed out that the SP effectiveness depends also on the manner in which a SP is introduced to the system : either simultaneously in the mix water or by a delayed addition [2,19-21]. For instance, it has been described that a preliminary treatment of cement with even a small amount of water produces superplasticized concrete mixes that perform as well as the best concrete produced by delayed addition of PNS or PMS [2]. The effect would be related to the production of an ettringite coating on the surface of cement particles during the preliminary water treatment. The adsorption of PNS or PMS molecules on the prehydrated cement surface is reduced and more SP molecules are left in the pore solution for dispersion. That causes the subsequent dispersion action to be more effective than that recorded in the absence of preliminary treatment. It has been shown that the type of added sulfates and their difference in solubility rate could promote the early formation of some ettringite with the C_3A by providing Ca^{++} and SO_4^- ions and therefore contribute to reduce more or less the amount of adsorbed PNS-type SP [10, 12]. For the PCP-type SP's, it seems that adsorption does not depend so much on the method of addition, immediate or delayed [2]. Regarding the effect of added calcium sulfates in presence of the new generation of PCP-type SP's as a function of C_3A level, much less information is available and there are still unanswered questions regarding the effectiveness of specific cement / PCP-type SP combinations.

Therefore, in order to obtain more insights on the influence of PCP-type SP's as a function of the C_3A content and the nature of added sulfates on the fluidity retention of cement, a comparative study has been carried out .

The dispersing effect of a common PNS-type SP and of two PCP-type SP's as a function of the nature of added calcium sulfates (three types have been considered) and C_3A content of cement (two levels considered) have been evaluated over a period of 90 minutes on the rheological behavior of mortars prepared at a W/C of 0.5. During the mortar preparation, the cement has undergone a preliminary water treatment. In addition, the SP adsorption rate has also been monitored in the mortars. Results obtained are discussed in the frame of cement-SP interactions.

2. MATERIALS AND METHODS

2.1 The SP's selection

Three commercially available SP's in liquid form, one of the PNS type, having sodium as the counter-ion and two of the PCP-type based on metacrylate, having different solids content have been selected. A feature of the PCP-SP type is that the chemical structure has the potential to be modified because it is composed of several components. In this study, the chemical structure of SP's was not analysed but, due to their different dispersing properties, it is assumed that the two PCP-type SP's have been synthesized according to a different designed chemical structure. Table 1 gives details of the available manufacturers' specifications. Owing to the different SP dry content, the dosage of SP has been expressed as dry content % by weight of cement in the study.

2.2 Laboratory cements preparation

Two industrial clinkers having a high (clinker A) and moderate C_3A content (clinker B), according to Bogue calculations, have been selected for this study and their compositions are listed in Table 2.

Table 1. Manufacturers' specifications for the 3 SP's.

	PNS	PCP N°1	PCP N°2
Specific gravity (20°C)	1.21 (+- 0.02)	1.05 (+- 0.02)	1.1 (+- 0.02)
PH	8.1 (+- 0.1)	6.8 (+- 0.1)	6.8 (+- 0.1)
Total dry content in %	44.5 (+- 1)	20.2 (+- 1)	36.1 (+- 1)
Wt % free sulfate	1% (+- 0.05)		

Table 2. Industrial clinkers composition (oxyde wt % and Bogue % calculation)

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	SO ₃	TiO ₂	P ₂ O ₅	Free lime	L.O.I
Clinker A	22.58	4.99	1.63	68.22	0.45	0.13	0.02	1.0	0.31	0.13	0.5	0.26
Clinker B	21.96	4.75	2.25	67.55	0.76	0.19	0.19	1.2		0.1	0.3	0.69

	C ₃ S	C ₂ S	C ₃ A	C ₄ AF
Clinker A	66	15	11	4.9
Clinker B	71.4	9.9	7.8	5.7

Starting from each clinker, a series of 3 laboratory cements have been prepared by the addition of blends of calcium sulfates having different solubility rates. The nature and ratios of the added calcium sulfates have been as follows: 70% hemihydrate - 30% gypsum (H/G - high solubility rate), 70% gypsum - 30% hemihydrate (G/H - moderate solubility rate) and 70% anhydrite - 30% gypsum (A/G - low solubility rate). High purity (> 95%) laboratory grade gypsum and anhydrite have been provided for the study while hemihydrate has been prepared by dehydration of the laboratory grade gypsum. The calcium sulfates have been suitably added to the clinkers during the grinding in a laboratory planetary mill. Cements with a total calcium sulfate content of 3.5% and specific surface of 330 m²/kg have been prepared from the clinker A, while cements with a total calcium sulfate content of 2.5% and specific surface of 300 m²/kg have been prepared from the clinker B.

2.3 Mortars preparation and mixing

A fluid concrete formulation, with a W/C of 0.5 and providing at least 35 MPa compressive strength at 28 days in the laboratory, has been selected for reference and the recipe is shown in Table 3.

Table 3. Reference concrete formulation

Aggregates Fraction size (in mm)	0/0.315	0.315/1	1/4	4/8	8/12.5	12.5/20	Cement	Water
Content In Kg / M ³	284	246	260	190	350	480	350	175

The different mortar formulations have been designed with the same W/C as the reference laboratory concrete recipe. Since it was not possible to prepare cement pastes containing the various dosages of SP at such W/C without facing settling and bleeding problems, it has been decided, instead, to prepare mortars using a dry silica sand commercially available having a particle size

ranging from 0 to 315 microns. To prepare the mortars, it has been decided to keep the same ratio cement / “0-315 microns” sand as for the laboratory concrete.

Since the PNS-type SP's dispersing action is strongly dependent on the SP addition method (immediate or delayed) and, on the contrary, the PCP-type SP's are much less sensitive to the addition method [2], it has been decided to select a method of SP addition offering the best conditions for a comparison of SP efficiency, that is a method corresponding to a slight delayed addition of the SP. Some part of the water (38%) has been added to the dry sand prior to the cement addition. This step corresponds to the cement preliminary water treatment as mentioned earlier. Note that the 38% value would correspond to the total water content originated from all the concrete aggregates. A typical water content of 6% for the fine aggregates (0-4 mm) and 1.5% for the coarse aggregates (4-20 mm) have been considered. Therefore, to prepare 500 ml of mortar, following composition has been used: 420 gr dry cement, 340 gr dry sand, 210 gr water (including 81 gr water to wet the sand) and the selected dosage of SP. Following procedure has been used to mix the mortar: weight the dry sand, add wetting water and stir gently for 1 minute; add cement to the mixture and stir gently for 1 minute; add the remaining mixing water (containing the SP dosage) and stir 30 seconds; pour the mortar mixture in a high speed laboratory propeller and mix for 1 minute at 3500 rpm. A high speed energy propeller has been indeed preferred for the mortars mixing, knowing the importance of laboratory mixing technique on the flow behavior [22].

2.4 Fluidity measurements

Fluidity has been measured as a function of the SP dosage over time. The fluidity measurements have been carried out by means of the mini-slump test. This method, extensively described elsewhere [7] consists in carrying out a slump test on a small amount of mortar. After the mixing stage, part of the mortar mixture is poured into a plexiglas cone with the same geometry as Abram's cone for common slump tests but with reduced size (namely: height of 60 mm, top inner diameter of 20 mm, bottom inner diameter of 40 mm). The minicone, standing on a glass board is lifted smoothly and quickly and the subsequent area of the mortar spread is measured and expressed in cm². Fluidity measurements have been performed after a period of 5, 15, 30, 60 and 90 minutes respectively. In the interval of time between the measurements, the mortars samples have been poured in a close-tight jar standing horizontally on rolling cylinders set at a speed of 5 rpm.

2.5 Measurement of SP adsorption on particles in mortar

When appropriate, after the same periods of time as for the fluidity measurements, the amount of SP adsorbed on mortars particules, has been evaluated by means of a total organic carbon (TOC) analyser, namely a TOC 5050A Shimadzu apparatus. The aqueous phase of mortar has been separated by filtration under suction (using a 4 microns Whatman® filter). The filtrate has been then suitably prepared for the TOC analysis. The reduction in the TOC value (at a period of time of 5, 15 and 90 minutes after mixing) compared to that of the mixing water with SP before contact with particles from the mortar, has been supposed to give the amount of SP adsorbed on mortar particles. Results have been expressed as the percentage of adsorbed SP relative to the total amount of SP.

3. RESULTS

3.1 Mortars rheological behavior

3.1.1 Comparison of the fluidity after a period of 5 minutes

Results of rheological measurements on the different laboratory cements as a function of the different SP's and as a function of the type of added calcium sulfates are illustrated in Figures 1 and 2. In Figure 1 the mortar spread results are represented as a function of the SP dosage for cements made from the clinker A (high C₃A content). Examination of this figure allows one to make the following comments: In the absence of SP, the fluidity of the cements with H/G or G/H is similar while the fluidity with A/G is lower. The evolution of the fluidity as a function of the SP dosage tends to follow an exponential law regardless of the nature of SP. The amount of PNS that is

required to obtain a given level of fluidity is much higher than the amount of PCP required to obtain the same given level of fluidity. Moreover, to obtain a given fluidity, the situation differs as a function of the type of added calcium sulfates. Regardless of the type of SP, dosage is always the highest with the cement containing A/G. Regarding the cements with other types of added sulfates (H/G and G/H), it can be seen that the trend is similar in presence of PNS and PCP N°2 : the necessary dosage of SP being the lowest with the H/P addition. The situation differs when the PCP N°1 is used: in this case, the cement with the G/H addition requires the lowest dosage. For a given dosage of SP, the PCP-type SP's effectiveness also seems to be more sensitive to the type of added calcium sulfates since the difference between the mortar spreads are more pronounced.

In Figure 2, the mortar spread results are represented as a function of the SP dosage for the cements prepared with the clinker B (moderate C_3A content). Examination of the figure allows to make the following comments. As for the cement with high C_3A content, in the absence of SP, the fluidity of the cements with H/G or G/H is similar while the fluidity with A/G is lower. The evolution of the fluidity as a function of the SP dosage tends to follow also an exponential law regardless of the nature of SP. For each type of SP, the overall dosage that is necessary to obtain a given fluidity is lower when compared with the cement with high C_3A content. Between SP's, the amount of PNS required to obtain a given fluidity is much higher than the dosage required when the PCP-type SP's are used. To obtain a given fluidity, regardless of the type of SP, the A/G cement is still the most difficult to disperse, while the SP dosage is roughly the same for the cements made with H/G or G/H.

Figure 1. Mortar spreads (area in cm^2) as a function of SP dosage (% dry content) for the 3 types of added sulfates in cement with high C_3A content.

Figure 2. Mortar spreads (area in cm^2) as a function of SP dosage for the 3 types of added sulfates in cement with moderate C_3A content.

3.1.2 Comparison of the fluidity retention over a period of 90 minutes

In Figures 3 to 5 are shown the comparisons of fluidity retention in the cement with high C_3A for each type of added sulphates as a function of each SP dosage. The fluidity retention is always poor with the A/G sulfates when PCP –type SP’s are used while a slightly better fluidity retention is obtained with PNS –type SP (see Figure 3). In this last case, one must remember that the SP dosage is much higher. For the other types of added sulfates systems, fluidity retention behaviour vary significantly as a function of SP’s type and dosage. For the G/H system (see Figure 4), a good fluidity retention is observed with the 2 PCP-type SP’s at different dosages. With high dosage of PNS-type SP, a sharp decrease is first observed at short term, followed by a period of relative stability in the fluidity retention. For the H/G system (see Figure 5), roughly the same behavior as for G/H is observed in the presence of PNS-type SP and PCP-type SP N°2 (but at lower dosage). Concurrently, the situation differs drastically in presence of the PCP-type SP N°1. Indeed, an optimum of fluidification is observed around a period of 30 minutes. It is also observed that the value of the optimum increases as a function of the SP dosage. This feature sheds light on the behavior observed at a period of 5 minutes as described in the previous paragraph. The H/G requires a higher PCP-type SP N°1 dosage at 5 minutes when compared to G/H, contrary to what is observed with the 2 other SP’s. In the H/G system, a delay occurs before the maximum dispersion is obtained only after a period of 30 minutes.

Figure 3. Mortar spread (area in cm²) as a function of time and dosage of SP for the high C_3A cement containing A/G added calcium sulfates

Figure 4. Mortar spread (area in cm²) as a function of time and SP dosage for the high C_3A cement containing G/H added calcium sulfates

Figure 5. Mortar spread (area in cm^2) as a function of time and SP dosage for the high C_3A cement containing H/G added calcium sulfates.

In Figure 6 is shown the comparison of fluidity retention in the high C_3A cements for a given dosage of each SP as a function of 2 types of added sulfates, the H/G and G/H respectively. It can be observed that the shape of the fluidity retention is very sensitive to the type of added sulfates when PCP-type SP's are used. Same comparison is shown in Figure 7 for the cements containing moderate C_3A content (cements made with clinker B). In this case, the fluidity retention shape is much less sensitive to the nature of added calcium sulfates regardless of the SP type.

Figure 6. Mortar spread (area in cm^2) as a function of time and type of added sulfates for the high C_3A cement at given SP concentration

Figure 7. Mortar spread (area in cm^2) as a function of time and type of added sulfates for the moderate C_3A cement at given SP concentration.

3.2 SP adsorption in mortars over a period of 90 minutes

TOC measurements, as illustrated in Figure 8, have been performed on mortars prepared with the clinker with high C_3A content, calcium sulfates in the form of G/H and H/G and in presence of PNS or PCP N°2. The SP dosage selection and subsequent mortar early fluidity at 5 minutes are listed in Table 4.

Table 4. SP dosage and early fluidity on mortar selected for TOC measurement

SP % (dry content)	G/H cement	H/G cement
0.45 % PNS	95 cm ²	135 cm ²
0.12 % PCP 2	100 cm ²	190 cm ²

The results shown in Figure 8 indicate clearly that, apart from the fact that less dosage of PCP N°2 is needed to obtain a given fluidity when compared to the PNS-type SP, less amount of PCP N°2 has been adsorbed on the particles after a period of 5 minutes. Indeed, in presence of PNS-type SP, most of the adsorption has occurred in the first 5 minutes and furthermore, the adsorption does not evolve much beyond this initial period. On the contrary, adsorption is still important between the interval 5 and 15 minutes in presence of the PCP-type SP. For both SP's, less amount of SP is adsorbed in the H/G cement over the whole period of time. However, it is confirmed that the PCP-type SP efficiency seems to be more sensitive to the type of added calcium sulfates after a period of 5 minutes since the difference of adsorption between the cements made with H/G and G/H is more significant when compared to the PNS-type SP. Such results fully support the hypotheses that have been drawn from the fluidity results.

Figure 8. Adsorbed SP % in mortars in presence of PNS and PCP type SP for high C_3A cement containing H/G or G/H added sulfates at 5, 15 and 90 minutes

4. DISCUSSION

On the basis of these results, the difference of rheological behavior as a function of the nature of the added sulfates can be explained as follows. During the preliminary water treatment of the cement containing high C_3A , the added calcium sulfates will provide more or less Ca^{++} and $SO_4^{=}$ ions to the pore solution as a function of their dissolution rate, the A/G system having the slowest rate and the H/G system having the fastest rate. Those ions, depending on their immediate availability, could promote the early formation of ettringite prior to SP addition by reacting with a C_3A content that is high. The faster the ettringite is promoted before the SP addition, the less the incorporation of the SP in the early hydration products and the better the efficiency. In the H/G system, ettringite can form quickly prior to the addition of SP and consequently, less SP will be incorporated after its

addition, leading to higher efficiency and therefore, such system requires the lowest SP dosage. In the G/H system, less ettringite can form prior to the SP addition and consequently, more SP will be incorporated after its addition and therefore, the system requires an intermediate SP dosage. This hypothesis seems to be valid in presence of PNS and PCP n°2 while the feature observed in presence of PCP N°1 is unclear. The delay in the maximum dispersion effectiveness seems to be related to a particular mechanism of action of the particular SP.

In the presence of A/G, much less ettringite can form prior to the SP addition and the early hydrates formation after the SP addition consumes a higher amount of SP and therefore, the system requires the highest SP dosage. This hypothesis seems to be valid for the 3 SP's.

Regarding the cement with a moderate C_3A content, the similar behavior observed for the H/G and G/H systems (same SP dosage necessary for a given fluidity) can be explained as follows. The systems H/G and G/H do not have the same dissolution rate, but in both cases, sufficient Ca^{++} and SO_4^- are provided to the pore solution prior to the SP addition for the production of a sufficient ettringite coating on the moderate amount of the C_3A . Consequently, for both systems, the efficiency of the SP is in the same range. This hypothesis seems to be valid for the 3 SP's.

For the A/G system, the same explanation as for the high C_3A cement can be proposed.

Considering the fluidity retention shape, it seems that the fluidity loss observed in some cases is linked to some subsequent higher consumption of the SP after the initial period of 5 minutes. It is likely that this consumption is due to a higher formation rate of hydrates between 5 and 90 minutes in such systems. However, the optimum of fluidization over the time observed with the PCP-type SP N°1 is unclear and requires further investigations.

5. CONCLUSIONS

In this study, the effect of different types of SP's on the fluidity retention of Portland cement mortars as a function of the nature of added calcium sulfates and C_3A content has been investigated.

After a preliminary water treatment of the cements, the results indicate that less dosage of PCP-type SP's is required to obtain a given initial fluidity when compared to PNS-type SP. Apart from the fact that the overall SP dosage is lower, the SP adsorption is also lower when compared to PNS-type SP's.

For a high C_3A level, cement dispersion is very sensitive to the nature of added calcium sulfates: the initial fluidity increases as a function of the calcium sulfates' solubility rate, regardless of the type of SP. It seems that the PCP-type SP's dosage is also more sensitive to the calcium sulfate nature.

For a moderate level of C_3A , the dosage of SP is reduced and the cement dispersion is less sensitive to the nature of added calcium sulfates, regardless of the type of SP.

Thus, the PCP-type SP's dosage, like the PNS-type SP's, depends also on C_3A content and the subsequent production of early hydrates. Like PNS-type SP's, the PCP-type SP's efficiency is also dependant on the type of added calcium sulfates.

Furthermore, the effectiveness of the fluidity retention in presence of PCP-type seems to be also very sensitive to the nature of added calcium sulfates when the cement C_3A content is high. This sensitivity is much less pronounced when the C_3A level is moderate.

ABSTRACT

The effect of Zn, Ni, Pb and Cr on the burnability of raw meals, clinker formation processes, properties of clinker and cement as well as their long term environmental effect in concrete was investigated. Zn, Ni and Pb do not influence clinker formation, or cement/concrete properties, and their use does not present any hazard during long-term behaviour. However Cr can be dangerous: in the atmosphere of cement burning the original Cr^{3+} is oxidized to Cr^{6+} , which negatively influences alite formation, and is soluble in water or weak acids, thus in long-term use it can be environmentally hazardous. By properly adjusting the sulfatization degree, the quantity of water-soluble chromates can be decreased. In certain cases, reducing agents are necessary to transform hexavalent Cr to a trivalent form.

1. INTRODUCTION

If wastes are used as alternative raw materials and/or fuels, the number and quantity of trace elements (esp. those of heavy metals) is increasing. Their amount may cause changes in the chemistry of cements and also their environmental influence must be known. During this research the effect of zinc (Zn), nickel (Ni), lead (Pb) and chromium (Cr) on the burnability of raw meals was investigated, jointly with their effect on clinker formation, clinker and cement properties. The distribution of heavy metals in various clinker phases, their characteristics were also studied. From an environmental point of view, the fate of the heavy metals during the use of cement is of utmost importance; to investigate this, various leachability tests were done.

1.1 Cement Chemistry

1.1.1 Methods

To investigate burnability, a “standard” raw material was preprepared, made of high purity materials. Moduli of this standard: Lime saturation = 0,90, silica modulus = 2,2, alumina modulus = 1,7. Raw materials were mixed with various amounts of ZnO , NiO , PbO and Cr_2O_3 in quantities ranging 0,05 to 2,5 m/m%, ground to approx. 500 m^2/kg (Blaine), pressed to pellets and fired in an electric laboratory kiln (in air) at 1400 °C for 30 min. The free lime content was determined in these clinkers (ethylene glycol method) and investigated by XRD, optical microscopy (reflected light), SEM and EDAX. Selective dissolution methods were used for the investigation of heavy metals in various clinker phases.

To study the effect of heavy metals on physical and mechanical properties of cement, clinkers were ground to surface area approx. 320 m^2/kg (Blaine), with added gypsum ($\text{SO}_3 = 3,5 \text{ m/m}\%$).

In order to study the environmental effect of heavy metal-containing cements, leachability tests were also undertaken. The total heavy metals content was determined according to the Hungarian standard ^[1], by ICP-AES, from solutions after an attack by nitric acid / hydrogen peroxide.

Leachates were prepared as follows:

- leaching in de-ionised water, in order to study direct environmental hazard; this gives information on heavy metals which are released by the clinker when mixing with water, i.e. concrete manufacture;
- leaching in an ammonium acetate buffer of pH = 4.5; this gives information on heavy metals which are released during the working life of cement by the attack of weak acids;
- leaching in 2M nitric acid; this gives information on the “total quantity” of heavy metals. This gives information on the “potential” hazard of landfilling with demolished concrete.

The working life of cement in concrete can be investigated by analysing the heavy metal content of pore solutions. For these tests industrial clinkers were used: cements were made, after grinding in a lab mill and mixing with gypsum. Cylindrical samples were made of these cements using a 0.6 w/c ratio; demoulding was done at the age of 24 h, followed by storing in polythene bags. Pore solutions were expressed at ages of 28 and 120 days, by a pressing force of 600-650 kN.

2. RESULTS

2.1 Cement chemistry

Burnability results are tabulated in Table 1. It can be seen that by adding ZnO, NiO and PbO in increasing amounts, the free lime content was decreased, showing that these heavy metals improve clinker formation.

Table 1. Effect of Zn, Ni and Pb on the burnability (free CaO, in m/m%) of raw meal

Oxide content, m/m%						
0	0.05	0.10	0.25	0.50	1.0	2.0
ZnO						
1.20	1.05	0.85	0.75	0.73	0.68	0.55
NiO						
1.20	0.85	0.74	0.65	0.57	0.46	0.29
PbO						
1.20	0.98	0.87	0.72	0.65	0.60	0.50

On-hand SEM-micrographs and their EDAX spectra (Figure 1.), as well as results of selective dissolution (Table 2.) show that Zn is mainly concentrated in the alite- and aluminoferrite phase, while Ni and PbO in the aluminoferrite phase (although their presence can also be detected in the silicate phases).

Table 2. Distribution of heavy metals in clinker phases (m/m%)

Clinker phase	Zn	Ni	Pb
Silicate (alite, belite)	0.40	0.23	0.20
Aluminoferrite	0.72	1.82	2.00
Aluminate	0.15	0.18	0.12
Potential mineral composition of clinker (Bogue)			
C ₃ S = 59,5 m/m% C ₂ S = 19,8 m/m% C ₃ A = 9,2 m/m% C ₄ AF = 11,5 m/m%			
Metal oxide content in clinker: 0,5 m/m%			

XRD tests proved that these model clinkers contain monocline alite (M_I and M_{II}), as shown by the shape of the alite peak at $2\Theta = 51 - 53^\circ$.

Figure 1. SEM micrographs and energy dispersive X-ray spectra of Zn- and Ni-containing clinkers

If the model clinkers contain $< 0,1\text{m/m}\%$ of metal oxide, the physical-mechanical properties of cement made of it do not differ from those made of no-heavy-metal clinker. This is illustrated by the cement containing ZnO (Table 3.)

Table 3. Comparison of physical-mechanical properties of cements made of standard (C_0) and $0.1\text{ m/m}\%$ ZnO-containing (C_{Zn}) clinker

Property	C_0	C_{Zn}
Surface area (m^2/kg)	323	325
Setting data		
water to reach standard slump	27.0	27.5
initial set (h-min)	3-20	3-00
final set (h-min)	4-30	4-20
Soundness (Le Chatelier ring), mm	1.0	1.0
Compr. strength (MPa)		
2 days	15.8	15.0
7 days	26.2	25.8
28 days	34.8	35.2

Figure 2. The $2\theta = 51 - 53^\circ$ part of XRD patterns in ZnO-, NiO- and PbO-containing clinkers

The free CaO-, C_3S - and C_2S -content of clinkers, fired of raw meals containing various amounts of Cr_2O_3 , is shown in Figures 3 and 4, respectively.

Figure 3. Free CaO-content of clinkers with various amounts of Cr_2O_3

Figure 4. C₃S and C₂S content of clinkers with various amounts of Cr₂O₃

It is evident that by increasing the Cr₂O₃ –content, the free CaO-content is increased, showing that chromium is disadvantageous from the point of burnability. Jointly with the increasing of Cr₂O₃ and of free CaO, the C₃S and C₂S content of the clinker is decreasing, and increasing, respectively; in case of adding 2.5 m/m% of Cr₂O₃, the C₃S-content of the clinker is almost zero (Figure 5.). All this shows that the presence of Cr₂O₃ decreases the alite (C₃S) content, by the stabilization of β-C₂S.

Figure 5. The 2θ = 51 – 53° part of XRD patterns in Cr₂O₃-containing clinkers

SEM-micrographs and EDAX-spectra, jointly with selective dissolution show that chromium is mainly concentrated in the silicate (alite, belite) phases, although its presence in the aluminate-ferrite phase is also evident. (Figure 6A). A SEM-micrograph of a clinker, with maximum (2.5 m/m%) Cr₂O₃ addition shows decomposing alite, as well as belite and CaO crystals (Figure 6B).

Figure 6. SEM micrographs and energy dispersive X-ray spectra of clinkers containing 0.1 and 2.5 m/m% Cr_2O_3

In the case of chromium-containing clinkers the micrograph shows large ($>100 \mu\text{m}$) “emerald” alite crystals, being strongly reflective. The green colour of alite is a consequence of chromium-incorporation (Cr^{3+} or Cr^{6+}). Chromium improves the grindability of clinker. If the chromium content in model clinkers is $<0.1 \text{ m/m\%}$, the cement has practically equal physical-mechanical properties as the no-Cr clinker.

2.2 Leachability

Results of leachability tests are summarized in Table 4.

Table 4. Heavy metal content and leachability of clinkers

Heavy metal content ppm (mg/kg)	Model clinker [*]	Industrial clinkers	
		Clinker	CEM I 42.5N
z i n c			
total	793	66	93
leachability in water	<0.1	<0.1	<0.1
leachability in buffer ^{**}	<0.1	<0.1	<0.1
n i c k e l			
total	780	23	22
leachability in water	<0.1	<0.1	<0.1
leachability in buffer ^{**}	<0.1	<0.1	<0.1

l e a d			
total	890	27	33
leachability in water	<1	<1	<1
leachability in buffer**	<1	<1	<1
c h r o m i u m			
total	632	78	75
leachability in water	46.7	1.2	3.3
leachability in buffer**	48.0	1.5	3.6

* Metal oxide content: 0.1 m/m%

** Ammonium acetate, pH=4.5

Leachability of model clinkers shows that zinc, nickel and lead are bonded in clinker phases during burning very strongly: leachout was almost negligible in water and also in slightly acid media (pH = 4.5). However chromium-containing clinkers behave in a different way: the water leachate contains 46.7 ppm chromium as Cr^{6+} (of the 632 ppm total Cr-content model clinker), although Cr was added as Cr^{3+} (Cr_2O_3). Actually the oxidizing atmosphere of the kiln converts a part of Cr-content to a hexavalent state; this is partly bonded in clinker phases, but the rest is soluble in water or slightly acid media. These findings are supported by industrially produced clinkers and cements (20 and 55 samples, respectively).

The long-term leachability behaviour of cement (in concrete) can be studied by the pore fluid analysis of hardened cement paste. Results are tabulated in Table 5.

Table 5. Cr, Zn, Ni and Pb content of pore solutions, ppm (mg/kg)

Age	Cement label											
	C ₁				C ₂				C ₃			
	Heavy metal content of pore solutions											
	Cr	Zn	Ni	Pb	Cr	Zn	Ni	Pb	Cr	Zn	Ni	Pb
28 days	1,1	<0,1	<0,1	<1	0,9	<0,1	<0,1	<1	2,1	<0,1	<0,1	<1
120 days	1,6	<0,1	<0,1	<1	1,5	<0,1	<0,1	<1	2,9	<0,1	<0,1	<1
	Heavy metal content of cements											
Total	75	177	27	13	107	88	26	24	147	70	35	20
Water soluble	12	<0,1	<0,1	<1	16	<0,1	<0,1	<1	17	<0,1	<0,1	<1

* Remark: pH of pore fluids was between 13.37 and 13.63

It is obvious that pore fluids do not contain Zn, Ni or Pb, and their Cr-content is much lower (at ages 28 or 120 days) than in aqueous leachates. This shows that during cement hydration, soluble Cr-content is bonded in hydrate phases.

3. SUMMARY

Heavy metal containing wastes are increasingly used in cement manufacture, although their effect is not fully known. This research is aimed at examining the effect of Zn, Ni, Pb and Cr on the burnability of raw meals, clinker formation processes as well as physical-technical properties of clinkers and cements. The long-term behaviour of cement in concrete was studied by analysing leachates (in water and weak acid, pH=4.5) and pore fluids (age: 28 and 120 days).

Results prove that ZnO, NiO and PbO, (from 0.05 to 2.00 m/m%) promote burnability and clinker formation. Zn is mainly incorporated in the alite and the ferrite phase, while Ni and Pb mainly in the ferrite, although it can be detected in the silicate phases too. Clinkers with 0.2 m/m% ZnO, NiO or PbO contain monoclinic alite. Clinker with ZnO addition shows well crystallized, hexagonal, prismatic and similar alite crystals of 10-50 μm size. Clinker with NiO contains well crystallized, but irregularly formed (rounded) alite of 15-20 μm size, while PbO causes prismatic, elongated alite crystals of 80 μm size and unusually high amounts of interstitial material. Leachates of cements in water and weak acid ($\text{pH} = 4.5$), as well as pore fluids of hardened cement contain practically nil ($<$ than detection limit) of these heavy metals. These findings are also in accordance with the results of several industrially manufactured clinkers and cements.

The behaviour of chromium is different. In the range of 0.05 – 2.50 m/m% Cr_2O_3 content burnability and alite formation is deteriorated. This can be attributed to hexavalent chromium (Cr^{6+}), formed from the trivalent one in the oxidizing atmosphere of the burning. The presence of Cr^{6+} stabilizes $\beta\text{-C}_2\text{S}$; this is due to the replacement of $[\text{SiO}_4]^{4-}$ anion by $[\text{CrO}_4]^{2-}$ anion.. This stabilization causes dissolution of $\beta\text{-C}_2\text{S}$ in the melt to be slowed down, thus deteriorating the formation of alite. The same replacement takes place in the lattice of alite too. Chromium can be not only in the form of $[\text{CrO}_4]^{2-}$ but also as Cr^{3+} in the lattice of C_3S and C_2S [2,3]. In the case of 2.5 m/m% Cr_2O_3 , this replacement led to the decomposition of alite. Clinkers containing chromium show under the microscope large ($> 100 \mu\text{m}$) alite crystals of green “emerald” colour. Leachates and pore solutions of Cr-addition contain hexavalent (Cr^{6+}) chromium; however the Cr-content of pore fluids was much less than in leachates, showing that water-soluble chromates are bonded during cement hydration.

There are several sources of Cr in cement manufacture: besides wastes as alternative raw materials: it may come to the raw meal by the wear of grinding media, from refractories, by kiln dust recycling, etc. Although this Cr is usually trivalent, this is transformed into a hexavalent state in the oxidizing atmosphere of the kiln. A large part of this Cr^{6+} is bonded in clinker phases, but a part remains as soluble alkali chromates. Thus e.g. potassium chromate ($\text{K}_2\text{Cr}_2\text{O}_7$ or K_2CrO_4) was found in XRD patterns of high-chromium clinkers manufactured semi-industrially. Several factors determine oxidation, clinker formation and Cr-bonding in the kiln, e.g. burning temperature, oxygen level of the kiln, degree of sulfatization. The investigation of a number of industrial clinkers show that 1.5 – 11.0 % of the total the (Cr^{6+}) content becomes water soluble. Clinkers of almost identical total Cr-content contain more soluble (Cr^{6+}), where the sulfatization degree was not properly adjusted, i.e. those containing alkali surplus.

Cements made of model clinkers, containing 0.1 m/m% ZnO, NiO, PbO or Cr_2O_3 have physical-mechanical properties (water demand, setting time, soundness, strength at age 2, 7 or 28 days) similar to those without these oxides.

As a summary, it can be stated that clinker formation and properties of cements made by using alternative raw materials of usual Zn-, Ni- and Pb-content can be used without restriction; even the long-term behaviour is environmentally safe. Chromium, on the other hand, may dangerous, even if present in low quantities: it hinders alite formation. Still worse, a part of trivalent Cr is oxidized during burning to hexavalent Cr, which forms soluble chromates. This must be taken into consideration for the “working life” of concrete structures, as environmentally hazardous chromates might be released. If using Cr-containing wastes as raw materials, certain measures must be taken to decrease the soluble/insoluble ratio of chromium, e.g. adding reducing agent to prevent oxidation.

ABSTRACT

This paper describes preliminary results from a part of a current European Research Programme project addressing superplasticizers of improved properties for cement and concrete. In the project we are producing new superplasticizers and testing them in model systems and real concrete systems. The main goal of the project is to carefully study the mechanisms involved in the adsorption of polymers in concrete and the mechanisms with which they work. In this paper preliminary results are presented for one modified polycarboxylate polymer and one lignosulfonate polymer. Results are from rheological measurements, adsorption studies and AFM-colloidal probe measurements show the importance of the ionic concentration of the dispersing media both for model MgO powders and cement suspensions. The ionic medium composition (with or without Ca) influences in particular the polycarboxylate polymers. The ionic strength seems to control the relative contributions of the steric and electrostatic contributions to the repulsive interparticle forces, which manifests itself in a modification of the rheological behaviour.

1. INTRODUCTION

The performance demand on concrete is continuously increasing and this leads to the continuous development of new improved chemical admixtures used in concrete. Superplasticizers, one of the most important classes of chemical admixtures, are used for mainly three reasons, i) to produce highly workable concrete for easy placement ii) to produce concrete with a low water content for higher strength and durability or iii) to produce concrete with low cementitious and water contents for better economy. In this project we take a fundamental and systematic approach to analysing the plasticizing mechanisms of two classes of superplasticizers, modified polycarboxylates and lignosulfonates, in different cementitious systems. Our approach will be to carefully study the interaction between the polymer and the powder (cement or model system) to get more information on how the polymer is adsorbed on the surface and what the dominating dispersing mechanisms are. This approach demands that we use a model system for cement, since for example in the AFM-

colloidal probe measurements a reactive surface would not be possible to use. We have chosen to use dead burnt MgO as a model system. This has previously been used by Flatt *et. al.* with good results [1].

The results presented in this article are the first results in a larger project. The measurements have been performed in different labs and during slightly different conditions. This makes the interpretations a bit more difficult, but we think that the results are important and that they give information that is important for the understanding of the adsorption and the performance of superplasticizers in concrete.

2. EXPERIMENTAL

2.1 Materials

2.1.1 Polymers

The polymers used are experimental products specially produced for this project. The lignosulfonate polymer (LS) was produced by ultrafiltration of a sample of fermented, sugar reduced sodium LS. The ultrafiltration was carried out as a two-step ultrafiltration, starting with a small cut-off ultrafiltration membrane, followed by running the retentate through a high cut-off ultrafiltration membrane. The ultrafiltration was done to increase the molecular weight to a level above the molecular weight of current commercial available LS. Sugars and other “impurities” were also removed during the ultrafiltration. The overall MW for the LS polymer is about 157,000 g/mol.

The modified polycarboxylate polymer (PCP) is a branched polymer with methacrylic acid backbone and side chains of polyethylene glycol. The side chains are bound by ester linkages to the polymethacrylic backbone. The overall MW of the molecule is 45.000 g/mol.

2.1.2 MgO model powder

We used dead burnt MgO from Martin Marietta Magnesia (USA) of type MagChem P-98 in this work as non-reactive model powder for cement. This powder has a particle size distribution of $D(v, 0.1)=2.88\ \mu\text{m}$, $D(v, 0.5)=17.59\ \mu\text{m}$ and $D(v, 0.9)=54.65\ \mu\text{m}$ with a span of 2.94 as measured by laser diffraction. To perform careful analysis on the interaction between the polymers and a powder it is absolutely necessary to use a model system for cement, since the errors would be too large with a reactive powder like cement. The reactivity of the powder has been tested by contacting the powder with 0.01M NaOH during 30 minutes, 1 hour and 24 hours, followed by filtering and drying at 110°C. The BET surface area was measured on the dry powders and the results indicate that there is a rapid hydration of the surface of the grains on contact with the solution, between 30 and 60 minutes no further change was observed. The powder is therefore regarded as a good “non-reactive” model powder for cement during this 30-minute period after an initial 30 minutes in contact with 0.01 M NaOH. The surface of the powder would then consist of $\text{Mg}(\text{OH})_2$. The main characteristics and properties of this model powder are described in another article submitted to this congress [2].

2.2 Methods

2.2.1 Rheology

Previous experience in the evaluation of superplasticized grouts led to the development of a special rotor head for the Carri-Med CSL500² specifically for use with high solids content suspensions. Thus when considering the rheological evaluation of the model powder pastes containing the experimental superplasticizers, the Helix B test head was the best available tool, combining accuracy of determination with an ability to prevent settling of solids during the test.

The testing procedure was as follows. The powder and liquid were weighed separately and mixed together for 30 seconds by hand and then the paste was poured into the test cup and the test sequence initiated. The paste was subjected to 2 minutes of stirring at a shear rate of $50\ \text{s}^{-1}$, before

the initial test run was carried out. The shear stress was measured at 20 controlled shear rate points from 0-10 s⁻¹, and then another 20 controlled shear rate points from 10-200 s⁻¹. The paste was stirred for a further 5 minutes at a shear rate of 500 s⁻¹, which is designed to break down any existing structure in the paste. The test procedure was then run again. The total time for the whole procedure was approximately 25 minutes.

2.2.2 Adsorption

Adsorption isotherms of the PCP and LS polymers on MgO were measured by the depletion method. In this method, the amount of polymer is measured in a solution before and after contact with the powder. The reduction in polymer concentration in the aqueous phase before and after contact is assumed to be the adsorbed amount. The polymer solutions are analysed by High Performance Liquid Chromatography (HPLC) with a light scattering detector for PCP and by UV spectroscopy for the LS polymer. The samples were prepared by mixing 10 g MgO with 18 ml 0.01 M NaOH for 30 minutes when the polymer is added. After a further 30 minutes the supernatant was recovered by filtering through a 0.45 µm filter before the polymer concentration was measured.

The adsorption of the polymers onto MgO was also followed by acoustophoretic measurements using an AcoustoSizer II from Colloidal Dynamics. 53 g MgO powder was dispersed in 200 ml NaOH 0.01 M (gives a slurry of 21 wt%) under vigorous agitation and ultrasonic treatment for 15 minutes. The suspension was then allowed to cool down to 25 °C for another 15 minutes. Once the solution was loaded into the sample reservoir and pumped up through the measurement cell, polymer solution was then added as aqueous solution with a microburette. Between two additions, the suspension was allowed to equilibrate.

The AcoustoSizer II is only sensitive to particles that are smaller than 10 µm. Since our powder contains also larger particles the apparatus sees it as a dilution of the sample with large, invisible particles, and hence we detect a lower value than the real one. We have tested this interpretation by using an air-classified version of the MgO used in this project. This powder has only particles smaller than 10 µm and here we detect higher negative charge on polymer addition compared to the MgO powder with both small and bigger particles. Further work is being carried out to confirm that this is a quantitative approach. However, the trends that are found in our results for powders with particles >10 µm are good qualitative indications of the trends and very interesting to follow.

2.2.3 AFM colloidal probe

The atomic force microscope (AFM) was originally developed as a means of high resolution imaging of non-conducting samples. The AFM can be used not only as an imaging tool, but also as a powerful technique for surface force measurements [3]. The magnitude of the normal surface force between the tip and the sample can easily be evaluated by approaching and retracting the tip and registering the deflection as a function of the movement of the scanner in the Z direction. The raw data is transformed into a true force curve by a series of manipulations. The zero force level and the point where the surfaces are in "hard contact" are established from the raw data. The spring constant of the cantilever is used to transform the deflection data into force units, and a force curve as a function of surface separation is obtained [4]. Both attractive and repulsive forces can be measured, corresponding to negative and positive deflection respectively. By using a liquid cell, surface forces in organic or aqueous media can be studied.

Instead of using the tip as one surface in a surface force measurement, a customised probe can be attached at the apex of the cantilever. This is called the "colloidal probe technique" [5]. Although the probe can be made of any material it is preferable that it has a well-defined geometry *e.g.* a sphere shape, so that the data can be correctly interpreted.

The AFM liquid cell was mounted with a flat MgO substrate and a cantilever with a sphere of MgO. The cell was first flushed with 1 mM KCl, and then a first measurement was performed. After this the cell was flushed with a polymer solution containing 100 ppm polymer (pH 10). The adsorption of the polymer on the two surfaces was allowed to equilibrate for about 30 minutes before the polymer solution was flushed away with 1 mM KCl. After these procedures measurements were performed in different electrolytes. After each flushing with a new electrolyte the cell had to rest for about 15 minutes to allow all motions in the liquid and the cantilever to stop.

An AFM microscope has previously been used to measure the forces in cementitious systems in liquid by other groups [6-9], but this is believed to be the first time, that MgO has been used as a model system to study the forces between surfaces in liquid covered with superplasticizer.

2.3. Results

2.3.1 Rheology

Initial tests with the supplied MgO powder P98, showed that it was coarser than expected, *i.e.* than a typical OPC. It was possible to reduce the w/c ratio to 0.25 and still test the paste in the CSL. A check of the lowest tolerable w/c ratio of the three chosen OPCs gave a realistic lower w/c ratio limit of 0.375. Earlier work had indicated that the surface area of the powder under test has a marked influence on the observed rheology [10]. To verify this 1kg of the MgO powder was ground in a ceramic ball mill for one hour (MgO(B)), and a second 1kg was ground for 2 hours (MgO(C)). Comparison of the 25 μm residues revealed that for MgO(A) 55% passed a 25 micron sieve, for MgO(B) 74% and for MgO(C) 85%, indicating that MgO(C) was near to the specified OPC. A secondary influence was identified to be the electrolyte environment surrounding the cement particles. To simulate this a synthetic ‘soup’ was made up based on a chemical analysis of cement electrolyte solutions. The soup was made from 1 litre of water saturated with $\text{Ca}(\text{OH})_2$ and in which 7 g Na_2SO_4 , 6.5 g K_2SO_4 and 6 g KOH were dissolved. The results show that the slurry rheology is very sensitive to powder surface area, with MgO(C) giving a similar performance to the Caudon OPC at shear rates up to 60 s^{-1} (Figure 1). It is also apparent that the slurries are more fluid when made with the soup compared to slurries made with water; the effect lessening with increasing 25 μm residue such that with MgO(A) the difference is minimal.

The PCP and LS polymers have been tested on MgO(C) pastes of 0.375 w/s ratio at a loading of 0.175 % (by weight of cement) for the PCP polymer and 1.0 % for the LS polymer (Figure 2). The PCP polymer shows a marked thickening of pastes made with soup compared to those made with water. In contrast, the LS polymer shows no such effect in pastes made with either water or soup. This indicates a different dispersion mechanism compared to the PCP polymer.

Figure 1. Rheology of MgO powders made from as-received (A) and milled (B,C) powders with soup and water compared to OPC w/c=0,375.

Figure 2. Rheology of MgO(C) with no additive, 0.175% PCP or 1% LS polymer in water and soup.

2.3.2. Adsorption

The adsorption measurements of PCP and LS presented in Figure 3 indicate that the adsorbed amount of polymer increases sharply for both polymers to a plateau value between 1 and 1.2 mg/g (milligram polymer per gram MgO). For PCP the plateau is reached at an initial polymer/powder ratio between 3 and 4 mg/g whereas for the LS polymer it is reached already at 2 mg/g. As can be seen in figure 3, the uncertainty in the measurements of the PCP polymer is rather large (about 20%). This is not very satisfactory, but still gives a good indication regarding the adsorption behaviour. The adsorption was also followed by acoustophoretic measurements. In Figure 4 the results of zeta potential as a function of polymer concentration are shown, and here we see that the powder has a positive charge without polymer, but that adsorption of either polymer gives the surface a negative charge. The LS polymer gives a slightly more negative charge compared to PCP. The same type of adsorption behaviour can be observed from the electroacoustics measurements as from the depletion measurements, with a sharp increase followed by a plateau, although the plateau is not as clear in the electroacoustics measurements as in the depletion measurements.

Figure 3. Adsorption Isotherms of PCP and LS on MgO measured by the depletion method.

Figure 4. Variation of zeta potential as a function of added PCP or LS.

2.3.3 AFM colloidal probe measurements

The AFM colloidal probe measurements are performed to get an idea of how the polymer is adsorbed onto the MgO surface and what mechanisms are dominant in the dispersion of the powder. The two forces that are generally thought to be present when polymers are used to disperse a powder are electrostatic stabilisation, where surface charges induce a repulsion, and steric stabilisation that works through physical overlap of the polymer chains. The electrostatic effect is strongly affected by the ionic strength of the surrounding electrolyte since charges in the electrolyte screen the electrostatic force, therefore the electrostatic force acts over shorter distances for electrolytes with higher ionic strength. The steric forces, on the other hand, are not directly affected by the ionic strength of the solution, unless this has a strong effect on the conformation of the polymer. In figure 5 below the force/radius between a flat MgO surface and an MgO sphere covered with PCP and in KCl electrolytes of different ionic strength is shown together with EDL (Electric Double Layer) curves. The EDL curve is the expected slope that the force curve would have for different ionic solutions if only electrostatic forces were present in the system. The curves are not full DLVO calculations with boundary conditions but rather approximations according to the formula:

$$F/R = B * e^{-\kappa D} \quad (1)$$

where F is the force, R the radius of the sphere used, B a constant, D the distance between the flat surface and the sphere, and κ is the *Debye-Hückel parameter* given by:

$$\kappa = 3.288\sqrt{I} \quad (2)$$

at 25°C in a 1:1 electrolyte where I is the ionic strength of the solution [5, 11]. As can be seen in figure 5 the curves for 1, 10 and 100 mM KCl all match the slopes of the EDL lines very well for distances above about 4 nm, but for shorter distances they do not overlap at all with the EDL lines. Here on the other hand, the three curves overlap with each other. These results indicate that for distances longer than 4 nm between the two surfaces the electrostatic force is the dominant force for all electrolytes tested here, but for shorter distances steric forces are the dominant forces.

Figure 5. Force diagrams for two MgO surfaces covered with PCP in 1, 10 and 100 mM KCl, as measured with the AFM colloidal probe technique.

The results presented in Figure 5 are obtained with the PCP polymer adsorbed from a 10 mM solution of CaCl_2 at pH 10. We have also tried to adsorb the polymer from water and from a 100 mM KCl solution, and in both cases the polymer initially seems to adsorb onto the surfaces, but the adsorption does not seem to be very strong. When the measurements are performed the liquid cell containing the MgO surfaces are flushed with electrolytes of different ionic strength. When this was performed for the polymers adsorbed from water and KCl we observed a desorption of the polymer whereas this was not the case when the polymer was adsorbed from a CaCl_2 solution. We interpret this as being the effect of the Ca^{2+} ions on the adsorption of the polymer, making the adsorbing bond stronger by perhaps bridging the polymer-MgO interface.

3. DISCUSSION

From the rheological measurements in Figure 2 we could see that the effect of adding the “soup” compared to measuring in a water slurry was large both for the slurry without polymer and on addition of PCP but very small when LS was added. For the MgO slurry without polymer the flowability was increased on use of the soup compared to water, and this effect was largest for the powder with the finest particles (Figure 1). One explanation for this behaviour could be that the powders are agglomerated both in water and in soup, but that they are more highly aggregated in water. When the slurry is sheared, the agglomerates are broken, but it is much easier to break agglomerates between large particles compared to agglomerates between small particles. Therefore the aggregates in the MgO(A) slurries both with water and soup are broken rather easily, and we cannot detect any marked difference between them. For the slurries made with MgO(B) and MgO(C) more force is needed to break the agglomerates, and we detect a clear difference between the aggregated powder in soup and the strongly aggregated powder in water. As the shear rate is increased we see that the difference between soup and water get smaller and smaller, and this confirms this theory since more agglomerates are expected to be broken at a high shear rate. The experiments most relevant for cement slurries and concrete are probably those made with soup since the soup is an electrolyte that mimics cement water.

When PCP is present in the MgO slurry the flowability is decreased on use of the soup compared to water, *i.e.* the opposite behaviour compared to the pure MgO slurry, and when LS is used there is almost no difference in the flowability between water and soup. This indicates that the soup has a negative influence on the PCP polymer. One explanation could be that the polymer adsorbs more easily to the MgO powder in water, probably because the surface is positively charged (pH below

iso-electric point, (i.e.p.) and the PCP polymer is negatively charged, whereas when the soup is used the MgO particles have a negative charge (pH above i.e.p.), and there could also be a competitive adsorption from the ions in the soup. Another explanation could be that the PCP polymer conformation is affected by the ions in the soup giving a less favourable conformation. Even if there is a difference in the performance with water and soup the flowability is much higher in the presence of PCP than without. There could be several reasons why the LS polymer is not affected by the change from water to soup and this could be that it does not have any conformational changes on addition of soup, that the adsorption of the polymer is not affected by the soup or that it is added in such high amount that even if the adsorption is affected there is still enough polymer there to disperse the system. According to the adsorption measurements presented in Figure 3 the used PCP polymer concentration of 0.175 % is about half the concentration needed to reach the adsorption plateau whereas for the LS polymer the concentration 1 % is 5 times the concentration needed to reach the adsorption plateau. It would be interesting to see if the observed effects are concentration dependent.

Other authors have also recognised the importance of both cations and anions for the adsorption of polycarboxylate type polymers on different surfaces [12-14]. We conclude that since the ions seem to have such large importance for the adsorption of polymers, and also for the rheology of the system without polymer, it is very important to work with a relevant electrolyte when using a model system for cement and further detailed investigations are being carried out in this light. However we believe that the soup used in this work contain the essential ingredients for a model electrolyte and are confident that when used together with MgO it creates a relevant model system for cement slurries.

The measurement of the adsorption of the polymers was performed in two different ways in this work, a depletion technique and through acoustophoretic measurements. The results are rather similar but with the plateau reached at a slightly higher polymer concentration for the acoustophoretic measurements. The measurement procedure was rather different for the two methods. In the depletion measurements, the polymer concentration was measured in a solution that was filtered and fed into a machine, whereas in the acoustophoretic measurement the results were measured directly in the relevant slurry. Therefore we prefer the latter measurement technique that imposes less work in the laboratory and is more reliable at least for screening different polymers.

The AFM colloidal probe results presented in Figure 5 show that the PCP polymer gives steric repulsive forces between the two MgO surfaces up to 4 nm, indicating that the polymer layers are about 2 nm thick, since both surfaces are believed to be covered by polymer. This indicates that the PEG chains of the polymer have adopted a rather coiled conformation on the surface. The observation that the polymer desorbs more easily when the polymer has been adsorbed from water or a 100 mM KCl electrolyte compared to when the polymer is adsorbed from an electrolyte containing 10 mM CaCl_2 indicates that the Ca^{2+} ions make the interaction between the MgO surface and the polymer stronger. This might sound a bit contradictory to the statement above that the PCP polymer is adsorbed more readily from a slurry made from water than from one made with “soup”. However, the strength of the interaction and the adsorption amount does not have to follow the same trend. We also have to remember that the AFM measurements are performed at pH 10 independent of the other ingredients of the electrolyte, whereas for the rheological measurements in this work the pH is different between the slurry made with water and the one made with soup. The AFM liquid cell can unfortunately not cope with a pH higher than 10, since it is made from glass.

4. SUMMARY

Preliminary results using an MgO powder as a model for cement have shown interesting results for both effects of polycarboxylate and lignosulfonate superplasticizers. The lignosulfonates are more robust and the make up of the surrounding electrolyte has little effect on MgO suspension rheology. The lignosulfonates induces a small negative potential on the powder surface and is an effective dispersant. The polycarboxylate is also an effective dispersant for the MgO model powder but is more sensitive to the electrolyte composition. The results suggest an interaction between Ca^{2+} ions and the polycarboxylate-MgO interface, which has an important influence on the polymer adsorption strength. Further work on the electroacoustics method and adsorption isotherms should help clarify the nature of this interaction. The next steps in the project are to extend the work to other polycarboxylate and lignosulfonate systems and then move toward a quantitative description of these systems

ACKNOWLEDGEMENTS

This work was funded by the 5th European Framework Programme (Contract G5RD-CT-2001-00435). It also received funding from Vinnova in Sweden and from the Swiss Federal Office for Education and Science (contract No 00.273-1).

ABSTRACT

In industrialised nations the technology of using lime binders was well established before the advent of cement, but has now been lost. However, much of the historic built environment predates modern cements and restoration and conservation projects on such buildings require binders which are compatible with the original limes. Contemporary industrial production of lime gives a product which is inappropriate in many ways and there is much interest in rediscovering the complexity of the original materials. In addition, lime is in many ways a more sustainable product than cement and offers advantages in situations where great strength or rapid hardening are not necessary.

An Experimental Lime Kiln (ELK) of 20 tonne capacity has been constructed and fully instrumented. It is a single shaft vertical kiln for use in a traditional batch process. Monitoring of the burning process includes recording of inlet air flow, temperature distribution and exit gas composition. It offers, for the first time, the integration of the properties of source limestone, fuel type and burning regime with the final properties and performance of traditionally produced lime based mortars and related materials. It will permit analogous studies of historic material and direct experimentation to unravel the complexity of historic production and working practices.

Details of the design and construction of the ELK are given and selected experimental results are presented to give insights into the relationship between raw material, product structure and properties and current research programmes outlined.

1. INTRODUCTION

The ELK is a facility for the production of fresh quicklime for the development of better building mortars, renders, grouts and plasters, primarily for use in the conservation of historic masonry structures, but also ultimately to produce better products for contemporary building works.

Awareness is increasing of the benefits of using appropriate, compatible materials, for the conservation and repair of historic masonry buildings. The use of inappropriate mortars, particularly those containing cementitious, hydraulic components where none were used originally has caused damage to historic fabric, including increased stone decay and the early loss and failure of the mortars, through spalling and leaching, for example.

In the study of the properties of historic mortars effort was initially directed toward the identification of composition, especially the ratio of binder to aggregate, and the hydraulic or non-hydraulic composition of the binder itself using wet chemical techniques [1, 2]. Increasingly,

however, more information is sought on the detailed composition and texture of historic binders. For example, the identification of hydraulic components in 19th century mortars by Callebaut et al [3] recently began a debate about the possibility of the presence of hydraulic components such as C_3S in early natural hydraulic mortars and cements, and the technology employed in their manufacture.

Work by Hughes and Cuthbert on the petrography of historic mortars has partially clarified their complex component assemblages. Features that relate to the raw materials, the burning process and the post production hydration and use in mortars are becoming clear [4]. Comparisons with current commercially available limes, even when aged for up to ten years as mortar, reveals a world of difference from their historic counterparts [5]. This has raised the question of whether our current limes and restoration mortars are compatible with the historic mortars they interface with and with stone and brick. The selective preservation potential of historic buildings means that the mortar materials examined today are likely to be the successful, compatible ones, the ones we need to emulate. However, it is clear that the materials we use to replace them with are not the same texturally, to a lesser extent compositionally and differ in their means of production.

To investigate the problem of producing compatible lime-based mortar materials for the conservation and restoration of historic masonry we must experiment directly on the methods of production to understand how to make quicklimes and mortars in the ways used historically to construct the buildings we are now trying to repair. Experimentation to reproduce historic burning methods will also allow us to investigate the links between the features observed in historic mortars and burning regime parameters. Experimentation in a small laboratory furnace, though useful for careful characterisation of material reactions, is ultimately inadequate as it does not replicate the complex set of conditions to be found within a real kiln, or the complexities of fuel-stone interaction which affect the physical and compositional properties of the resultant quicklime. Hence the need to burn lime on a sub-industrial scale, to allow us to test the parameters of traditional burning methods. This is the reasoning behind the inception of the ELK.

2. LOCATION

The ELK is located in Charlestown (Figure 1) a village on the north shore of the Firth of Forth, in east central Scotland. Charlestown is one of the most significant industrial archaeological sites in Scotland. From 1776, Charlestown was Scotland's largest limeworks, with 9 operational kilns at its harbour (that survive to this day), supplied by waggonways linking the limestone quarries to the north of the village directly to the kilns [6]. The hinterland of the village comprises large-scale near-surface outcrops of Carboniferous age limestone, which was easily extracted for lime production. The lime produced until the 1950s was used widely throughout Scotland for building and other industrial uses.

3. DESIGN AND CONSTRUCTION

The ELK is a batch mode, single shaft vertical kiln. It has a capacity of up to 24 tonnes of combined fuel and stone. Full, computerised instrumentation is incorporated into the ELK, allowing the continuous monitoring of temperature, inlet air velocity and exhaust gas CO_2 , CO and O_2 content. The ELK is a facility for fundamental, practical-based research into the

Figure 1. Location of the ELK at Charlestown, South East Fife. Map shows main outcrops of limestone in Scotland. From Robertson et al. (1949) [7].

production of lime-based masonry binders using traditionally based methods of production.

The ELK site is located at the south west edge of the steeply banked rubble fill of the mid quarry site in Charlestown, where limestone for the production of lime was extracted for many years. The infill forms a steep bank against which the ELK was constructed. A reinforced concrete foundation slab was poured for the ELK itself, and to provide the basis for storage bays for stone and fuel. The concrete slab foundation is a minimum of 300 mm thick with 16 mm reinforcing bars at 200 mm spacing top and bottom, and with 40 mm minimum concrete cover.

Figure 2 shows cross sections through the ELK. An ash pit was constructed across the width of the kiln shaft and beneath a draw arch cast from Tri-Mor Hicast Super refractory concrete.

Figure 2. Vertical and horizontal cross sections through the ELK.

Figure 3. General side view, showing; mechanical hoist for top loading ELK, sloping front façade and restraining bars and end points of thermocouples arranged vertically on side next to hoist.

The circular shaft base was constructed from Burnaxe SP fireclay refractory bricks and finished at the level of the planned grate with a ring beam of refractory concrete. The ring beam was constructed with sufficient width to accommodate the double thickness brick shaft and the surrounding double thickness layer of Molar Supra insulating bricks (Figure 5). The brick kiln shaft then continued upwards to its full five metre height, construction being guided by a circular wooden former (Figure 4). The brick shaft was laid with 2 mm thick joints in fireclay, bentonite mortar. The surrounding insulating bricks were laid with bentonite clay and restrained by plastic strapping on every course.

Once the kiln shaft was complete the square concrete block skin was built up in a conventional brick bond using a 1:2 St Astier NHL 5 and topped out at the same level as the brick kiln shaft. The space between the block outer skin and the kiln shaft was then filled with a low strength insulating concrete of 1:2 St Astier NHL 3.5 : vermiculite. However, before the insulating concrete was poured, ducts for the monitoring sensors were inserted through the kiln shaft and the exterior concrete block skin (Figure 6). The holes for the sensor conduits were cored horizontally from the inside face of the kiln lining. The brick kiln shaft was also lined with paper before the concrete insulation was poured, to accommodate thermal movements between the shaft and the insulation during operation. Once the insulating concrete was in place the structure was closed off at the top by the pouring of a final refractory concrete slab, that provides a walking area for maintenance of the chimney and the control of kiln loading. The front elevation of concrete block skin extends laterally wider than the rear structure of the kiln and is on a slight 2 to 3 degree slope backwards (Figure 3). Metal restraining bars joined with tightened threaded ends and bolts wrap the kiln to counteract the thermal expansion and contraction forces that the kiln encounters during operation.

A steel firegrate runs along the length of the ash pit, and completely to the outside at the rear of the kiln. A steel frame fire door is fitted in two sections connected to the cast concrete door frame. The door itself is filled with refractory concrete. An interchangeable lower section is louvered to allow the airflow into the kiln beneath the grate to be controlled. It is on the inside of this section that an air velocity transmitter is fixed to measure the airflow. The welded steel chimney has in its lowest metre a double thickness steel cavity filled by an insulating blanket to reduce heat loss. The chimney has a welded door cut into its side, hinged to allow the loading of the kiln from above.

Temperature distributions around the interior surface of the kiln are continuously recorded using nine stainless steel K-type thermocouples placed through austenitic stainless steel (304) conduits inserted through the body of the kiln. The thermocouples rest 20 mm retracted from the interior surface of the kiln shaft brick lining. Temperatures are recorded by an ABB Instrumentation PR100 recorder linked to an Commander MR250 Chart Recorder. A hand-held thermocouple mounted on a 2 metre lance can be inserted through a further five vacant, normal steel conduits on the front and side of the kiln. These conduits can also be inserted into the centre of the kiln fill during loading. This permits the measurement of temperatures within the stone fuel mix while burning and the temperature in the wall of the kiln. A thermocouple is also inserted in the upper portion of the chimney, to record kiln exhaust gas temperature.

Gas compositions are monitored in a semi continuous fashion. CO, CO₂ and O₂ are measured by a Siemens Ultramat 23 gas analyser. Gas is collected at the vertical portion of the chimney and transferred by pipe to the analyser, via a simple moisture trap. Unfortunately, due to technical difficulties it was not possible in the burns completed to date to record the gas composition, so no data are presented here. Air flow into the kiln is recorded in the lower front door section using a Dwyer 640 Air Velocity transmitter. All the recording equipment are mounted on the outside of the kiln, protected from the weather in a wooden cabinet. Data from the monitoring is transferred through a permanent cable from there to a PC in nearby office accommodation, where it saves the data and allows it to be presented and interpreted on site.

4. OPERATION OF THE ELK.

Before loading the kiln with stone and solid fuel, a layer of wood pieces, coke and anthracite is first placed across the base of the kiln shaft and over the grate to establish the fire after lighting. Loading of the ELK is performed by the use of a hoist equipped with a bucket which is filled manually at ground level and then raised to the hatch on the chimney where it tips over and empties into the kiln shaft (see Figure 3). The hoist can hold approximately 80kg and loading in this fashion can take up to 3 days. The limestone and fuel are mixed together and are not layered. However, the overall distribution of fuel can be altered in order to control the pattern of burning. The fuel used to date is a mixture by mass of 1 part high volatility Pet-coke and 1 part low volatility anthracite. This was mixed in the initial firings in a concentration of 1 part fuel to 9 parts stone, by mass, mixed in the kiln. The fuel types were chosen for a clean burn and low ash content.

To light the kiln, a zinc plasterer's bath is filled with wood and paper kindling and set alight. This is then inserted into the kiln underneath the grate which is covered with more fuel. Early on in the burning cycle if the kiln burns a little slowly or does not seem dynamic enough to reach the temperatures required for calcination the draught can be assisted using an electric fan that can be attached to the door of the kiln below the grate. During operation the temperature is monitored continuously and changes made to draught conditions as seen necessary.

Figure 7 schematically depicts the locations of the thermocouples within the kiln and Figure 8 shows the temperature evolution during an actual firing of the ELK [8]. The evolution of a burn is not even throughout the kiln.

Figure 7. Schematic diagram of ELK showing locations of thermocouples.

Figure 8. Temperature distributions during a firing of the ELK.
(See Figure 7 for locations of thermocouples.)

This is controlled by the origin of the draught, through the grate at the base of the shaft that runs in a rectangle form from front to back (Figure 2). This ensures that the temperature rises up the back and front initially. Differing calcination conditions occur in the kiln during operation. Also, the temperature of the exit gases during operation peak at just under 500°C. This is very hot, and represents one of the main thermal inefficiencies of the traditional method of lime production. Non continuous lime kilns will inevitably lose a considerable amount of energy through exhaust gasses which are not totally used to preheat stone above the burning front. Preheating of the stone higher up the kiln does take place, but the insulating layer of stone above the burning zone becomes thinner during burning. How to usefully recover this heat within a traditional process is a difficult question.

The full burning cycle takes approximately 36 hours and the kiln is cool enough to unload after approximately 72 hours. Unloading is done by hand, and takes up to three days to complete. The lime produced from the first burns was very reactive and had a degree of conversion of 75%. This figure is based on the loss of mass of similar volumes of quicklime and raw limestone, with knowledge of the LOI value for the limestone [9].

5. QUICKLIME CHARACTERISTICS.

In the initial firings of the kiln, high calcium, Carboniferous age Shap Limestone, from Cumbria, England, was used. This limestone is used for the large scale commercial production of lime, predominantly for the steel industry and other chemical uses, at a high temperature of 1200-1300°C, compared with temperatures encountered in the ELK of between 700-900°C. The limestone has a CaO content of 55.44% (from XRF analysis) and a Loss on Ignition value of 43.49%. Samples of the quicklime produced were subjected to a heat of hydration test based on EN 459-2 with samples prepared to ASTM C110. After crushing, ELK lump-lime was screened through a 3.35 mm aperture sieve. Figure 9 shows the result of this test for three sub-samples of the low-temperature quicklime produced in the second firing of the ELK, and compared with results from the commercially produced high-temperature quicklime. It clearly presents some considerable variation in character within the sampling from a single kiln firing with a time to 50°C of between 12 and 23 minutes, contrasting with the reactive commercial material which achieves 50°C in about 2.5 minutes.

Figure 9. Heat of hydration of 3 samples of ELK Burn No. 2 of high calcium Shap quicklime (blue) compared with high-temperature, commercially produced quicklime of same limestone (red).

A Hitachi S4100 Cold Field Emission Scanning Electron Microscope was used to qualitatively compare the microstructures of the commercially produced quicklime, with those of the quicklime produced in the ELK.

Figure 10. Commercially produced quicklime from Shap limestone, showing coalesced textures. Temperature approximately 1200-1300°C

Figure 11. Quicklime produced from Shap limestone in the ELK, showing dimensions of CaO crystallites and porosity. Temperature approximately 700-900°C.

Figures 10a and 10b show examples of coalesced structures in the commercially produced high-temperature material. Figures 11a and 11b show typical microstructures of the low-temperature quicklime from the ELK. The textures in the low-temperature quicklime are very varied, however, but no examples of microstructure comparable to that seen in the high-temperature material were discovered. The low-temperature quicklime exhibits larger apparent surface area whereas the high-temperature material has a lower apparent surface area, but a larger volume of apparent porosity. This may account for the increased hydration reactivity of the high-temperature quicklime, as suggested by Boynton [10]. The form and size of the crystallites of CaO in the respective quicklime samples are related to temperature of calcination and to residence time [11]. This is an established relationship, through which it may be possible to calibrate microstructure in quicklime produced from a particular limestone to conditions within the kiln. Work has begun looking at the quantification of the microstructure of quicklime and its relationship to temperature and residence time as a possible guide to conditions within a traditional lime kiln. There is a clearly evident difference between the microstructure of quicklime produced traditionally in the ELK and that produced in a modern high temperature industrial process. It would be surprising if such a difference were not reflected in their performance as lime binders for masonry and conservation.

6. CONCLUSIONS

A fully instrumented ELK has been constructed, following traditional principles. The initial part of the project has clarified the operating parameters of the ELK, and demonstrated some simple performance characteristics of the quicklime produced using a traditional method. The recording of temperature in the ELK demonstrates that temperature evolution within a traditional type kiln is not even, and relates strongly to draft. In addition, the heat of hydration behaviour of the traditionally produced low temperature quicklime contrasts strongly with that of higher temperature commercially produced quicklime. Contrasts in apparent microstructure between traditional and commercial materials furnish a possible explanation of heat of hydration behaviour.

P.F.G.Banfill

Phil Banfill studied chemistry at the University of Southampton and spent two years working in an industrial chemistry laboratory before returning to study for a PhD. He graduated in 1978 from the University of Liverpool with a thesis on waste materials in the construction industry, which initiated his interest in construction materials. He was lecturer and senior lecturer at the University of Liverpool from 1977 to 1994, before being appointed to the chair of construction materials at Heriot-Watt University, where he leads a research group with interests in rheology, chemistry, durability and conservation of cement, concrete and related materials. He has over 80 research publications, is a Fellow of the Royal Society of Chemistry and is active in education for professionals involved in conservation of historic buildings.

THE RHEOLOGY OF FRESH CEMENT AND CONCRETE – A REVIEW

P.F.G. Banfill

School of the Built Environment, Heriot-Watt University, Edinburgh, EH14 4AS, UK.

E-mail: P.F.G.Banfill@hw.ac.uk

ABSTRACT

The rheology of fresh cement, mortar and concrete is described and selected features of the behaviour of these materials are interpreted from a rheological perspective, making use of research results from the past 20 years.

1. INTRODUCTION

The hard, strong and durable cement-based product required by the user is only achieved following a period of plasticity but the attention paid to its fresh properties is small, despite the far-reaching effects of inadequate fresh performance. Pumping, spreading, moulding and compaction all depend on rheology and thanks to an increasingly scientific approach it is becoming possible to predict fresh properties, design and select materials and model processes to achieve the required performance. Rheology is now seriously considered by users, rather than being seen as an inconvenience and specialised branch of cement science.

This paper aims to review selected developments in our understanding of the rheology of cement-based materials since about 1980. During this period a comprehensive book [1], and proceedings of several conferences at which rheology of cement-based materials have played a major part [2,3,4,5] have appeared. In addition, papers on cement and concrete have been published in most of the rheology conferences -for example, the International Congress of Rheology and the conferences of the European Society of Rheology (both every 4 years)).

2. RHEOLOGY

Rheology is the science of the deformation and flow of matter, and the emphasis on flow means that it is concerned with the relationships between stress, strain, rate of strain, and time. Publication of accessible introductory texts [6,7] has helped to overcome perceptions of the difficulty of rheology with its often mathematically complex relationships. Flow is concerned with the relative movement of adjacent elements of liquid and in shear flows liquid elements flow over or past each other, while in extensional flow elements flow towards or away from each other. In a shear flow imaginary parallel layers of liquid move in response to a shear stress to produce a velocity gradient, which is referred to as the shear rate, equivalent to the rate of increase of shear strain. Elongational or stretching flows are rarely found in cement systems but there may be some elongation at the entry or exit of a pipe. They will not be considered further here. The rich variety of material behaviour can be characterised in various ways, of which the flow curve showing how shear stress and shear rate are related is very common, but equally data may be presented as the variation of viscosity (the ratio of shear stress to shear rate) with shear rate or time.

The Deborah number, defined as $De = t_r/t_0$, gives an indication of whether solid-like (elastic) or liquid-like (viscous) behaviour is likely for a particular material. When the relaxation time t_r is similar to a time characteristic of the experimental measurement t_0 the material exhibits both types of behaviour and the material is said to be viscoelastic. Such behaviour is shown by dispersions of solids in water, since the interparticle forces resulting from surface charges and the electrical double layer (see Appendix) cause t_r to be in the range 10^{-4} to 10^4 seconds which is comfortably within the range of most laboratory instruments. Obviously long time-scale measurements are irrelevant for cement systems because they set before the measurement can be completed. In the flow and remoulding of cement-based materials the liquid-like behaviour is likely to be more important and can be measured in a variety of viscometers, both rotating and tubular. Established formulae enable shear stress and shear rate to be calculated from the torque and speed of rotation respectively in a rotational viscometer, or from pressure drop and flow rate in a tube.

Clearly there are also many situations where solid-like behaviour is important. Cement-based materials are able to stand unsupported without flowing under their own gravity and during setting they develop strength and stiffness. The simplest analysis involving solid-like behaviour is that of the Bingham model

$$\tau = \tau_0 + \mu \dot{\gamma} \quad (1)$$

where the material is an elastic solid at shear stress $\tau < \tau_0$, the yield stress, but flows at higher stresses, (μ is the plastic viscosity, $\dot{\gamma}$ the shear rate). The yield stress is a consequence of the interparticle forces, but these links are often broken irreversibly by shear and the measured shear stress is found to depend on time and previous shear history as well as on shear rate. An indication of yield stress can be obtained from controlled stress rheometers [8] where the shear stress to initiate flow is measured; from penetrometers [9] in which the force needed to insert a needle into the material is measured; from vanes [10] where the shear stress to overcome the internal structure and set the material in motion is measured; and the pulse shearometer [11] where the shear modulus can be determined from the velocity of propagation of a shear wave. Finally, oscillatory rotational and translational shear, enabling the elastic and viscous components of the material's response to be separated, and stress relaxation methods have all been used to a limited extent [12,13,14]. These have given information on the structure in the cement-water system.

In concentrated dispersions of solid in liquid, like cement systems, the proximity of particles gives rise to strong interactions, the strength of which depend on the shape of the particles, their size distribution, their concentration, their surface properties and the composition of the liquid. Commonly there is a net attraction which causes flocculation - the consequence of randomly moving particles coming together and sticking (see Appendix). The size and architecture of the flocs play a major role in the rheology of the dispersion, with vigorous shearing reducing the flocs to the primary particles accompanied by a reduced resistance to flow, often followed by reflocculation and thickening when the dispersion comes to rest. These shear-induced changes in microstructure take time and, if fully reversible are called thixotropy, but in cement systems it is better to refer to the two processes as structural breakdown and build-up. Their existence means that the rheology of cement systems is best studied in experiments where the shear rate is held constant until equilibrium is reached, but it will be shown below that progress can nevertheless be made from other approaches. Despite considerable advances in computational modelling of liquid rheology resulting from increases in computer power, it is not yet possible to model from first principles the flow of suspensions as complex as cement systems [15] but success can be anticipated in the next decade.

3. CEMENT-BASED MATERIALS - TESTING METHODS

There are well-established rules for the sizes of apparatus and sample to ensure that rheological measurements are reliable, chiefly that any gap must be 10 times the size of the largest particles and that the ratio of outer cylinder radius to inner must be less than 1.2. For coarse granular materials like concrete this means that a coaxial cylinders viscometer is impracticably large, requiring a sample volume of 2.5m^3 [1], whereas a specially designed one for mortar is feasible [16,17] and cement pastes are well within the capability of any of the wide range of laboratory instruments available commercially. These principles are equally applicable to other geometries and mean, for example, that the cone and plate viscometer cannot be used for suspensions because the gap is zero under the apex of the cone. This led to the development of the truncated and annular plate and cone geometries [8].

3.1 Solutions for fresh concrete

Because of the impracticability of using a coaxial cylinders viscometer of anything like ideal dimensions for fresh concrete, Tattersall and co-workers developed a highly successful and practical apparatus in which an interrupted helical impeller rotates in a cylindrical bowl of fresh concrete and the behaviour is analysed using the theory of mixing [1]. This has been developed further by Domone and Banfill [18] and the current computer assisted model of the Two-point apparatus is available commercially [19]. Following calibration it can deliver the yield stress and plastic viscosity of fresh concrete in fundamental units.

Other, broadly equivalent, approaches to the measurement of fresh concrete rheology have produced the IBB rheometer [20], the BML rheometer [21] and the BTRHEOM [22]. These instruments were developed in different countries and the question naturally arose as to whether the results can be compared. The first attempt to answer this was a programme of comparisons achieved by bringing all four instruments together at a single location with a fifth, the Cemagref-IMG [23], a large (0.5m^3) coaxial cylinders instrument used as a standard, all under the sponsorship of the American Concrete Institute [24]. While each instrument characterised fresh concrete as a Bingham material and the yield stresses and plastic viscosities measured on the 12 concretes tested remained in the same rank order, the results fell into two groups. The Cemagref-IMG and BTRHEOM agreed well, and the Two-point and BML agreed well, with the second group giving a generally lower yield stress. Pairwise correlations were highly significant and enable the result of one test to be predicted from another. Since the BTRHEOM uses parallel plates, the Cemagref-IMG uses coaxial cylinders, the Two-point uses an interrupted helix rotating in a cylinder and the BML uses coaxial cylinders this agreement is encouraging.

3.2 Solutions for mortar

Mortar can be considered to be fresh concrete without the coarse aggregate and its testing has attractions for the study of the effects of ingredients at small scale. A coaxial cylinders viscometer, while feasible, proved to be inconvenient and Banfill described the use of the Viskomat as a small calibrated mixer for mortar testing [25]. More recently Jin [26] used a scaled down interrupted helix (like the Two-point impeller) in an extensive study of the mortar fraction for design of self compacting concrete and demonstrated that its rheology could be predicted with a high degree of certainty from tests on the rheology of the mortar.

3.3 Progress with cement paste

Experimental challenges for testing cement pastes and slurries are the risks of slippage at the walls of the viscometer, sedimentation of the particles and plug flow. Depletion of particles at the viscometer surface can result in a thin ($<1\mu\text{m}$) layer of water which facilitates bulk flow of the sample, superimposed upon the shearing flow within the rest of the material. The result is an

underestimate of the stiffness of the sample [27]. The slip can be avoided using a roughened surface and Mannheimer [28] showed convincingly that slippage reduced measured yield stress by 85%. This is supported by comparisons between smooth coaxial cylinders and a vane-in-cup apparatus: slippage in the former reduced the measured yield stress by 50% but oscillatory measurements at lower stresses were indistinguishable [29]. However, proof that slippage does not occur with roughened surfaces above the yield stress has been elusive. At the high water contents representative of concrete, the particles in cement pastes may separate gravitationally and centrifugally and this can cause errors. When measurement geometries include devices to keep the paste homogeneous the results are much more satisfactory. These include angled blades to lift the particles [30], recirculating pumps [31], blades with interlocking fingers [32] and more conventional mixers [33]. The problem of plug flow, when the shear stress does not exceed the yield stress everywhere in the sample and some part of the sample does not shear, was first raised by Tattersall and Dimond [34] but has never been satisfactorily resolved. They found that hitherto irreconcilable anomalies in breakdown measurements were explained when filming the flow in the gap of a coaxial cylinders viscometer revealed that a solid plug of paste formed and was either stationary (rough cylinders) or slid round slowly (smooth cylinders). No satisfactory explanation has ever been offered for this anomalous plug flow but its existence casts doubt on all experimental data where full shearing flow has not been confirmed visually.

4. CEMENT-BASED MATERIALS - RHEOLOGICAL RESULTS

It might be expected that the rheology of the more complex material, concrete, containing a wider range of particle sizes, would be more complicated than that of one of its constituent materials, cement paste, but in fact fresh concrete has proved to be simpler. Considerable practical progress has been made with it and, more recently, with mortars.

4.1 Concretes

Much work has been done on the effects on the rheology of concrete of mix constituents and their relative proportions, cement properties and admixtures and cement blending agents [1,17,20,21,35]. Concrete conforms to the Bingham model and does not show structural breakdown over the range of shear rates used in the test. Yield stress and plastic viscosity vary in a complex fashion with composition and this makes rheology measurement a versatile way of controlling the quality of fresh concrete production: tests carried out on the fresh concrete can show up changes in the mix composition which may have implications for the concrete's hardened properties and performance in use [35]. With the recent advent of self-compacting concrete, characterised by a very low yield stress, it has been found that the thickeners used to prevent segregation in use by raising the viscosity of the water also change the flow curve from the normal Bingham behaviour to Herschel-Bulkeley type behaviour (see below) [26].

4.2 Mortars

Mortars undergo structural breakdown and measured data are sensitive to the previous shear history of the sample, but the equilibrium flow curve conforms to the Bingham model [25]. The effects of composition are similar to those observed in fresh concrete, and mortar tests can be used as small scale predictors of concrete rheology [26, also Banfill, unpublished].

4.3 Cement pastes

There are qualitative and quantitative disagreements between the results for cement paste reported by different research workers. The flow curve has been reported to fit several different mathematical forms, all of which indicate the existence of a yield stress:

$$\text{Bingham [1]} \quad \tau = \tau_0 + \mu \dot{\gamma} \quad (1)$$

$$\text{Herschel-Bulkley [7]} \quad \tau = \tau_0 + A \dot{\gamma}^B \quad (2)$$

$$\text{Robertson-Stiff [6]} \quad \tau = A(\dot{\gamma} + B)^C \quad (3)$$

$$\text{Modified Bingham [36]} \quad \tau = \tau_0 + \mu \dot{\gamma} + B \dot{\gamma}^2 \quad (4)$$

$$\text{Casson [7]} \quad \sqrt{\tau} = \sqrt{\tau_0} + \sqrt{(\mu \dot{\gamma})} \quad (5)$$

$$\text{De Kee [36]} \quad \tau = \tau_0 + \mu \dot{\gamma} e^{-A \dot{\gamma}} \quad (6)$$

$$\text{Yahia and Khayat [36]} \quad \tau = \tau_0 + 2\sqrt{(\tau_0 \mu \dot{\gamma} e^{-A \dot{\gamma}})} \quad (7)$$

where A, B and C are constants.

Additionally the numerical values reported for the rheological parameters cover a very wide range, which cannot be wholly explained by variations in the materials used. It can only be accounted for by accepting that differences in experimental technique and apparatus of different workers have a much greater effect than has been generally realised. Differences in the shear history at the time of test, undetected plug flow and slippage at the smooth surfaces of a viscometer could all combine to give experimental variations as large as those reported. However, there is general agreement on two fundamental qualitative aspects of the behaviour of cement pastes.

First, the material breaks down during the test and hysteresis loops with the downcurve falling to lower stresses than the upcurve are obtained when the flow curve is determined over a short cycle time. The shape changes systematically with increasing cycle time through loops with a crossover point to loops showing structural build up [37], attributable to chemical reaction during the course of the test, but Hattori and Izumi [38] explained the effect in terms of the competition between coagulation and deflocculation processes. The apparent need to fit the range of models in equations 1-7 may be the result of not allowing for the possibility of structural breakdown during the test.

Second, the material has a yield stress which decreases, in line with reductions in the apparent viscosity indicated by the rest of the curve, as the total amount of shearing energy experienced by the paste increases. Thus, successive hysteresis loops fall to progressively lower values of torque in a coaxial cylinders viscometer [39], yield stress and plastic viscosity fall to an equilibrium value as the time of mechanical mixing is increased [40]. The effect can be quantified in terms of the total shear energy received by the sample prior to the test [41,42]. This structural breakdown has been amply confirmed by experiments carried out under both continuous steady shear rate and continuous steady stress. In the former the relationship between shear stress and time is affected by the shear rate in the experiment and was explained theoretically by Tattersall [39] using a linkage theory, in which the links between particles are broken by the work done in shearing the paste.

Space precludes description of the large amount of work carried out on the effect of experimental variables on the rheological parameters of cement pastes. It is sufficient to note that investigations have included paste concentration (water/cement ratio or % solids) cement composition (portland cements) and fineness, aluminous cement, oilwell cement, non-shrinking cement, flyash, silica fume, slags, chemical admixtures, polymer latexes, and effects of age and temperature [1,43].

4.4 Comparison of cement pastes, mortar and concrete

Table 1 shows that there is a trend in the rheological properties of cement-based materials, as quoted in the literature, which can be explained semiquantitatively by the presence of aggregate in the coarser grained materials. The flow properties of suspensions are governed by the interfaces

between solid and water and, in terms of the surface area of contact, the dominant contribution is due to the cement-water interface. This is progressively diluted by the presence of aggregate. Thus, for example in one comparison, two cements which gave pastes whose rheological parameters differed by a factor of two produced concretes of indistinguishable flow behaviour [1].

The yield stress and plastic viscosity increase as the maximum particle size increases. This is because in a typical concrete at least 50% by volume is in the form of aggregate which is capable of withstanding the applied stresses without deformation: consequently the yield stress is higher, a point confirmed by the increase with increasing aggregate content in concrete [1]. The increased plastic viscosity is partly due to the increased interparticle contact and surface interlocking, as demonstrated by the fact that for two concretes with the same yield stress containing rounded and angular coarse aggregates, the plastic viscosity of the latter is higher. It is also partly due to the inability of the aggregate to be sheared: when an overall shear rate $\dot{\gamma}$ is applied to an imaginary concrete consisting of aggregate and paste 50:50 per cent by volume, the shear rate within the solid aggregate particles is zero and that in the paste is $5\dot{\gamma}$. This higher shear rate results in a higher stress and resistance to flow in the paste which in turn accounts for the increase in measured plastic viscosity of the bulk material.

Table 1. Rheology of cement paste, mortar and concrete

Material	Cement paste, grout	Mortar	Flowing concrete	Self-compacting concrete	Concrete
Yield stress N/m ²	10-100	80-400	400	50-200	500-2000
Plastic viscosity Ns/m ²	0.01-1	1-3	20	20-100	50-100
Structural breakdown	Significant	Slight	None	None	None

In contrast, the yield stress and plastic viscosity of cement paste increase as the cement gets finer [44], which reflects the dominance of the water-cement interface in this system. Evidently the influence of particle size is a surface area effect in fine grained pastes and a simple volume effect in the coarser grained concretes. Perhaps further work on particles suspended in dispersions will suggest the particle size range where the change from one influence to the other occurs.[45]

The trend in structural breakdown behaviour may be explained qualitatively in a similar way. The work of shearing done on a material in unit time is proportional to the square of the shear rate. Structural breakdown experiments on cement paste show that the breakdown resulting from this work is rapid at first and complete in a few minutes and also that the rate of decay is proportional to the square of the shear rate. Thus, in the 50:50 concrete mentioned above the total shear work done on the paste by the end of a three minute mixing period at a mean shear rate of 10 sec^{-1} is equivalent to that done in a viscometer in 45 seconds at 100 sec^{-1} or 12 seconds at 200 sec^{-1} . This is enough to give almost complete breakdown and explains the absence of structural breakdown when concrete is tested: all the breakable structure has been broken down before the material leaves the mixer. Furthermore, the higher the aggregate content, the higher the shear rate in the paste and the more complete the breakdown at the end of mixing.

5. A STRUCTURAL MODEL

Any proposed structural model must be able to explain the irreversible breakdown which occurs on shearing cement-based systems, and which is different from thixotropic behaviour. Such a model is shown in Figure 1 [1,46], in which the yield stress can be accounted for by the usual Van der Waals

attraction (see Appendix) and electrical double layer repulsion effects. These result in links between particles reforming reversibly when the particles come to rest, but the irreversibly destroyed structure is much stronger than this. When dry cement powder first comes into contact with water the hydrated skin or membrane may form around pairs or groups of particles. When the skin is broken by the action of shear and the particles separate, that region of one particle that was in contact with other particles is exposed and hydrates to heal the broken skin. Because of this healing these links cannot then reform in the same way when the structure comes to rest, i.e. the breakdown of skin linkage is irreversible. This model is consistent with both the instantaneous formation of a protective layer on cement [47], and the notion of links between particles first proposed by Tattersall [39].

Figure 1. A structural model for the shear induced breakdown in cement systems.

6. MODELS FOR PARTICULAR SITUATIONS

6.1 Pumping

Transport of fresh concrete by pumping through pipes to the point of placement has been used since the 1930s, and is an obvious candidate for rheological study to help select pumping equipment and conditions. Pipe flow of a Bingham material is well characterised and the variation of shear stress from a maximum value at the wall of the pipe to zero at the centre line means that a plug of solid unsheared material moves surrounded by a zone of shearing flow from which pressure-flow rate equations have been derived [1,7]. However, this assumes that the material is homogeneous, whereas pumped concrete actually forms a layer of paste that lubricates the wall and facilitates flow. Therefore, the pumpability of a concrete is mainly governed by its ability to form and maintain this layer under the pumping conditions and an acceptance test has been developed [48]. In

fact, practical problems with blockage of pipework have meant that most pumping trials have had to be done at full scale, which is both costly and inconvenient.

Kaplan found that the pressure loss-flow rate relationship is independent of pressure for saturated concretes and formulated the wall lubrication law as follows [49]

$$\tau_i = \tau_{oi} + \eta V \quad (8)$$

where τ_i is the shear stress at the interface, τ_{oi} the interfacial yield stress, η the interfacial viscosity and V is the speed of the boundary layer. The full pressure loss-flow rate relationship with its zones of shearing and lubricated flow depends on these parameters and on the rheological constants for the material, which he measured by the BTRHEOM apparatus [22]. He determined the interfacial parameters in a modified version of the apparatus, using smooth cylinders to promote slippage (a so-called tribometer), and performed 36 full scale pumping tests in an experimental loop 150m long with pipe of 125mm diameter using a range of concretes (ordinary, high performance, self compacting and air-entrained). This innovative use of slippage measurements produced a model which was able to predict the pressure-flow relationship with a high degree of accuracy and therefore can be used for pumping system design.

A point of obvious interest is whether there is any relationship between the interfacial parameters and the bulk values: clearly there is no reason to expect one since the interfacial parameters depend on the ability of the concrete to establish and maintain a lubricating layer. In fact, Kaplan obtained excellent numerical agreement between the interfacial values from the tribometer and from the pumping tests, with τ_{oi} in the range 0-150 Pa and η 300-1200 Pa.s/m, the former being considerably lower than the corresponding bulk yield stresses of 300-2000 Pa. There was a broad positive correlation between τ_{oi} and τ_o for about half of the tested concretes but there were some extreme outliers in both directions, especially for some high yield stress concretes which had zero interfacial yield stress. There was no correlation between interfacial viscosity and the plastic viscosity of the concrete. These results confirm that while bulk rheology has a part to play in the flow of concrete in pumping the dominant lubricating effect is influenced by other properties of the concrete

6.2 Interactions at the surface of formwork

A related problem requiring a knowledge of friction at a concrete-wall interface is the pressure on formwork, which is lower than the equivalent hydrostatic pressure because of the yield stress within the material and the friction at the wall [50], but empirical predictions underestimate the actual pressures measured for modern highly fluid concretes. Friction between steel and fresh concrete was measured in a tribometer based upon moving a steel plate between opposed pressurised cylinders filled with concrete which exert a known stress normal to the surface [51,52,53]. Applying the coefficient of friction between steel and concrete determined in this apparatus enabled preliminary estimates of the formwork pressures exerted by fluid and self compacting concrete to be compared with those measured in full size formwork up to 12 metres high. This confirmed the complexity of the factors affecting formwork pressure and showed that it is about 25% less than hydrostatic for a self-compacting concrete, but the contribution of friction depends on surface roughness, concrete rheology and particle size distribution. Unfortunately, information on the rheology of the concrete used is not available (only slump and slump flow were measured) but Vanhove found that the friction stress (equivalent to τ_i in equation 8) is independent of velocity and roughly proportional to the normal stress, from which the coefficient of friction can be determined for use in pressure calculations. Vanhove's friction stress and Kaplan's τ_i can be compared only if Vanhove's data is extrapolated a long way to zero normal stress, an unreliable process. However, there is no doubt that this fundamental work on friction has the potential to contribute to the understanding of this important practical area.

6.3 Vibrational compaction

Vibration is the most popular means of compacting fresh concrete into formwork and around reinforcement and there is an extensive literature on the effects of such features as frequency, amplitude and acceleration, but several recent papers have significantly advanced understanding. Practically vibration removes the yield stress of fresh concrete which then flows under its own weight [54,55] and the important characteristic of the vibration is the peak velocity. The fluidity of vibrated concrete, defined as the reciprocal of its low shear rate viscosity, is proportional to peak vibrational velocity up to a critical value, above which it is constant, and the viscosity of the vibrated concrete is proportional to the plastic viscosity of the unvibrated concrete [56]. This work enabled the effect of vibration to be defined phenomenologically but a more rigorous investigation was recently completed by Teixeira et al [57].

They studied the propagation of vibration through analysing the effects of shear and compressive waveforms on the oscillatory flow of fresh concrete, and concluded that there is a liquid region near the vibrator where the flow is controlled by the shear waveform and in which hydrodynamic theory may be used in the calculations. Beyond this, there is a solid region where the motion is controlled by compressive waveforms and structural vibration theory is used in the predictions. The interface between the liquid and solid regions corresponds in practical terms to the radius of action of the vibrator. This wave propagation analysis was validated experimentally and was able to predict correctly the rapid decay of vibration near the source, a phenomenon that has previously been attributed to cavitation [58]. A software solution enabled the radius of action to be predicted from yield stress, plastic viscosity, density and the vibrational parameters and while experimental work on a range of concretes confirmed that the radius of action decreases linearly as yield stress increases, the measured and calculated values differ significantly for stiff concretes. These findings are encouraging and suggest that solution of the fresh concrete vibration problem may be near.

6.4 The action of superplasticisers

It has long been established that superplasticisers can have spectacular but sometimes unpredictable effects on the rheology of cement systems. The yield stress of cement and concrete are reduced to very low values by the dispersion of flocculated cement particles [1]. However, the progress of the hydration reaction causes stiffening (slump loss) and this can be a serious practical problem. Based on an extensive review of experimental data, Flatt and Houst proposed that there are three components of the behaviour of the superplasticiser added to the system [59].

The first part is consumed by intercalation, coprecipitation or micellization (see Appendix) within the hydrating cement minerals, forming an organo-mineral phase. These chemical reactions during the formation of Aft and C-S-H, mean the admixture is no longer available for dispersing flocs and are most important in the first minutes after addition, when the precipitation rate of Aft is highest, governed by the availability of sulphate. As a consequence, at the same addition level, a cement with a high degree of consumption will have less favourable rheology than an otherwise identical cement but with a low degree of consumption. Delayed addition can reduce this consumption, especially for long chain polyelectrolyte polymers, which are trapped in the organo-mineral phase, but has less effect on polymers with side chains extending through the surface hydration layers into the solution.

The second part is available for adsorption at the surface of cement particles and is effective in dispersing the flocs, but the adsorbed amount is not easily measured since current analytical methods are based on the amount removed from the solution and this cannot distinguish between admixture consumed in the first part (above) and adsorbed on surfaces. Consequently the dispersive power of superplasticisers and their effect on rheology can only be evaluated using model powders which do not react or under conditions of full surface coverage in cements.

The third part consists of the superplasticiser that remains dissolved in the aqueous phase and may play a part in dispersing cement particles [60], but has otherwise been ignored in experimental studies. They point out that too little attention has been paid to differentiating adsorption from consumption in the interpretation of data. Work on tailoring improved superplasticisers, based on these considerations, is currently in progress [61].

7. CONCLUSIONS AND FUTURE POSSIBILITIES

Rheology is important because of the scope it offers for characterising fresh cement paste, grout, mortar and concrete, and for understanding how they perform in practical applications. Without satisfactory fresh properties it is unlikely that the desirable properties of the hardened materials can be achieved. Their rheology is dominated by the structure that exists in the cement paste, but in mortar and concrete the structure has been partially or fully broken down during mixing. As a result they conform closely to the Bingham model and their behaviour during pumping, vibration and in formwork can be explained by reference to that model.

Reliable instruments for testing the coarser grained materials are available and experience in comparing the data is growing. In contrast there remain apparently conflicting results for cement pastes, which are probably due to the different experimental techniques used by different workers. The important effects of shear history, mixing energy and wall slippage on the results obtained in viscometers are only now being generally understood.

Building upon our current understanding of the rheology of fresh cement and concrete the future developments are likely to be incremental in the following areas:

- Steady increases in computing power and better algorithms will improve the modelling of more complex systems. A numerical model for the rheology of cement paste can be anticipated soon.
- The rheological modelling of practical situations will enable better tailoring of solutions in fields such as pumping, vibration, self-compacting flow, efficient grouting of voids and estimation of formwork pressures.
- There will always be a need for production quality control testing of rheology and inter-comparisons between the different instruments can be expected to enable a common basis of agreement to be established.
- Rheology will continue to be a product development tool as new materials become available and require objective and discriminating evaluation

APPENDIX: GLOSSARY OF TERMS

Co-precipitation: The precipitation of one substance from solution, encouraged by the tiny solid nuclei which form during precipitation of another. Both substances precipitate together.

Electrical double layer: A model for the situation at a charged solid surface in solution where ions of opposite charge are attracted to the surface, but try to diffuse away to remain uniformly distributed in the solution, resulting in two plates of an electric condenser – the charged surface and a balancing charge in solution spread over a short distance from the surface.

Flocculation: The process by which particles in a suspension are mutually attracted by a combination of van der Waals and electrostatic forces, stick together to form agglomerates and either settle out of the suspension as flocs or form a three-dimensional network throughout the suspension.

Intercalation: The incorporation of molecules of one substance into the crystal lattice of a solid as it precipitates from solution.

Micellization: A process where polymer molecules with both hydrophobic and hydrophilic parts (such as detergents) group together in aqueous solution such that the hydrophobic parts associate to form regions from which water is excluded. The hydrophilic parts remain on the outer surface to maximise their interaction with the water. There is a critical concentration above which the dissolved polymer mostly exists as micelles and is therefore unavailable for active dispersion of the solid.

Van der Waals attraction: Weak forces of attraction between any pair of molecules due to oscillations in the charge distribution inside the individual atoms which produce electrostatic forces. When two solid surfaces are brought close together, all the atoms in the surface zones contribute to the forces of attraction, which are then large enough to be measurable.

THE RHEOLOGY OF FRESH CEMENT AND CONCRETE – A REVIEW

P F G Banfill

Phil Banfill studied chemistry at the University of Southampton and spent two years working in an industrial chemistry laboratory before returning to study for a PhD. He graduated in 1978 from the University of Liverpool with a thesis on waste materials in the construction industry, which initiated his interest in rheology and concrete. He was lecturer and senior lecturer at the University of Liverpool from 1977 to 1994, before being appointed to the chair of construction materials at Heriot-Watt University, where he leads a research group with interests in rheology, chemistry, durability and conservation of cement, concrete and related materials. He has over 80 publications from his research on rheology and cement-based materials and is Honorary Secretary of the British Society of Rheology, as well as a Fellow of the Royal Society of Chemistry.

COMPARATIVE STUDY TO EVALUATE THE REACTIVITY OF AGGREGATES

Ali Akbar Ramezaniapour

Civil Engineering Faculty, Amirkabir University of Technology, Tehran, Iran.

E-mail: aaramce@cic.aku.ac.ir

ABSTRACT

Alkali-aggregate reactivity in concrete is an undesirable chemical reaction that may occur between soluble alkalis in the pore fluid and certain types of aggregates. Alkali-aggregate reaction often develops as a slow progressively deteriorating process, with the first visible signs taking anywhere from a few months to many years to develop. AAR produces concrete expansion and can generally lead to a loss of strength, stiffness (cracking), and generates undesirable deformations and disturbances in the equilibrium of internal forces.

It is essential that the potential alkali-reactivity of aggregates be assessed prior to their utilization in concrete. This is usually carried out by a number of accelerated and long-term standard and proposed laboratory test methods. They have given satisfactory results for some aggregates, while in a number of cases and for aggregates in different parts of the world test results were unreliable. These contradictory results were observed in some of siliceous and carbonate aggregates, which were examined.

In this research program a comparative study of test results using three different methods is presented. The test methods are rock cylinder, accelerated mortar bar (NBRI-like test), and an accelerated concrete prism test. Aggregates obtained from various sources which were used or will be used in concrete mixtures of a number of dams. In order to control the alkali aggregate reaction of reactive aggregates several mixes containing silica fume were tested. The main test methods used to determine the reactivity level of the aggregates include the chemical method, accelerated mortar bar and concrete prism methods.

Results of the rock cylinder test show that almost all the aggregates investigated were non-reactive while in the accelerated concrete prism test some of the aggregates were found to be potentially reactive. Test results indicate that silica fume is highly effective in reducing expansion due to alkali silica reactions of some aggregates. The expansion reduction rate is related to the amount of silica fume used in the concrete mixtures.

Keywords: Alkali aggregate-reaction, carbonate rocks, accelerated tests, rock cylinder, mortar bar, concrete prism, silica fume, expansion

1. INTRODUCTION

Alkali aggregate reactions (AAR) are chemical reactions in concrete that can induce the premature distress and loss in serviceability of the concrete structures affected. The AAR related problems were first identified in California. Since then, AAR has been recognized in many countries around

the world. It is likely that the problems associated with AAR exist in almost all countries in the world but the severities are different.

Many test methods and guidelines for the prevention of alkali aggregate reaction in new concrete structures have been adopted by various national and international organizations around the world [1]. Most of these standards and guidelines are dealing with alkali-silica reaction and those related to carbonate rocks are really rare [2]. The tests are usually carried out by a number of accelerated and long term laboratory methods [3]. Prior to mortar bar and concrete prism tests, petrographic examination, chemical tests and rock cylinder tests are carried out. They have given satisfactory results for some aggregates, while in a number of cases and for aggregates in different parts of the world test results were not reliable [4]. The contradictory results were observed in most of the carbonate rocks which were assessed.

A few concrete dams and other concrete structures in Iran are suffering from deterioration induced by alkali-aggregate reaction that impairs the durability, serviceability, and also endangers the safety of the structures in future. Most of the aggregates used for the construction of these structures and those for dams to be constructed in the future are carbonate rocks [5].

The aim of this investigation is to study the reactivity of some carbonate aggregates from different sources which have been considered as concrete aggregates to be used for construction of dams. For comparison purposes and for evaluation of the validity of test methods, the rock cylinder test (ASTM C586-92)[6], the accelerated mortar bar test (NBRI-like test)[7], and an accelerated concrete prism test proposed for carbonate rocks were used throughout this investigation.

2. TEST PROGRAM

2.1 Materials

Portland cement - The physical properties and the chemical composition of the cement used is given in Table 1.

Aggregates - In this study four types of aggregate from four dam sites namely Rajai (R1), Maroon (M1), Karkheh (K1), and Ahar (A1) were selected for testing. The petrography and physical properties of the aggregates are given in Table 2. The grading of aggregates in the different test methods were selected in accordance with the specified grading curves in the different standards (Reference grading curves for fine aggregates in mortar bar tests and grading curves for coarse aggregates in concrete prism tests)[6,7].

2.1 Test methods

In this investigation three test methods were used. In the first test method (rock cylinder test), standard rock cylinders (9 mm diameter and 35 mm length) were immersed in a solution of sodium hydroxide at room temperature and the length changes were measured up to 8 weeks. Expansions in excess of 0.1 percent at 28 days are an indication of chemical reaction and additional tests are required. In the second test method (NBRI-like test) and similar to CAN/CSA A23.2-25A (Canadian Standard 1994), mortar bars (2.5 by 2.5 by 28.5 cm) were immersed in a 1 N sodium hydroxide at 80 C for 14 days and expansions were recorded. For some specimens measurement continued up to 56 days. In this test method expansions in excess of 0.1 percent for limestone aggregates are indicative of highly reactive aggregates. In the third test method i.e. concrete prism test [8], concrete prisms were prepared according to the proposed test method except that instead of using 310 Kg cement and addition of alkalis to 1.25 percent, 334 Kg cement with no addition of alkalis was used in all concrete mixes. This is believed to eliminate the increase of sulfate in the solution by the addition of sodium hydroxide [9]. The length changes of specimens are measured up to 180 days.

Table 1. Chemical and Physical Characteristics of the Cement

<u>Chemical properties</u>		<u>Physical properties</u>
<u>Chemical oxides</u>	<u>Percent</u>	
SiO ₂	20.65	Fineness : 2960 cm ² /gr

Table 2. Petrography and Physical Properties of Aggregates

Aggregate	R1	M1	K1	A1
Type	Quarried carbonate Rock	Gravel glacial deposit	Carbonate rock	Carbonate rock
Rock Type	Limestone(more Calcite and less Dolomite)	Limestone(calcite dolomite quartz)	Siliceous limestone Quartz and feldspar calcite)	Siliceous limestone (calcite,quartz, feldspar)

3. TEST RESULTS AND DISCUSSIONS

The results of the rock cylinder tests (ASTM C586) for all aggregate types are shown in Table 3. For each aggregate three specimens were prepared and the length changes were measured. The average length changes presented as the expansion of rock cylinders for R1, A1, M1, and K1 aggregates are 0.031%, 0.022%, 0.038%, 0.043% respectively. It is clearly seen that the expansion of all specimens is well below 0.1 percent which is the expansion limit criterion in this method. Results show that these carbonate aggregates can be assessed as non-reactive.

Results of the expansion of mortar bar specimens containing various aggregates are illustrated in Figure 1 to Figure 4. The length changes of at least two specimens for each aggregate are shown in these figures. It can be seen that the expansion of mortar bars containing R1, M1 and K1 aggregates have exceeded 0.1 percent after 14 days while the expansion of specimens containing R1 aggregate is less than 0.1 percent. Thus, from the results of the mortar bar accelerated test, three aggregates were classified as highly reactive.

Table 3. Results of Expansion of Rock Cylinders

R1 Aggregate				A1 Aggregate			
Specimen No.	R1-1	R1-2	R1-3	Specimen No.	A1-1	A1-2	A1-3
Expansion (%)	0.029	0.040	0.026	Expansion (%)	0.024	0.018	0.024
Average (%)	0.031			Average (%)	0.022		
M1 Aggregate				K1 Aggregate			
Specimen No.	M1-1	M1-2	M1-3	Specimen No.	K1-1	K1-2	K1-3
Expansion (%)	0.036	0.041	0.038	Expansion (%)	0.044	0.055	0.030
Average (%)	0.038			Average (%)	0.043		

Figure 1. Expansion of mortar bars containing R1 aggregate

Figure 2. Expansion of mortar bars containing A1 aggregate

Figure 3. Expansion of mortar bars containing M1 aggregate

Figure 4. Expansion of mortar bars containing K1 aggregate

Results of expansion of concrete prisms incorporating aggregates from four different sources at various ages up to 180 days are depicted in Figure 5 to Figure 8. In these figures specimens containing R1, M1 and K1 aggregates have shown greater expansion when compared with the expansion of specimens containing A1 aggregate. These three aggregates can be evaluated as moderately reactive aggregates.

Figure 5. Expansion of concrete prisms containing R1 aggregate

Figure 6. Expansion of concrete prisms containing A1 aggregate

Figure 7. Expansion of concrete prisms containing M1 aggregate

Figure 8. Expansion of concrete prisms containing K1 aggregate

Comparison of the results obtained from the three different test methods reveals that results of the mortar bar method coincide with the results of the concrete prism test. However, the reactive aggregates in these two test methods were evaluated as non-reactive aggregates by the rock cylinder test method (see Table 3). It seems that fine reactive particles will react with sodium hydroxide in the solution and create expansion of specimens in both mortar bar and concrete prism tests. This is not the case when rock cylinders are tested. It is seen that aggregates with different reactivities cannot be detected within 28 days by the rock cylinder test method. Comparison of results obtained with the rock cylinder test and mortar bar test shows that the mortar bar method can be a severe test for carbonate aggregates and aggregates rejected in this test should be checked using the other methods. Contradictory results of three different tests in this investigation support the fact that further alkali-carbonate reaction test methods applicable for particular areas are required.

4. CONCLUSIONS

From the test results obtained in this investigation, the following conclusion can be drawn:

- Contradictory results were obtained in evaluation of reactivity of various sources of carbonate rocks when tested by rock cylinder, accelerated mortar bar and concrete prism methods.
- Results obtained by the rock cylinder test method, show that aggregates with different reactivities can not be detected by this method. Further methods such as accelerated mortar bar and concrete prism tests are necessary for the final assessment of acceptance or rejection of carbonate aggregates.
- The concrete prism test method seems to be an appropriate test for evaluating the reactivity of carbonate aggregates.

5. RECOMMENDATIONS

Laboratory test methods for alkali-carbonate reactivity evaluation need further improvement in order to assess aggregates from various sources.

ABSTRACT

Lignosulphonates are an important group of plasticising additives for concrete. Different lignosulphonates have different effects on slump, slump loss and setting time. Lignosulphonates have a broad molecular weight distribution, and contain a number of different functional groups. We have investigated how the different functional groups influence the setting time by investigating the interactions between 18 different model compounds and both cement and a model system for cement. The functional groups include, carboxylic acids, sulphonic acids, phenols, catechols, metoxyls, guajacyls, esters, aldehydes and acetals.

We have also looked at the interactions between these model compounds and the cations commonly found in the pore water.

1. BACKGROUND

Lignosulphonates are an important group of plasticising additives for concrete. Different lignosulphonates have different effects on slump, slump loss and setting time. Lignosulphonates have a broad molecular weight distribution, and contain a number of different functional groups. The functional groups include, carboxylic acids, sulphonic acids, phenols, catechols, metoxyls, guajacyls, esters, aldehydes and acetals. There have been some attempts to correlate some of these structures with specific performance in concrete or mortar [1-4].

The model compounds in this study span all the most important functional groups in lignosulphonates and Kraft lignins, and also several combinations of these functional groups.

Usually, the effect of lignosulphonates on the properties of concrete has been discussed based on the adsorption of lignosulphonates to the surface of the cement particles. Cement is a reactive system. To avoid this complication we used magnesium oxide particles as a model for the cement minerals [5,6]. An additional benefit that became apparent during this investigation was that we also avoided colour changes due to the interactions between some of our model compounds and iron(III) ions.

2. EXPERIMENTAL

2.1. Model compounds used

The model compounds were either commercially available (Nos 4, 5, 6, 7, 8, 9, 11, 15, 16, and 18) or synthesised in our laboratory, using simple, standard organic chemistry procedures (Nos 1, 2, 3, 10, 12, 13, 14, and 17).

The structures of the compounds are shown in Figure 1.

Figure 1. The compounds used in this study.

2.2. Isotherms

The model compound was dissolved in a solution adjusted to pH 12.8 with NaOH and saturated with CaCl_2 . This is to approximate the pH and ionic strength of the water in cement pastes. Approximately 1% (10,000 ppm) solutions were made for most compounds. Some were only sparingly soluble and weaker stock solutions were made. The solution was further diluted with the solvent to the required strength.

1.0 gram of magnesium oxide was placed in a test tube. 10 ml of the solution with the model compound was added. The test tube was shaken vigorously to disperse the MgO and further shaken for 30 minutes on a Rock'n'Roller from Labinco. The MgO was removed by filtration through a 0.22 micron Millipore filter. The resulting solution was diluted with NaOH solution before UV measurement. The appropriate dilution was found for each compound. The adsorbance was measured for the longest wavelength peak in all cases, except vanillin where the peak at 248 nm was used. The amount of substance left was found from calibration curves. The difference between the amount left and the amount added was regarded as the amount adsorbed. The adsorbed amount was calculated as $\mu\text{mol/g}$ substrate in all cases. As usual for adsorption isotherms the amount

adsorbed was plotted as a function of the equilibrium concentration in the solution. No tests were performed to check that the value after 30 minutes actually is an equilibrium concentration. 30 minutes were used to conform with the isotherms for cement and cement minerals.

Some of these model compounds, particularly the dihydroxy compounds, are unstable under the conditions used. The UV adsorbance would change over time. Fresh solutions were always used for the adsorption studies. It was also in all cases attempted as far as possible to use the same waiting times between dilutions and measurements. For catechol and dihydroxybenzoic acid methyl ester, the best isotherms were obtained by waiting for approximately 24 hours between the dilution of the samples and the UV measurements. During this time the dilute samples were fully oxidised and the UV spectra of the *ortho*-quinones were obtained instead.

Some of these compounds also change colour dramatically in the presence of ferric ions. All chemicals were of technical grade or purer to avoid contamination.

2.3 Setting times

The samples were dissolved in the mixing water for the cement paste at 0.20% sbwc dosage. The paste consisted of ordinary Portland cement at w/c-ratio of 0.30. The hydration was measured with a Vicat apparatus which automatically drops a needle into a sample of cement paste. In this way initial and final setting time is determined.

3. RESULTS

Table 1 shows a summary of all the results. A comparison between Table 1 and Figure 1 immediately shows the importance of the catechol group. All compounds with a catechol group and no sulphonic acid groups are strongly accelerating.

Table 1. Setting times for 0.20% addition of selected organics.

Sample	Initial setting/ min	Final setting/ min	Initial slope/ ml/g
1	171	220	0
2	~20	<30	167
3	167	212	0
4	~20	<30	50
5	158	221	0
6	~20	<30	118
7	166	240	0
8	182	244	4.2
9	190	223	0
10	208	276	4.2
11	153	221	0
12	207	272	8.0
13	173	219	5.7
14	137	191	0
15	251	320	1.8
16	~5	9	134
17	202	258	21
18	161	183	0
blank	137	205	n.a.

It was also noticed that several of the compounds tested gave strongly coloured cement paste samples. As phenols are known to give colour reactions with ferric ions we checked this further.

Table 2 shows the results. We see clearly that the accelerating compounds also give strong colour reactions with ferric ions. Several of the model compounds are sparingly soluble, and KOH was added to obtain solutions. In most cases this resulted in a white precipitate with Ca^{2+} , and often a reddish brown precipitate with Fe^{3+} .

Table 2. Interactions between the model compounds and different ions.

Com- pound	+ Al^{3+}	+ Ca^{2+}	+ Fe^{3+}	+ Fe^{2+}	UV max for isotherms
1	no change	no change	no change	greenish	249 nm
2	no change	white precipitate	bluish violet	reddish violet	302 nm
3	no change	white precipitate	reddish brown	no change	298 nm
4	no change	precipitate	red	no change	302 nm
5	no change	white precipitate	reddish brown	no change	298 nm
6	no change	no change	green	green	485 nm
7	dark yellow	white precipitate	reddish brown	no change	248 nm
8	no change	white precipitate	reddish brown	no change	296 nm
9	no change	white precipitate	reddish brown	light brown	289 nm
10	no change	white precipitate	reddish brown	light brown	296 nm
11	no change	white precipitate	reddish brown	reddish brown	303 nm
12	no change	dark yellow	bluish violet	violet	307 nm
13	no change	white precipitate	reddish brown	light brown	296 nm
14	no change	white precipitate	reddish brown	no change	298 nm
15	no change	no change	violet	reddish violet	298 nm
16	no change	bluish violet	dark green	blue green	296 & 311 nm
17	no change	no change	violet then green	dark blue	480 nm
18	no change	no change	brown precipitate	no change	290 nm

We then tested the adsorption of the different model compounds on to the magnesium oxide surface under conditions resembling cement.

Most compounds did not adsorb at all to the MgO surface. The ones that did adsorb all contained groups that can easily chelate metal ions. Either the catechol group (with two phenolic groups in ortho position) or the salicylic group (with a acid or ester and a phenolic group in ortho position). Molecules with sulphonic acid groups adsorb much less than those without.

We notice that fairly similar compounds give dramatically different results. The vanillic acid gives no adsorption but by removing one methoxyl group we obtain 3,4-dihydroxy-benzoic acid; this compound is more polar and we would expect it to be more water-soluble. Nevertheless, it shows a classical Langmuir isotherm. Sulphomethylating 3,4-dihydroxy-benzoic acid, the behaviour again changes and we obtain a linear relationship between the amount added and the amount left.

This compound seems to be more soluble and, we do not reach a plateau in the adsorption isotherm with the amounts used in this study.

Figure 2. Adsorption isotherms for the compounds with a benzoic acid group.

The same trend is observed for the 4-methyl catechol, guajachol, sulphomethylated 4-methyl catechol triplet. Sulphomethylating the non-adsorbing guajachol also gives a product that does not adsorb, or only adsorbs to a very small degree. The 4-hydroxy-benzyl alcohol is also non-adsorbing.

Figure 3. Adsorption isotherms for $C_7H_8O_2$ compounds, and their sulphomethylated versions

None of the three relatively non-polar vanillin derivatives, vanillin, vanillin dimethyl ketal, or vanillic acid methyl ester, adsorbs.

Figure 4. Adsorption isotherms for the vanillin derivatives.

Figure 5. Adsorption isotherms for the salicylic acid derivatives.

Salicylic acid and salicylic acid ethyl ester shows the same adsorption while the more soluble 5-sulpho salicylic acid adsorbs much less.

Figure 6. The pH dependence of the adsorption for catechol.

Figure 7. The adsorption of dihydroxybenzoic acid methyl ester.

All the catechols complexes with iron(III) ions. For 3,4-dihydroxy benzoic acid (#4) we also find increased amounts of iron and aluminium in the pore water. Compounds 6, 12 and 17 also give slightly increased amounts of aluminium in the pore water.

4. DISCUSSION

Other well-known complexing agents, like EDTA, also give acceleration. This implies that the formation of iron and/or aluminium complexes could be important. The catechol compounds 2, 4, 6 and 16 are all strongly accelerating. These four compounds also complex with iron(III) ions in solution, and adsorb strongly to the surface. Sulphomethylating the compounds give products which are non-accelerating. It is difficult to see why the sulphomethylation should destroy their complexing abilities. They also give the same type of coloured complexes with Fe^{3+} . In fact, for the salicylic acid it is only with the sulphonated compound that we observe coloured complexes.

If complex formation is important, just mixing lignin with the appropriate compounds should give acceleration. The mixing should not influence the formation constant for these complexes much. However, experiments show that a physical mixture has no such accelerating effect. The difference in behaviour must thus be due to their different adsorption characteristics.

We also see from Table 1 that the initial slope for the adsorption isotherms is closely related to the accelerating effect. A high slope (≥ 50 ml/g) gives a strong acceleration of the setting, while a low slope (< 25 ml/g) shows no accelerating effect. The surface area of the cement used is $0.36 \text{ m}^2/\text{g}$ and that of magnesium oxide $0.27 \text{ m}^2/\text{g}$. Within the accuracy of these determinations, they have about equal surface areas. We find at saturation coverage of 31-78 mg/g MgO. This corresponds to 115-290 mg/m^2 . For benzoic acid, models show about that they occupy about $1.0 \text{ m}^2/\text{mg}$. The saturation coverage thus corresponds to many layers of organic material. However, the saturation coverage is of little relevance to the cement system. Only 0.2% organics on cement weight are added. This corresponds to 2 mg/g (or $5.6 \text{ mg}/\text{m}^2$). Moreover, not all the organics adsorb to the surface. The lowest slope among the compound that accelerate was found for #4. Here the saturation is reached at 10 mM concentration in the water phase. In the mortar used the w/c ratio is 0.3. This implies that 0.5 mg or one quarter of the organics is still in the water phase. This still gives a surface coverage of $4 \text{ mg}/\text{m}^2$, or enough to cover the entire surface. The non-accelerating compounds reach saturation at higher concentrations in the water phase, and there is not enough material to cover the entire surface.

The problem remains, though, why should something that adsorbs to the surface give a faster reaction?

The adsorbed species could form nucleation sites and thus promote reaction. Nucleation and growth usually requires a good match between the crystal structure of the “seed” and the growing crystal. It seems unlikely that the four different organics that are accelerating should all have crystal structures that match the growing phases of cement.

The organic materials that adsorb onto the surface are negatively charged, and will neutralise positive charges from the adsorbed metal ions at the surface. This will make it easier for other positively charged species to approach the surface.

In cement systems it is possible that the compounds will adsorb to some minerals and not to others. This could promote reaction at some sites and prevent reaction at other sites. The hardening demands contact between the different cement grains. Reaction at specific sites instead of all around the grains will promote the growth of needles instead of rounded particles. This will give a faster setting, as the needles are much more likely to contact each other, forming a network.

5. CONCLUSIONS

Although the mechanisms behind the effect are unresolved it is clear that catechol compounds that adsorb to the surfaces have a strong accelerating effect on the setting time of mortar samples.

Bernt O. Myrvold

Master of Science in organic chemistry and Ph.D. in Physical Chemistry.

From 1985 to 1992 I worked in the R&D department of several smaller Norwegian and Swedish companies, as well as Manchester University, all in the field of liquid crystal displays. Most of the work was related to the understanding of the relationship between chemical structure and macroscopic properties. The work included both polymer synthesis and characterisation work.

February 1992 to September 1993 I worked as Visiting Researcher at Hitachi Research Laboratory in Japan. The work included polyimide synthesis, test device fabrication and optical measurements. All synthetic and fabrication work took place in a clean room environment. The result was a good understanding of the relationship between polymer structure and the effect on the liquid crystals, and of how chemical changes in the liquid crystals affect the interaction with the surface.

January 1994 – October 1995 I did Post Doc. research at the University of Oslo, department of Chemistry in the Colloid and Interphase group. I was mostly doing modifications of natural polymers for rheology control in oil wells.

November 1995 I joined Borregaard LignoTech. Here, I have worked on characterisation and chemical modifications of Kraft lignin and lignosulphonate polymers. I have brought new additives for starter batteries from the laboratory to successful production. I have also worked on new products for the oil industry, both gels for enhanced oil recovery, and emulsifiers for transport of heavy crude oils.

I have written 35 publications, 2 sports books and have 5 patents.

ADSORPTION STUDIES OF LIGNOSULPHONATES ON CEMENT AND CEMENT MODEL COMPOUNDS

ABSTRACT

Lignosulphonates are important plasticizers for concrete. To learn more about their interactions with the cement adsorption isotherms were obtained for a high molecular weight lignosulphonate. The chemical reactivity of cement makes it impossible to obtain true isotherms. The different minerals present also have different adsorption characteristics. To overcome these problems several model systems, e.g., dicalcium/tricalcium silicate mixtures, tricalcium aluminate/tetracalcium aluminate ferrite, tricalcium aluminate, alumina, ferric oxide, magnesium oxide, calcium silicate, and kaolin were also investigated. In addition, Standard Portland Cement and White Aalborg Cement were used. All model systems were investigated at high pH, and moderate to high ionic strength to simulate the situation in pore water.

The lignosulphonates show adsorption isotherms that match the expected isotherms for polyions. The high molecular weight fraction of the lignosulphonates are preferably adsorbed. The di- and tri-valent cations present interact with the lignosulphonates and this interaction is important for the adsorption. The interaction with multivalent ions renders the lignosulphonate more hydrophobic.

1. BACKGROUND

Lignosulphonates are added to concrete to improve the flow of the fresh concrete. Exactly how they reduce the viscosity has been the subject of much speculation. Most workers assume that the first step is an adsorption of the lignosulphonate to the cement grains. A steric or electrostatic repulsion will then prevent the cement grains from approaching each other and impart colloidal stability to the system. The cement grains themselves are non-homogeneous and lignosulphonates will probably have a different preference for the different minerals. The mineral composition of the surface will also in most cases be different from the bulk. There might also be a difference in composition between grains of different sizes. It is thus clearly of interest to see how the lignosulphonates interact with the different minerals present.

There have been some studies of adsorption of lignosulphonates to cement [1-3] and cement model compounds. The model compounds studied are C_3S [4,5,6], β - C_2S [3,6], C_3A [3,6-8], C_3AH_6 [8], $C_3A \cdot CS \cdot H_{12}$ [7], $CaSO_4$ [4], C_4AF [4], C_2F [4], $Ca(OH)_2$ [4,5], CH [5], $H-C_3S$ [5]. Most of these studies are fairly old, and many of them use ill-characterised lignin samples.

2. EXPERIMENTAL

2.1 Adsorption isotherms

1.0 gram of the substrate was placed in a 25 ml tube. For the isotherms with salts present 10 ml of a salt solution with twice the required strength was added. 0 to 98 ml of water and 10 to 1 ml of the lignosulphonate solution was added. Always adding a total of 10 ml water and lignosulphonate solution. The tube was corked and shaken for 25-30 minutes.

For experiments with saturated salt solutions the lignosulphonate was dissolved in the salt solution. 1.0 gram of the substrate was placed in a 25 ml tube. 0 to 9 ml of the pure salt solution and 10 to 1 ml of the lignosulphonate solution was added. Always adding a total of 10 ml solution. The tube was corked and shaken for 25-30 minutes.

The solid substrate was removed by filtering through a 0.22 micron Millipore filter. At high pH there is no loss of lignosulphonates during the filtration step. Some fluid is trapped in the glass frit that supports the Millipore filter. The amount is small, and to reduce any dilution effects the series of solutions were either run from the strongest to the weakest, or from the weakest to the strongest. Repeated runs were performed in opposite directions if possible, but we could see no difference in calculated adsorption depending on the whether we started with the strongest or weakest solution.

The filtered solution was diluted with NaOH solution to the required strength for UV adsorbance measurements. The extinction constants of lignosulphonate are pH dependent and a high pH (>11) was thus used for all measurements. The content of lignosulphonate left in solution was calculated from the characteristic UV adsorbance band at 280-283 nm. A new standard curve from solutions of known strength was made for each set of measurements.

The adsorbed amount of lignosulphonate is calculated as the difference between the initially added amount and the amount left in the solution. The adsorbed amount is expressed as mg. pr. gram of substrate. In the isotherms the adsorbed amount is plotted against the equilibrium concentration, e.g. the concentration left in the solution.

For convenience we will use the term adsorbed, although consumed lignosulphonate will probably be more correct in many cases. As we will see, there is precipitation in many cases. In the more reactive systems, some of the lignosulphonate might also be buried in the reaction products.

To obtain reproducible isotherms gypsum had to be added to the C₃A/C₄AF phase, and also additional gypsum had to be added to the White Aalborg Cement.

2.2 Materials

The lignosulphonate used in this study is Ultrazine NA, an ultrafiltrated Norwegian Spruce soft wood lignosulphonate. The counter ion is sodium.

Characterics of the lignosulphonate used.

Mn	8.8 kDa
Mw	53 kDa
Organic Sulphur	5.1 %
Carboxylic Acids	4.5 %
Phenolic Hydroxyls	1.9 %
Methoxyl	10.9%

The substrates used were Standard Portland Cement from Embra and White Aalborg Cement from Aalborg Portland Cement were used. The C₃S/C₂S mixture (approximately 3.5:1) was obtained by extraction of the Embra standard portland cement with KOH/ sucrose solution. The C₃A/C₄AF mixture (~1:1) was obtained by extraction of the Embra standard portland cement with maleic acid in methanol. The rest of the substrates were commercially available in chemically pure form.

Alumina (Al₂O₃) from Fluka, lot no. 409370/1 32700

Ferric oxide (Fe₂O₃) from Fluka, lot no 411837/1 31101

Calcium silicate (CaSiO₄) from Alfa, lot no C04H03

Magnesium oxide (MgO) from Merck, lot no TA904765 129

Washed Kaolin from Prolabo, lot no 513G.

Salts of ferric chloride (FeCl₃), ferric sulphate (Fe₂(SO₄)₃), and aluminium chloride (AlCl₃), aluminium sulphate (Al₂(SO₄)₃), calcium chloride (CaCl₂), sodium chloride (NaCl), sodium sulphate (Na₂SO₄) and potassium sulphate (K₂SO₄) were added to some of the solutions.

2.3 Molecular weight determination

Molecular weights were determined on a Jordi Glucose DVB 10000 Å column. The mobile phase consisted of 10% DMSO in water buffered to 10.5 with a sodium hydrogen phosphate buffer and 0.1% SDS added. A spectra System AS3500 sampler, P4000 pump, and UV2000 detector were used. The software allows the calculation of the different molecular weight averages (M_n, M_w, M_z and M_{z+1}) as well as polydispersity. The molecular weights are given relative to two in-house standards with M_w of 68,000 and 8,300 Da, respectively. The relative values of the different lignosulphonate fractions are accurate to +/-2000 Da, while the absolute values depend on the accuracy of the standards. For the purpose of this study, the absolute molecular weights are of less importance.

3. RESULTS

We found strong adsorption to Standard Portland Cement (containing 8 % C₄AF), White Aalborg Cement (containing 1% C₄AF), the C₃A/C₄AF phase and Fe₂O₃, while we could not detect any adsorption to the C₂S/C₃S phase, CaSiO₄, or Al₂O₃. This is in disagreement with the literature, which reports strong adsorption of calcium lignosulphonates also to the C₂S/C₃S phase [4,5]. We thus redid our experiment with this phase with Ultrazine CA, a product that has been ultra filtrated, but without any ion exchange. This product behaves as described in the literature. Adding calcium chloride to the solutions with Ultrazine NA also gave adsorption of the lignosulphonate.

Figure 1 shows the adsorption to alumina at three different pH levels. While Figure 2 shows the effect of adding Al³⁺ ions.

Figure 1. Adsorption of Ultrazine NA to alumina at three different pH values.

Figure 2. Adsorption of Ultrazine NA to alumina at different concentrations of Al^{3+} .

Figure 3 shows the “adsorption” of Ultrazine CA or Ultrazine Na in the presence of CaCl_2 to $\text{C}_2\text{S}/\text{C}_3\text{S}$. This looks more like a precipitation, where a constant portion of the lignosulphonate disappears.

Figure 3. Adsorption of Ultrazine CA and Ultrazine NA with Ca^{2+} present.

Figure 4. Desorption of Ultrazine NA in the presence of 10 mM Al^{3+} .

In the presence of Fe^{3+} Ultrazine NA will adsorb to $\text{C}_2\text{S}/\text{C}_3\text{S}$. This is shown in Figure 5.

Figure 5. Adsorption of Ultrazine NA to C2S/C3S, in the absence (open circles), and presence (filled circles) of Fe^{3+} .

For the $\text{C}_3\text{A}/\text{C}_4\text{AF}$ substrate the situation is more complex. As Figure 6 shows we obtain good isotherms except for one or two points. These two points correspond to the direct addition of lignosulphonate solution without any water first. It is clear that during the 30 to 60 seconds between the water being added and the lignosulphonate solution being added, the substrate changes enough to give different adsorption isotherms. As the particle size distribution of our substrates are unknown we are not comparing the absolute surface coverage. It is clear that both the $\text{C}_3\text{A}/\text{C}_4\text{AF}$ and its hydration product adsorbs Ultrazine NA, and no further investigation of the difference between them was performed. The results are shown in Figure 6.

Figure 6. Adsorption isotherms for Ultrazine NA on $\text{C}_3\text{A}/\text{C}_4\text{AF}$. Open circles addition of lignosulphonate solution. Filled circles addition of water followed by lignosulphonate solution.

Figure 7 shows the adsorption to ferric oxide. We obtained a nice adsorption isotherm. In this case we probably underestimated the adsorption. Ferric ions interact with lignosulphonates to give a darker product. This ferric adduct also has a higher UV adsorption at 281 nm. Thus the UV method for determining the lignosulphonate content in solution will overestimate the amount of lignin left. When the amount left is overestimated the adsorbed amount consequently will be underestimated. As we are not concerned with the absolute coverage this problem is of no concern for our discussion.

Figure 7. The adsorption isotherm for Ultrazine NA on ferric oxide.

All the substrates, to which Ultrazine NA adsorbs, contain ferric oxide. This means that there will be some soluble Fe^{3+} ions present. We saw in Figure 5 how the adsorption to $\text{C}_2\text{S}/\text{C}_3\text{S}$ changed when 10 mM FeCl_3 was added to the solution.

Some experiments were performed by keeping the amount of Ultrazine NA and varying the amount of iron(III) ions present. 5000 ppm Ultrazine NA was used for the MgO substrate and 1000 ppm for the kaolin substrate. The intention was to determine the optimum amount of ferric ions required.

Figure 8. The effect of varying amounts of ferric ions on the adsorption to kaolin (blue) and magnesium oxide (red) at pH 10.1. Open symbols no additional salts, filled in 0.42 M NaCl.

The results in Figure 8 are in stark contrast to those in Figure 5. For these two substrates there seems to be no effect of the ferric ions.

We made a simulated pore water starting with a saturated solution of $\text{Ca}(\text{OH})_2$ in de-ionized water and adding 7.0 gr/l Na_2SO_4 , 6.0 gr/l KOH and 6.1 gr/l K_2SO_4 . This solution was filtered through a 0.22 micron millipore filter and split in three. One part was left. 500 ml was added 62.5 mg $\text{Al}_2(\text{SO}_4)_3 \cdot 16\text{H}_2\text{O}$ (0.4 mM Al^{3+}), 500 ml was added 2.0 mg $\text{Fe}_2(\text{SO}_4)_3$ (0.04 mM Fe^{3+}), and the rest left unchanged. Ultrazine NA was dissolved in the three different solutions. We obtained adsorption isotherms with MgO and kaolin as substrates.

Figure 9. Adsorption to MgO in the presence of different salts. Error bars correspond to two standard deviations (for clarity they are omitted from Al³⁺).

Figure 10. Adsorption to kaolin in the presence of different salts. Error bars correspond to two standard deviations. The symbols are as for Figure 8.

We see that both for the positively charged magnesium oxide and for the neutral (at this pH) kaolin the presence of trivalent ions there is a small and maybe insignificant increase in the adsorption.

The solutions shown in Figures 9 and 10 were further analysed with respect to the molecular weight of the remaining lignosulphonate. The results are given in Figures 11 and 12.

Figure 11. The molecular weight of the remaining lignosulphonates as a function of the fraction adsorbed.

Figure 12. The molecular weight of the remaining lignosulphonate as a function of the amount initially added. Open symbols kaolin substrate (low adsorption), filled symbols MgO (high adsorption).

These figures clearly tell us that the highest molecular weight fraction is preferentially adsorbed. As more and more of the total amount of lignosulphonates are adsorbed to the substrates a lower and lower molecular weight fraction will be adsorbed. We also see that there seems to be a lower limit. At least some of the lignosulphonates with a molecular weight of less than 10000 are not adsorbed.

4. DISCUSSION

Adsorption of polyelectrolytes is a complex process. The charge of the surfaces and the polyelectrolyte will give rise to electrostatic attractions, or repulsions. These charges will be pH dependent. In addition the surfaces will be more or less hydrophobic, hydrophobic interactions can thus not be neglected, either. Complexing the lignosulphonates will also alter their hydrophobicity.

Ions in solution can also give insoluble salts with lignosulphonates. With the experimental procedure used here, and commonly used to obtain adsorption isotherms, it is impossible to distinguish directly between adsorption and precipitation.

Fe_2O_3 has a point of zero charge (pzc) at pH 4.8-8.6, Al_2O_3 at 9.0, and MgO at pH 12.0. Kaolin consists of platelets with large negative surfaces and edges with (pzc) at 7.3.

Silica has a pzc at pH 2 – 3.7. For most of the silicate minerals used in this study the pzc is unknown, but we would expect it to be between that of silica and kaolin due to the chemical similarities. This means that all the substrates – except MgO - are negatively charged under the experimental conditions used. This means that for electrostatic reasons the surfaces should repel the lignosulphonate and we should observe no adsorption. Although these values are found for pure, simple systems, they might not be relevant to the cement paste where dissolved ions will modify the surface charges. Most workers seem to agree that cement has a slightly positive surface charge.

All the substrates with ferric ions give adsorption irrespective of their charge. Some ferric ions are leached into the solution, which can be shown by colour tests with phenolic compounds. In the solution the ferric ions will interact with the lignosulphonate to give a more surface active species. The ferric ions could also conceivably interact with the different substrates to give a more positively charged surface, which would also react stronger with the lignosulphonate. However, the same effect of the ferric ions is also found in emulsions where there is no solid surface for the ferric ions to bind to [9,10]. The same effect of ions leaching from the substrate and rendering the lignosulphonate more surface active has also been invoked to explain the difference between cleaned lead surfaces and native lead surfaces [11]. For the more hydrophobic, and near neutral lignosulphonate-iron complex there will be no electrostatic barrier to the adsorption. This complex will adsorb to surfaces that are negatively charged as well. For MgO the surface is positively charged, under the conditions shown in Figure 8, the surface is saturated with lignosulphonate without iron present (we are on the plateau shown in Figure 9). The addition of ferric ions will not increase the adsorption. The apparent lack of increased adsorption to kaolin in the presence of ferric ions, might be an experimental artifact due to the small area of the edges where lignosulphonates normally adsorb. The hydrophobicity of the kaolin might also be so low that there is little driving force for adsorption. The ion exchange capacity of might also interfere and effectively remove the ferric ions from solution.

For the calcium and aluminium ions the effect seems to be more like a precipitation. The amount consumed is directly proportional to the amount added, and there is no clear plateau in the adsorption isotherms. Although for calcium, this plateau could be at higher lignosulphonate concentrations than the ones employed in this study. We also see that the “adsorption” to C₂S/C₃S in the presence of Al³⁺ is irreversible (Figure 4). Above 4 mM Al³⁺ in the solution we can clearly observe a precipitate forming with the lignosulphonate. For Fe³⁺ no precipitation is observed with up to 10 mM Fe³⁺ added.

We see in all cases that the highest molecular weight fraction is preferentially adsorbed. This is also previously found for cement [3], and other systems [11]. This is what we expect for polymer adsorption. In Figure 8 we also see a small salting out effect. The increased ionic strength of the solution gives a somewhat higher adsorption. This has also been described earlier for lignosulphonates [12].

5. CONCLUSIONS

Sodium lignosulphonates on their own will only adsorb to some of the minerals in cement grains. These are the minerals containing ferric ions. The leakage of small amounts of ferric ions from the Fe₂O₃ grains of the cement give rise to a lignosulphonate that is less hydrophilic and readily adsorbs to all the different mineral phases.

Aluminium or calcium ions give some of the same effects, but it seems more like a precipitation.

Bernt O. Myrvold

Master of Science in organic chemistry and Ph.D. in Physical Chemistry.

From 1985 to 1992 I worked in the R&D department of several smaller Norwegian and Swedish companies, as well as Manchester University, all in the field of liquid crystal displays. Most of the work was related to the understanding of the relationship between chemical structure and macroscopic properties. The work included both polymer synthesis and characterisation work.

February 1992 to September 1993 I worked as Visiting Researcher at Hitachi Research Laboratory in Japan. The work included polyimide synthesis, test device fabrication and optical measurements. All synthetic and fabrication work took place in a clean room environment. The result was a good understanding of the relationship between polymer structure and the effect on the liquid crystals, and of how chemical changes in the liquid crystals affect the interaction with the surface.

January 1994 – October 1995 I did Post Doc. research at the University of Oslo, department of Chemistry in the Colloid and Interphase group. I was mostly doing modifications of natural polymers for rheology control in oil wells.

November 1995 I joined Borregaard LignoTech. Here I have worked on characterisation and chemical modifications of Kraft lignin and lignosulphonate polymers. I have brought new additives for starter batteries from the laboratory to successful production. I have also worked on new products for the oil industry, both gels for enhanced oil recovery, and emulsifiers for transport of heavy crude oils.

I have written 35 publications, 5 patents, and 2 sports books.

CORRELATION OF PERFORMANCE AND CHEMICAL DATA FOR ADMIXTURES IN CEMENTITIOUS SYSTEMS BY MEANS OF CHEMOMETRIC METHODS

ABSTRACT

Chemometrics, i.e. multivariate data analysis, can be a very useful and cost-efficient tool for interpretation and comparison of experimental data.

The chemical composition of an admixture decides the admixture's impact on cementitious systems. This investigation uses chemometric methods to correlate the chemical composition of different lignosulphonates to their performance in mortar by means of principal component analysis (PCA).

Commercially available lignosulphonates and experimental modifications of these were tested in mortar using ordinary Portland cement with respect to air entrainment, heat evolution, density, flow and setting time. Chemical analyses were performed to find the amount of some of the most typical chemical groups.

This paper describes a decision-making process using multivariate data analysis in the simplest way. The decision-maker is not required to have any deep knowledge about statistics, but must have information on the experiments analysed. It is important for the user to trust his intuition, but be critical and use his contextual knowledge. The purpose of this paper was to show that multivariate data analysis is a useful tool for analysing the large amounts of experimental data generated during R&D work. Multivariate data analysis was used to pick the best overall samples and to set the direction for further research. This has reduced the number of trial-and-error-experiments.

1. INTRODUCTION

The chemical composition of an admixture decides the admixture's impact on cementitious systems. This investigation uses chemometric methods to correlate the chemical composition of different lignosulphonates to their performance by means of statistical models called principal component analysis (PCA). This is a form of multivariate data analysis.

In principal component analysis, the principal components (PC) are plotted, not the actual input variables. PCA is a bi-linear soft model (BLM) where the individual input variables are combined into a few principal components. Scores are the connection between the samples and the PCs, and loadings between the variables and the PCs. PCA gives a visual impression of how the components and the properties interact. Variables situated close to each other in the loadings-plot will increase as one of them increases. Accordingly a variable on the other side of the axis will be inversely correlated. This is not necessarily a direct relationship between the variables, but it shows a correlation. PCA is an easy way to interpret the results for someone with some knowledge on how

the variables will interact with the samples. It is not required to have any formal training in statistics. A layman's guide to multivariate data analysis is described by Martens [1].

Outliers are samples that are abnormal in some way. The software can automatically detect outliers or the user can spot them by visual inspection of the plots. An outlier brings extreme values to the group and therefore they affect the model strongly. The outliers should be removed to calculate a valid model for the data set in question.

2. EXPERIMENTAL METHODS

Commercially available lignosulphonates and experimental modifications of these were tested at dosages 0.20% and 0.40% solid by weight of cement in mortar using ordinary Portland cement (OPC, EN197-1 CEM I 42.5R), w/c = 0.50. The performance properties measured are given in Table 1. Chemical analyses of the admixtures were performed to find the amount of some of the most typical functional groups, see Table 2.

Table 1. The performance tests performed.

Performance property	Short notation
Flow	flow
Flow retention, 30 min.	flow loss
Air entrainment	air
Density	dens
Setting time by flow evolution.	ST

Table 2. The chemical analyses performed.

Chemical property	Short notation
Molecular weight	Mw
Reducing sugar	Sugar
Total amount of sulphur	S
Inorganic sulphur	inorgS
Organic sulphur	orgS
Methoxy groups	metoxyl
Phenolic OH	ph-OH
Weak acid groups	COOH
Sulphate	-SO ₄
Sulphite	-SO ₃

The multivariate data analysis was calculated using The Unscrambler 7.6.

3. RESULTS AND DISCUSSION

The entire data set consists of 33 samples and 24 variables. Outliers are excluded from all the plots shown here. Because the two first principal components explain more than 50% of the variations in all plots, i.e. PC1 and PC2 span the largest variation in the data set, only the graphs made up of PC1 and PC2 are shown.

3.1 First Sample

The data set was built upon a few samples that was collected from various projects at our R&D department. Scores and loadings from PCA of this set are shown in Figure 1.

Figure 1. Scores (blue) and loadings (red) from the PCA for the first data set.

It can be seen that high molecular weight samples (HMwLS, MMwLS, polyLS1) are correlated to good initial flow, low air entrainment and low setting time. These samples are situated near the variables flow in the plot. It can therefore be assumed that performance tests of these samples give high values of the mentioned variables. The setting time at high dosage is situated near the variable Sugar because sugars retard setting time in cement. Thus, high dosage of an admixture that contains sugar will increase the setting time dramatically. Knowledge about the background of samples HMwLS, MMwLS and polyLS1 tells that they do not contain sugars, so the variable to compare with is ST0.2. This variable is inversely correlated in the plot, so these samples have low setting time. It can also be seen that these samples are at the opposite side from the variables describing the air entrainment. This is because these samples have a low air entrainment.

Attempting to improve the flow while lowering the setting time and air entrainment, it was decided to make a pure lignin sample with high molecular weight. The new sample was called DP684 and was included in the analysis in Figure 2.

Figure 2. Scores (blue) and loadings (red) for the first two principal components from the PCA for the data set including the first sample.

3.2 Second Sample

Further, samples based on hardwood (HW1, HW2) and Kraft lignin (oxyLS) were added to the data set, Figure 3, to span the model to cover more of the lignosulphonate qualities.

Figure 3. Scores (blue) and loadings (red) from the PCA when hardwood and Kraft lignin samples are included.

Phenolic-OH (ph-OH) groups seem to give good flow and low air entrainment. It was decided to make a desulphonated sample of lignosulphonate. Desulphonation increases the number of phenolic-OH groups and decreases the amount of combined sulphur. Organic sulphur (orgS) seems to increase the air entrainment and setting time and it was therefore desired to keep this amount as low as possible without losing the solubility.

Several desulphonation experiments were performed and the second sample, DP 702, was made based on the chemical analysis and Figure 4.

Figure 4. Scores (blue) and loadings (red) from the PCA including desulphonated samples.

3.3 Third sample

Figure 5 shows all samples until this point. To cover even more outskirts of the data set, it was decided to make a pure hardwood-based lignosulphonate sample, DP718.

Figure 5. Scores (blue) and loadings (red) from the PCA of the data set until this point.

The variable hardwood (HW) has a great impact on the picture, and the PCA is recalculated without the hardwood and softwood (SW) variables to better see the effect of the chemical compounds, Figure 6, where the third sample, DP 718 also was included.

Figure 6. Scores (blue) and loadings (red) of the entire data set except hardwood/softwood variables.

3.4 General discussion

Lignosulphonate is a very polydisperse material. This causes the results of chemical analysis to provide average values covering the whole molecular weight range. The data discussed in this paper show some correlation between chemical data and mortar performance of the lignosulphonate. The different segments of the molecular weight range have different properties, as discussed by Gustafsson and Reknes [2 and 3]. The correlation is expected to be much stronger when narrower molecular weight fractions (less polydisperse) are studied.

4. SUMMARY AND CONCLUSION

Section 3 describes a decision-making process using multivariate data analysis in the simplest way. The decision-maker is not required to have any deep knowledge about statistics, but must have information on the experiments analysed. It is important for the user to trust his intuition, but be critical and use his contextual knowledge. The purpose of this paper was to show that multivariate data analysis is a useful tool for analysing the large amounts of experimental data generated during R&D work.

Multivariate data analysis was used to pick the best overall samples and to set the direction for further research. This has reduced the number of trial-and-error-experiments.

ACKNOWLEDGEMENTS

This work was supported by the EC-project Design and function of novel polymeric admixtures for more durable high performance concrete, SUPERPLAST.

Thanks go to our technicians who performed all our experiments in an excellent manner.

Berit Guidding Petersen

Master of Science in inorganic chemistry.

I have worked as a research scientist at Borregaard LignoTech, Research and development department, since May 2001. My work mainly concerns plasticizing admixtures for construction, i.e. cement and concrete. My previous employment was as a scientific assistant at The Department of Inorganic Chemistry, Norwegian University of Science and Technology (NTNU), where my work was related to teaching and cement chemistry.

I finished my Master Thesis entitled “Water reducing admixtures for Cement and Mortar based on Combinations of Lignosulphonates and Calcium Nitrate” in 1999 at NTNU.

In addition to my position at Borregaard LignoTech, I am pursuing a doctoral degree on rheology of cement based binders.

HIGH PERFORMANCE SONIC IMPULSES – AN ALTERNATIVE METHOD FOR THE SELECTIVE CRUSHING OF CONCRETE

ABSTRACT

The high amount of concrete waste generated today requires the development of effective and sensitive crushing methods that allow the reuse of the material at a high level. In the paper a new method for crushing of concrete is presented. The stress needed for comminution is generated by high performance sonic impulses. Compared to the output of jaw and impact crushers, the crushed product of this method is of high quality. The coarse fractions have nearly no cement paste on the surface of the aggregates and provides an optimum size distribution. Thus it is possible to obtain high quality secondary aggregates and to reuse them in new concrete without any restrictions.

1. INTRODUCTION

Recycling of building materials becomes more and more important. In Germany about 77,100,000 Tons/a of Construction & Demolition Waste, i.e. 1 Ton/capita/a were generated in 1998 [1]. On the one hand in regions with a high population density the recycling of building materials can help to reduce the quantity of material that must be deposited. On the other hand in regions with a shortage of raw materials the recycling of building materials opens new sources.

In regard to concrete debris there are two main fields of application. Crushed concrete is often used as aggregate for stabilised or unstabilised sub-bases in road construction. In this case the processing with a jaw crusher or an impact crusher is well proven. The produced material almost meets the requirements with regard to the grading curve and the composition. The presence of old cement paste in these aggregates seems to be an advantage, because it causes a stabilising effect compared with inert material as sub-base material [2], [3]. If the concrete debris is to be reused as aggregate for new concrete, processing with crushers developed for natural rock is also possible but connected with some disadvantages. So the produced secondary aggregates are agglomerates of the old cement paste and the original aggregates. This causes a higher water adsorption and a lower strength of the grains. Moreover microcracks can occur between both components which are the result of initiated but not completed fracture processes. To overcome these problems the comminution by high performance sonic impulses for the processing of concrete debris was developed. This technology aims at the production of secondary coarse aggregates that can be used in new concrete without any restrictions.

The traditional crushing methods which are based on mechanical stresses are limited with regard to the quality of the produced material. They do not make possible a controlled effect of the stresses at the boundary layers of the concrete. The magnitude of the applied stresses results in an extensive destruction not only of the concrete, but also of the aggregates.

2. PRINCIPLE OF THE SELECTION BY HIGH PERFORMANCE SONIC IMPULSES

The tools of the new crushing method are high performance sonic impulses. The basic principle is the transformation of electrical energy (stored at a capacitor) into mechanical energy of sonic impulses. These impulses are generated under water by a disruptive electrical discharge. As a result pressure sonic waves are generated that propagate through the surrounding medium (in our case water). If they come across boundary layers of different densities, i.e. water and concrete or aggregates and cement paste, positive and negative interferences occur. As a result pressure and tensile stresses are generated directly at these boundary layers. The tensile stresses primarily destroy the bond between aggregates and matrix. Cracks mainly follow the boundaries between layers with different densities (Fig. 1).

Figure 1. Progression of cracks between aggregates and matrix [4]

The energy feed happens over the total surface, because the sonic waves propagate in the water spherically. The stresses occur over the total surface, not homocentric like in the jaw or in the impact crusher. Moreover the stress can be dosed more precisely by the setting of the electrical parameters.

3. EXPERIMENTS

3.1 Targets of the Project

The target of the research project is to prove the performance of the new method. Especially the quality of the secondary aggregates as function of the technological parameters of the process and of the parameters of the processed material should be determined. It makes sense to develop a concept for the complete processing technology including fields of application for the fine fractions based on the quality of the material produced and the required energy.

In the project investigations about the following topics are in progress:

- Investigations of the influences of the electrical parameters and the electrical energy feed on the size reduction and the separation of the concrete constituents;
- Optimisation of the energy balance of the system and the process parameters;
- Investigations of the influences of concrete properties on the separation by high performance sonic impulses;
- Comparison of the crushed product with the products of traditional crushing methods.

In this paper will be reported about the dependence between the required power and the resulting size reduction effect as well as the separation effect. However the main topic is the dependence between the features of the input concrete and the properties of the output product. If such a dependence exists, then it is the question whether it can be explained by our knowledge about the material properties of concrete. Finally, the crushed product was compared with that of traditional crushing methods, like jaw and impact crusher, to characterise the advantages of the new method.

3.2 Test Device

A scheme of the device used for the experiments is shown in Figure 2. It consists of the electrical equipment, the water filled outer container and the inner, perforated container in which the concrete is treated. The pre-crushed concrete is put in the water filled container. After closing the container the treatment is started. During the treatment the fine material comes out of the inner container through the perforation. After the treatment the container is emptied and the crushed products are separated from the water by sieving and sedimentation.

Figure 2. Scheme of the device for experiments [4]

The device is run with a capacity of capacitor C and a voltage of charge U_0 in the range of

- Capacity of capacitor C 6 ... 12 μF
- Voltage of charge U_0 20 ... 30 kV.

The electrical parameters and the operating parameters, like the distance between the electrodes and the number of the pulses, influence the properties of the crushed product. The experiments show that the particle sizes of the crushed product are mainly influenced by the number of impulses n , the voltage of charge U_0 and the interaction between them. An optimum is at a voltage of charge of 30 kV and a number of impulses of 30. Enhancing the number of impulses is more effective at a high level of voltage. The distance between the electrodes is less important for the mean particle size.

3.3 Parameters for the Evaluation of the Crushed Product

During the treatment of the concrete several things happen in dependence on the energy feed and the features of the material. The particle size is reduced as in a traditional crushing process. The separation between aggregate grains and cement paste occurs as an additional effect. If the treatment is too strong microcracks may be formed in the product. All three effects must be measured if the action of the sonic impulses as a crushing tool is to be evaluated completely. The parameters used for evaluation are shown in Table 1. They give information about the following effects:

- The reduction of the particle sizes was checked to evaluate the effect of the sonic impulses as a crushing tool. The particle size distribution of the crushed product was compared with the distribution of the aggregates used in the original concrete.
- The separation between aggregate grains and cement paste was evaluated by three different parameters:
 - The whole content of cement paste in the fractions was analysed by the hydrochloric acid method according to the German Standard [5]. In the coarse fractions (> 2 mm) this content gives information about the average percentage of cement paste stuck on the surfaces of the aggregates. In the fine fractions this content is the sum of the free cement paste and the cement paste of agglomerates.
 - The purity of the product 2-16 mm gives information about the agglomerated aggregates remaining after the crushing process, and/or the destroyed aggregates. It can be calculated from the parameters of the particle size distribution and the content of cement paste of all sorted fractions.
 - The degree of liberation is the portion of aggregates without cement paste in the fractions > 2 mm. It was determined by counting the clean aggregates.
- The rate of damage of the aggregate grains was examined at two levels. The particle size reduction caused by the treatment is interpreted from the comparison of the particle size distributions of the original aggregates and the crushed concrete. The effects on the microstructure of the coarse aggregate particles were examined in a first step by measurements of the water adsorption of the aggregates before the treatment and after. Because the water adsorption is influenced by the residues of cement paste on the surface of the aggregate grains, the grains must be cleaned by washing with hydrochloric acid before the measurement.

The methods of measurements of the parameters used for evaluation are shown in Table 1. In Table 2 the ranges of these parameters are summarised. Some important cases are discussed.

Table 1. Parameters for the evaluation of the crushed products

Evaluated effect	Parameter	Method of measurement
Particle size reduction of aggregates	Ratio of the mean particle sizes before and after crushing	Sieve analysis
Separation of cement paste and aggregates	Content of cement paste	Hydrochloric acid method
	Purity	Calculated from sieve analyses and hydrochloric acid method
	Degree of liberation	Counting
Effects on microstructure	Water absorption	24 h-Water absorption

Table 2. Discussion of the parameters for the evaluation of the different effects of the comminution by high performance sonic impulses

	Evaluated effect and used parameters	Typical cases	Explanation/ Example	
1	Particle size reduction of aggregates Ratio of mean particle sizes r_m $r_m = \frac{x_{m, crushing product}}{x_{m, original concrete}}$	$r_m = 1$	Ideal case, no destroyed aggregates (valid if the grains are cement paste free)	
		$r_m < 1$	Low effect on aggregate; agglomeration	
		$r_m > 1$	Intensive comminution; damage of aggregates	
2	Separation of cement paste and aggregate			
2.1	Content of cement paste c in the fractions i $c_i [\%]$ $c_i = 100 - (HCl\ Insolvable)$	Perfect separation $c_i = 0$	Aggregate grains without any cement paste; ideal case (valid for grains > 2 mm)	
		Partly separation $0 < c_i < c_{concrete}$	Aggregate grains with a certain amount of cement paste (valid for grains > 2 mm)	
		No separation $c_i = c_{concrete}$	Aggregates form agglomerates with a composition that agrees with the composition of original concrete (valid for grains > 2 mm)	
2.2	Purity P Quotient of the mass of aggregate in the product (fraction 2-16 mm) and the total mass of product	$P = 100\%$	Only clean aggregates in the product, the total cement paste is enriched in the fine fraction	
		$P > 100\%$	Too much aggregates in the product, because of the formation of agglomerates consisting of sand and cement paste	
	$P = \frac{m_{aggregate, crushing product}}{m_{crushing product}} \cdot 100$	$P < 100\%$	Too little aggregates in the product, because of the destroying of aggregates into grains < 2 mm	
2.3	Degree of liberation D_L Content of aggregates without cement paste per fraction	$D_L = 100 \%$	Ideal case; all aggregates are without cement paste on the surface	
3	Effects on microstructure Water adsorption	$W_{secondary aggregates} \approx W_{original aggregates}$	Ideal case	
		$W_{secondary aggregates} > W_{original aggregates}$	Damage of the structure	

3.4 Results

3.4.1 Influences of the electrical energy feed on the size reduction of concrete and the liberation of its components

The first step should be to find out the parameters for the best agreement of the particle size distribution of the crushed concrete with the particle size distribution of the original aggregates in the concrete. In Figure 3 some of the experimentally achieved particle size distributions after the

crushing by sonic impulses are shown. They will be compared with the particle size distribution of the original aggregates used in the concrete. The best agreement was found if the material was treated 50 times at a voltage level of 20 kV. Especially by variation of the number of the impulses the particle size distribution can be shifted in coarser or finer ranges.

Figure 3. Examples for particle size distributions between 2 and 16 mm after crushing with sonic impulses at different levels of electrical parameters (material: concrete with a nominal strength of 25 N/mm²)

The energy consumption for the treatment in the laboratory device results from the power that will be transformed in a very short time in the spark gap and the number of impulses that is necessary for a sufficient comminution. These parameters are summarised in the ratio $n \cdot W_{Fp} / t_{aPF}$ [4]. The term W_{Fp} means the power in the spark. The term t_{aPF} means the time in which the power rises (Fig. 4) and n means the number of the impulses. The terms W_{Fp} and t_{aPF} will be calculated during every test on the basis of measurements of electrical power and voltage.

Figure 5 shows the ratio of the mean particle sizes r_m of the crushed product and its purity P versus the parameter $n \cdot W_{Fp} / t_{aPF}$. From this figure it follows that the ratio r_m exponentially increases with increasing energy feed. The wanted ratio $r_m=1$ is achieved for an energy feed parameter of 10 kJ/μs. The purity increases with the energy feed also. The highest purity of the crushing product of 90 % is reached for a parameter of 13 kJ/μs.

Figure 4. The definition of the parameter $n \cdot W_{Fp} / t_{aPF}$ which is used for the description of the transformation of energy in the spark gap [4]

Figure 5. Ratio r_m (left) and purity P (right) versus parameter $n \cdot W_{Fp}/t_{aPF}$ for concrete with a Nominal strength of 25 N/mm^2

3.4.2 Characteristics of the crushed product

The crushed product is a composite material of cement paste and aggregate. But the cement paste is not distributed in all fractions consistently. As typical feature the content of cement paste increases at decreasing particle size (Fig. 6).

Figure 6. Typical feature: Dependence between the content of cement paste and the particle size

That means that in the fine fraction ($< 2 \text{ mm}$) the cement paste is enriched by a factor two. The reason is the fact that the comminution takes place in this component of a composite material with the lower strength.

The water adsorption of the cleaned secondary aggregates (2,16 mass-% on the average) is systematically higher than the water adsorption of the aggregates for the original concrete (1,13 mass-% on the average) (Tab. 3). Because the statistical tests do not confirm this difference, there are still no clear statements about the occurrence of microcracks caused by the sonic impulses.

Table 3. Water adsorption of secondary aggregates and original aggregates

Water adsorption in %				
	Fraction	Mean	Maximum	Minimum
Original aggregates	2/4 mm	1,07	1,31	0,82
	4/8 mm	1,09	1,54	0,64
	8/16 mm	1,23	1,43	1,03
Secondary aggregates	2/4 mm	2,66	3,82	1,76
	4/8 mm	2,16	2,97	1,07
	8/16 mm	1,68	2,57	0,80

Figure 7. Ratio of mean particle sizes of crushed concrete with various compressive strength

The particle size reduction and the liberation of aggregates also depends on the properties of the material, especially its strength as shown in Figure 7, where the ratio of particle size reduction is plotted for concrete with systematically varied compressive strength but constant raw materials. Concrete with low strength can be crushed very easily. Concrete with high strength is very brittle. In both cases high values of the ratio r_m result. Concrete with medium average strength is most difficult to crush, because it is tough. The conclusion of these investigations is that the elastic behaviour, as well as the quality of the interfacial transition zone between aggregates and cement paste, is very important for the crushing process. This property will be investigated in later works in more detail.

3.4.3 Comparison of crushing method by high performance sonic impulses with traditional crushing methods

In Figure 8 the particle size distribution of a concrete which was crushed in an impact or in a jaw crusher was compared with that of the same concrete crushed by high performance sonic impulses. The secondary aggregates of the treatment by high performance sonic impulses are in the favourable range of aggregates (AB16) according to the standard. The particle size distributions of the traditional methods are coarser.

Figure 8. Comparison of the particle size distributions of concrete crushed by high performance sonic impulses and by traditional methods [6]

The comparison of the degree of liberation D_L of the aggregates according to Table 2 related to the particle size is really interesting. Here the advantage of the crushing with sonic impulses is most distinct. In Figure 9 is shown very clearly that the degree of liberation of the product crushed by high performance sonic impulses is higher compared with traditional crushed products in all analysed fractions. It increases with increasing particle size up to 70 %. For jaw crusher and impact crushers the content of aggregates without cement paste is considerable lower. It decreases with increasing particle size. Only about 10 % of grains free from cement paste will be achieved in the coarse fraction of the product of the impact crusher.

Figure 9. Comparison of the degree of liberation for secondary aggregates generated by jaw-, impact crusher and by high performance sonic impulses [6]

In agreement with the high degrees of liberation, the apparent density of the aggregates of high performance sonic pulses is only a little lower than that of the original aggregates and considerably higher than that of the traditional crushed aggregates. The fractions 16/32 mm and 8/16 mm have densities between 2.4 and 2.6 g/cm³ if the concrete is crushed with high performance sonic pulses, and only 2.1 to 2.3 g/cm³ if the concrete is crushed traditionally.

4. CONCLUSIONS

The results show that it is possible to use high performance sonic impulses as a tool for the crushing of concrete. The most important features of the method and the product are:

- The method bases on the forces of pressure sonic waves that act at boundaries of different densities in the concrete. The parameters of the method can be controlled in a wide range. The most important influences on the particle size reduction and the quality of the crushed product are the number of the impulses and the voltage of charge. For the examined concrete with a strength of 25 N/mm² an optimum treatment is possible with an energy feed of about 13 kJ/μs.
- Secondary aggregates obtained from the described method show significantly less content of cement paste in the coarse fractions than the secondary aggregates crushed in an impact or a jaw crusher. Up to 70 % of the grains > 2 mm are free of cement paste.

The new method is more sensitive than the traditional crushing methods. So the considerable enrichment of cement paste in the fine fraction is due to the effects that the comminution takes place at the boundaries of concrete as composite material and that the cement paste as its component with the lower strength is destroyed most. Moreover the influence of the quality of concrete is recognisable at the obtained ratio of particle size reduction.

Topics for further research will be the investigation of the process parameters, the optimisation of the energy balance and the influence of concrete properties on the separation. The development of a

prototype for a laboratory device as the next step will be the prerequisite for the production of secondary aggregates and to test them for concrete manufacturing. By the end of the project a concept for the whole process including proposals for the reuse of the fine fraction will be developed.

ABSTRACT

The objective of our study is to obtain C_2S at low temperature in the presence of composite additives and to establish lattice parameters and constituent phase of C_2S and to determine the defect and its type and concentration formed by additive atoms.

Numbers of studies have been conducted into the field of production of belite rich cement with high hydraulicity. For Instance, although there are many works on rapid cooling of belite rich cement clinker, it encounters difficulties in realizing this under real conditions. We have investigated ways of increasing the hydration reactivity of solid solution $2\text{CaO}\cdot\text{SiO}_2$, especially by physical and chemical methods which is one way of solving this problem.

In this paper we present the research results on our synthesis of solid solution $2\text{CaO}\cdot\text{SiO}_2$ (Ca_2SiO_4) in the presence of composite additions. The crystal structure of Ca_2SiO_4 was determined by Rietveld profile analysis using the GSAS program (sp.gr. $\text{P2}_1/\text{n}$, $Z=4$, $a=5.05472 \text{ \AA}$, $c=9.32795 \text{ \AA}$, $\beta=94.1667^\circ$, $R_{\text{wp}}=4.1\%$, $R_p=2.9\%$, $R_E=2.8\%$). The synthesized Ca_2SiO_4 was $\beta\text{-C}_2\text{S}$ with a monoclinic symmetry and some Ca atoms disordered and substituted with atoms of Fe and Cu. In this way, some O atoms replaced F atoms in the β -phase. After refinement of X-ray powder pattern by the Rietveld method, the chemical composition of solid solution $\beta\text{-Ca}_2\text{SiO}_4$ was defined with the following formula:

Results of our research have shown that temperature of forming $\beta\text{-Ca}_2\text{SiO}_4$ could be decreased to $1150\text{-}1200^\circ\text{C}$ in the presence of composite mineralizers.

The solution of problems on the synthesis of C_3S and C_2S at low temperature will be helpful for production of cement clinker under low temperature conditions.

1. INTRODUCTION

Increasing numbers of studies have been undertaken on the production of belite rich cement with high hydraulicity [1,2,3,4]. It is observed from searching physical and physico-chemical research methods for increasing hydration reactivity that the rate of hydration of belite phase or the solid solution $2\text{CaO}\cdot\text{SiO}_2$ is slower than that of the alite phase. For instance, although there are many

works on rapid cooling of belite rich cement clinker, it encounters difficulties in realizing real condition [5].

Numerous publications have dealt with the synthesis of β -C₂S in the presence of some metal oxides. According to those study, defects formed such as substitution ($3\text{Ca}^{+2} \Leftrightarrow 2\text{Me}^{+3}$; $3\text{Si}^{+4} \Leftrightarrow 4\text{Me}^{+3}$) for Ca^{2+} , Si^{+4} . Interpretation depends on the metal ions radius therefore was changed cell parameters and stabilized modification β -C₂S and lowered by 100⁰-150⁰C temperature formation [6,7,8].

It is possible to obtain C₂S at low temperatures in the presence of a mineralizer whereas C₂S completely formed at 1400⁰ – 1450⁰ C in system of “2CaO + SiO₂” stabilized by Al₂O₃, Fe₂O₃. The solid solution formed spontaneously, because of increasing entropy of the system and decreasing free energy in the presence of addition [6].

It was established that there is a vacant defect form in the crystal lattice of β -C₂S during stabilization of calcium orthosilicate with a composition of Ca₂Me_xSi_{1-x}O_{4-x/2} (where: Me- Al, Fe, B; 0<x<1)[9]. Also M.Regourd defined lattice parameters a=5.506 Å, b=6.749 Å c=9.304 Å β =94.62⁰ in the β -C₂S. But lattice parameters of numerous polymorph modifications of the solid solution C₂S changed interval in the lower [10].

Studies on the texture of solid solution C₂S in the presence of CuO are insufficiently conclusive, and M.Enculescu examined the solid solution structure of β -Ca₂SiO₄ with CuO as a (Ca_{2-x} Cu_x)SiO₄ [11].

M.Diamon [12] separated the constituents from the clinker and analyzed them from the crystallographic point of view. Especially the belite crystal structure is refined as determined by the Rietveld method and the texture can be observed with the optical microscope SEM and TEM. As a result the crystal structure of the β -phase was almost consistent with the results for single crystals, although there was some difference in the lattice parameters and Si-O bonding distances between them.

The objective of our study is to obtain C₂S at low temperature in the presence of a composite additive «CuO+CaF₂» and to establish lattice parameters and constituent phases of C₂S and to determine any defect, and their type and concentration formed by the additive atoms.

2. EXPERIMENTAL

In order to synthesize C₂S chemically pure CaCO₃ and SiO₂ have been blended in molecular ratio 2:1 and were homogenized for 30 min with acetone in the ball mill, in the presence of (chemically pure) Al₂O₃, Fe₂O₃, H₃BO₃ stabilizers together with (chemically pure) CaF₂, CuO composite addition. The chemical composition of raw material is shown in Table 1.

Table 1. Chemical composition of the raw materials

	CaCO ₃	SiO ₂	Stabilizer			Composite addition	
			Al ₂ O ₃	Fe ₂ O ₃	H ₃ BO ₃	CaF ₂	CuO
Wt %	72.7	21.8	1.0	1.2	1.0	1.5	0.75

After mixing of the raw materials, pellets of Ø2.0 × 0.5 cm were pressed and dried at 105±5⁰C. The samples with a Pt cup were placed in a high temperature furnace, heated from room temperature to temperatures of 1000⁰C, 1100⁰C, 1150⁰C and 1200⁰C for 45 min. The heating-up rate is controlled at 20⁰C/min and the burnt samples were rapidly cooled in air. The Free CaO of the samples was determined by titration with ethanol-glycerol [13]. The study of the solid solution structure of the synthesized C₂S was carried out with an X-ray powder diffractometer (Guinier diffractometer D-

83253, RIMSTING, Germany, $\lambda = 1.540562 \text{ \AA}$, the $2\theta_0$ - range $0-50^\circ$, stepsize 0.001° , FWHM- 0.035°). The diffraction pattern was refined by Rietveld profile analysis using the GSAS program [14].

3. RESULTS

Comparative data of kinetics combining free CaO in the “ $2\text{CaO}+\text{SiO}_2$ ” system are shown in Figure 1.

Figure 1. Kinetics of combining of free oxide CaO depending on the burning temperature in the “ $2\text{CaO}+\text{SiO}_2$ ” system.
1- 1.5 wt% CaF_2 , 2- 1.5 wt% CaF_2 + 0.75 wt% CuO .

In Figure 1, it is clear that formation rate of C_2S solid solution is considerably increased and formation temperature is lowered to 1150°C in the system of “ $2\text{CaO}+\text{SiO}_2$ ” with CaF_2+CuO , addition used as shown in Table 1.

In the Figure 2, shows the x-ray powder diffraction pattern of C_2S with composite addition “ CaF_2+CuO ” at 1150°C .

The observed intensities are shown by dots (+), and calculated ones by the solid line. The positions of the Bragg reflections showed by the small vertical lines below the pattern. The line at the bottom indicates the intensity difference between the experimental and the refined patterns.

X-ray powder diffraction studies confirmed that one phase ($\beta\text{-C}_2\text{S}$: sp.gr. $\text{P2}_1/\text{n}$, monoclinic) without additional diffraction peaks which expressed another phase at diffractogram. The diffractogram of $\beta\text{-Ca}_2\text{SiO}_4$ did not show any diffusion peaks in the angle intervals $2\theta=13\div80^\circ$. The experimental and calculation lines are shown in Figure 2. It is clear from Figure 2 that there is a good fit between measured and calculated values.

In the initial model for refinement we used lattice parameters of the structure $\beta\text{-Ca}_2\text{SiO}_4$ [12] and refined parameters of background, profile of diffraction peaks, constant of unit cell (a , b , c , β), occupancy (n) of atoms, isotropic temperature factors (B_{ij}), co-ordinates (x/a , y/b , z/c) of atoms. The results of the refinement $\beta\text{-Ca}_2\text{SiO}_4$ are listed in Tables 2 and 3.

Figure 2. $\beta\text{-Ca}_2\text{SiO}_4$. Observed, calculated and difference X-ray powder diffraction pattern of crystal structure at 1150 °C ($\lambda=1.540562$ Å).

After refinement, the diffractogram established the parameters of unit cell as follows: $a=5.05472 \text{ \AA}$, $b=6.76212 \text{ \AA}$, $c=9.32795 \text{ \AA}$, $\beta=94.1667^\circ$, $V=346,285 \text{ \AA}^3$. The conditions of the x-ray measurement and the constants of the unit cell are shown in Table 2.

During refinement of the diffraction spectrum, some atoms of Ca(1) were substituted by atoms Fe and Cu, and some atom of O(1) were replaced by atoms of F (Table 3: $0.86\text{Ca} + 0.07\text{Fe} + 0.07\text{Cu}$; $0.73\text{O}(1) + 0.27\text{F}$). The R-factors improved appreciably in the first stage of the refinement structure with atoms Ca(1), O(1) being replaced by atoms Fe, Cu and F. The substitution of atoms was not noticeable in the change of parameters for the unit cell of $\beta\text{-Ca}_2\text{SiO}_4$. Obtaining positive means for isotropic temperature factors of atoms confirmed the selected structural model. The isotropic temperature factors chosen for substitution by other atoms provided the condition for stiochiometric substitution. In the first stage, calculation of diffraction spectrum R-factors were the following: $R_{WP}=5.4\%$, $R_p=3.2\%$, $R_E=3.1\%$.

In this structure model, the R-factors for the profile of peaks for the substituting atoms Fe, Cu and F was as follows: $R_{WP}=4.1\%$, $R_p=2.9\%$, $R_E=2.8\%$. In this selected model, the refined detail for isotropic temperature factors and atomic positions is shown in Table 2.

From the results obtained structural factors were used to calculate a Fourier map distribution density in the (110) phase of $\beta\text{-Ca}_2\text{SiO}_4$. The map distribution was calculated by using the GSAS program [14].

Figure 3 shows that the electron density is highest in the vicinity of Ca atoms, lower in the vicinity of Si atoms and lowest in the region where O atoms are present. The minimum electron density is $\rho_{\min} = -3.593e \text{ \AA}^{-3}$, the maximum $\rho_{\max} = 11.492e \text{ \AA}^{-3}$, $\Sigma \rho = 109.39e \text{ \AA}^{-3}$.

As we can see the corresponding symmetry is of monoclinic structure of $\beta\text{-Ca}_2\text{SiO}_4$ from the Fouriermap transformation of diffraction peaks. This calculation was consistent with research works [9, 12].

Figure 3. The distribution of density electron $\rho_{\text{exp}}(x,y,z)$ in the plane (110) of structure β - Ca_2SiO_4 . Shown fragment $7 \times 7 \text{ \AA}$ with coordinates centre $(1/2, 0, 1/2)$.
The number is indicated levels constant density electrons.

The isolated tetrahedrons SiO_4^{4-} were connected to two types of Ca^{+2} ions. Four atoms from 8 atoms $\text{Ca}(\text{Ca}(1))$ situated above and below tetrahedrons SiO_4^{4-} , formed the chains or stations. These stations are connected among themselves to another four atoms $\text{Ca}(2)$, which are located in the vacant structure between tetrahedrons.

The coordination $\text{Ca}(1)$ is not regular and the distance between Ca and O in the polyhedral CaO_n (where $n=6-9$) varied from a 2.25 to 3.19 Å, in one case but in another case from, but in other kinds – from 2.98 to 3.86 Å. Similarly $\text{Ca}(2)$ as well co-ordinated and the interatomic distance Ca-O varied between $2.39 \div 2.72$ Å.

Our synthesized β - Ca_2SiO_4 is deficient in atoms of Fe, Cu, and F the positions of almost all atoms are displaced from ideal positions (Table 3). The atomic distance of β - Ca_2SiO_4 was consistent with [9, 12] research works. For the polyhedron our calculations indicate that $\text{Ca}(1)$ was directly co-ordinated (bonded) to 9 oxygen atoms.

The Fouriermap transformation indicates a symmetric structure with the silicatetrahedra having $\text{Ca}(2)$ atoms parallel to this plane.

It was be concluded that the substitution of the $\text{Ca}(1)$ atoms by Fe and Cu mainly resulted in a disordered structure of β - Ca_2SiO_4 .

Figure 4. Atomic arrangement of structure β - Ca_2SiO_4 .

4. CONCLUSIONS

The forming temperature of the β - Ca_2SiO_4 at low temperature was decreased to 1150°C at synthesis of C_2S in the presence of composite addition.

Some Ca atoms were disordered and substituted by atoms of Fe and Cu, and some O atoms replaced F atoms in the β - Ca_2SiO_4 modification.

We are suggesting that the Ca(1)-O(2) 3.3774 Å bond is not contacted and defected in the crystal structure.

After refinement of the x-ray powder pattern by the Rietveld method, the chemical composition of solid solution β - Ca_2SiO_4 is defined by using composite addition. The final results show the following formula: β -($\text{Ca}_{1.86}\text{Fe}_{0.07}\text{Cu}_{0.07}$) $\text{Si}(\text{O}_{3.73}\text{F}_{0.27})$.

ABSTRACT

Granulated blast-furnace slag, BFS, exhibits a potential hydraulicity. Changes in the silicate anion structures during hydration of the BFS were studied with the trimethylsilylation method. A chain length development of the silicate anion during hydration was confirmed and an increase in relative abundance of trimer and pentamer was determined. Carbonation of the hydration products of BFS, ordinary portland cement and other binders resulted in shortening of the chain length of silicate anions. We concluded that the chain length distribution of silicate anion can reflect the degree of hydration as well as the degree of degradation of hardened body.

1. INTRODUCTION

Granulated blast-furnace slag, hereafter BFS, can be hydrated under an alkali stimulus exhibiting a potential hydraulicity. When BFS is added to ordinary portland cement, OPC, several new properties that can not be attained solely by the OPC are obtained. Thus BFS has been used as an admixture for concretes. Study of reactions during the hydration of these hydraulic binders and the resulting strength evolution of the hardened materials can be approached in terms of silicate structure. The silicate component in the hydraulic binders develops -O-Si-O- bonds during hydration forming polymeric silicate anions. The chain length development was determined by the trimethylsilylation, hereafter TMS, method in this study.[1]

We have studied the difference in surface structure of BFS with different Blaine surface areas by means of XPS, while in this study, effects of the Blaine surface area, type of alkali stimulus and age on the hydration of BFS powder were examined.[2] In addition, the chain length distribution of silicate anions during carbonation of BFS was also studied because the low resistance to carbonation, unlike to chloride attack, of the blast-furnace slag cement has been pointed out.[3]

2. EXPERIMENT

2.1 Materials used

The BFS powder specimen was a by-product of a factory and ground to a Blaine surface area of 4000, 6000, 8000, 11000 and 18000 cm²/g. Chemical compositions were similar, as shown in Table 1, and ranging from 32.7 to 33.4 percent for SiO₂, 12.6 to 13.4 percent for Al₂O₃, 40.9 to 41.7 percent for CaO and 6.9 to 7.8 percent for MgO.[4] Table 2 shows some chemical properties of BFS. Degree of vitrification was more than 98 percent for all the specimen and it was difficult to distinguish the BFS powders by the factors such as chemical composition, degree of vitrification and basicity.

Table 1. Chemical composition of blast-furnace slags

Blaine Surface Area (cm ² /g)	Composition (%)						
	MgO	Al ₂ O ₃	SiO ₂	CaO	TiO ₂	S	T · F e
4000	7.71	13.1	33.4	40.9	1.09	0.85	0.35
6000	7.63	12.7	33.1	41.7	1.10	0.85	0.26
8000	7.78	12.6	33.3	41.6	1.13	0.83	0.19
11000	6.9	13.4	32.7	41.6	---	0.3	0.5
18000							

Table 2. Chemical properties of blast-furnace slags

Blaine Surface Area (cm ² /g)	degree of vitrification	basicity
4000	98%	1.85
6000		1.87
8000		1.86
11000	---	1.89
18000		

2.2 Test Method

2.2.1 Hydration of BFS powder

Alkali stimulation of BFS powder was made using two types of alkali solutions: 0.1N-NaOH solution and Ca(OH)₂ saturated solution. 2.0 grams of BFS of each Blaine value was dispersed in 100 milliliters of the alkali solution and stirred thoroughly in an incubator. After being stimulated for a sufficient time, hydration of the BFS powder was interrupted by methanol and acetone and filtered under a reduced pressure to have the hydration products in a solid residue.

2.2.2 Carbonation of Hydrated Specimen

After hydration was interrupted, the suspension, a powder-water system, was subjected to an accelerated carbonation test. 3.0 grams of hydration product of OPC or BFS powder was dispersed in 300 milliliters of degassed water and stirred at a temperature of 20 °C, when a 100 percent carbon dioxide gas was introduced at a flow rate of 10 milliliters per minute for a specified time of 5, 10, 30 and 60 minutes. Subsequently, the suspension was filtered where hydration of the solid phase was again interrupted by methanol and acetone and subjected to silicate anion structure analysis.

2.2.3 Silicate Anion Structure Analysis by TMS Method

Derivatives of the hydration products of BFS were prepared according to the method improved for BFS trimethylsilylation by Sugihara and others[5],[6]. Trimethylchlorosilane (TMCS), hexamethyl-disiloxane (HMDS) and methanol were mixed at a volume ratio of 1:3:2. Resulting TMS agent of 18 milliliters was applied to 200 milligrams of specimen and stirred for 60 minutes at a temperature of 20 °C. 20 milliliters of pure water was added to the reacted specimen and soluble components were removed from the organic solvent phase by the liquid-liquid extraction. 2 grams of nonionic ion-exchange resin, AMBERLYST 15 (Rohm and Haas), was added to the organic solvent phase to prevent isomerization, and after 24 hours, it was filtered and thickened to less than 1.0 milliliter under nitrogen gas and analyzed by gas chromatography (GLC). Conditions of the analysis are as follows, GLC:GC-14B, detector: FID (Shimadzu), Column:Dexsil 400GC 2% on chromosorb w 60/80 AW, SUS column of 2 m x 3 mmφ (GL Science) and column temperature: 80-340 °C, 10 °C per minute. Composition of silicate anion was determined by integrating the peak area of GLC.

3. RESULTS AND DISCUSSIONS

3.1 TMS Derivatives of Silicate Anion

A gas chromatogram of derivatives of trimethylsilylated unhydrated BFS powder is shown in Fig. 1. Silicate anions with a chain length from monomer to hexamer were able to be analyzed by the GLC. Silicate anion structure of BFS with various Blaine surface areas was also trimethylsilylated and analyzed, but no significant difference was found as shown in Fig.2.

Figure 1. GLC chart of unhydrous BFS

Figure 2. Distribution of silicate anion of unhydrous BFS

3.2 Influences of the Hydration Time of BFS

Polymerization of silicate anion was generally found when the hydration time became longer, where monomer decreased and dimer increased. Components with a chain length greater than trimer were also found exhibiting the general tendency that the chain length of silicate anion developed with the evolution of hydration. An example of this change is shown in Fig. 3. A close look at changes in a silicate anion structure with a chain length greater than trimer showed that pentamer increased to a greater extent with ages though the detectivity was low compared to that of dimer. In contrast to the inactive changes of tetramer and hexamer, prominence of the pentamer increase is very distinctive and can be regarded as a parameter representing the degree of polymerization of the silicate anion structure.

Figure 3. Time course of silicate anion structure of BFS on hydration by $\text{Ca}(\text{OH})_2$

3.3 Influences of Alkali Stimulus

Changes in the distribution of monomer and dimer of silicate anions by the type of alkali stimulus are shown in Fig.4. When NaOH or $\text{Ca}(\text{OH})_2$ was used as an alkali stimulus, the tendency described in the previous section was reproduced while the rate of polymerization was slightly quicker with $\text{Ca}(\text{OH})_2$ than with NaOH .

Figure 4. The comparison of alkali activator on hydration of BFS

3.4 Influences of the Blaine Surface Area

Comparison of changes with hydration time in the silicate anion structure of BFS powder with different Blaine surface areas is shown in Fig. 5. At an early stage of hydration, no significant difference in structure was found between BFS powders with different Blaine surface areas. However under a longer hydration time, the BFS powder with a higher Blaine surface area exhibited a greater degree of polymerization. Only a BFS powder with a Blaine surface area of $4000 \text{ cm}^2/\text{g}$ showed nearly equal degree of polymerization without regard to alkali stimulus and age. As already proven by Tsuyuki and others [2], BFS powder with a different Blaine surface area exhibits several differences in the near-surface glassy phase. A BFS powder with a lower Blaine surface area has larger amount of $\text{Al}_2\text{O}_3\text{-SiO}_2$ glasses that shows lower reactivity than that of CaO-SiO_2 glass. Thus, when an alkali-stimulated hydration deposits C-S-H on the surfaces of BFS powder, considerable amounts of unreacted parts may be left inside of a BFS powder compared to those with a higher Blaine surface area. This accounted for the slow evolution in strength, at early ages, of a mortar partially substituted with BFS with a lower Blaine surface area. As a consequence from the viewpoint of silicate anion polymerization during BFS hydration, a considerable difference can be seen when the Blaine surface area of BFS, used as an admixture of OPC, exceeds $6000 \text{ cm}^2/\text{g}$.

Figure 5. The difference in the hydration velocity by blaine surface area of BFS

3.5 Influences of Carbonation on the Chain Length Distribution of Silicate Anions

Chain length distributions of silicate anion in OPC and BFS (8000 cm^2/g) treated in two different manners, hydrated for 28 days and then subjected to an accelerated carbonation, are compared in Fig. 6, Fig. 7, respectively. Similar to the case of OPC, silicate anion structure of hydrated BFS showed an increase in polymerization containing considerable trimers. When the hydrated BFS is subjected to accelerated carbonation, the chain length distribution tended to shift from longer to shorter and portion of monomer increased as the carbonation time increased. Thus the chain length distribution of silicate anion can reflect the degree of hydration as well as the degree of degradation of the hardened body.

Figure 6. Chain length distribution of OPC under the condition of hydration or carbonation

Figure 7. Chain length distribution of BFS under the condition of hydration or carbonation

4. CONCLUSIONS

Major findings in this study can be summarized as follows.

- (1) Chain length of silicate anions in BFS, particularly dimer and pentamer, developed with the evolution of hydration.
- (2) Hydration reactivity differed according to the Blaine surface area of BFS. Those with a larger Blaine surface area exhibited greater development in chain length during hydration, while those with a Blaine surface area less than 4000 cm²/g were supposed to be less reactive due to an accumulation of C-S-H gels on the powder surfaces.
- (3) When a hydraulic binder such as BFS or OPC is subjected to hydration or carbonation, the silicate anion structure, which is the main component of the reaction product, was altered greatly depending closely on the degree of hydration and carbonation.

ABSTRACT

Polycarboxylate superplasticizer (PC) is the most advanced cement dispersant having an excellent performance of water reducing and a superior workability retention ability to other superplasticizers. The fundamental dispersing mechanism of PC was presented at the previous ICCC. In order to estimate the behavior of fresh concrete containing PC, it is necessary to consider many other important factors affecting the performance of PC, *i.e.* the relationships of rheology among paste, mortar and concrete, the adsorption of PC, the adding effect of PC on the initial hydration of cement, the different adsorbing behaviors of PC on various cement hydrates, the adsorption equilibrium of PC, the competitive adsorption of PC with sulfate ions, and the molecular structure of PC. Considering these factors, based on the assumption that the performance of PC is proportional to the adsorbed amount of PC per surface area of solid phase (Ad/SSA), in this study, one model estimating the slump and its time change in concrete is proposed using only a few basic characteristics of cement and PC. In this model, PC is assumed to show a Langmuir type adsorption competitively with sulfate ions. This model is also applied to estimate the performance of several types of PC having different adsorbing abilities.

1. INTRODUCTION

In Japan, the studies of the working mechanisms of superplasticizer (PC) have been shifted from on beta-naphthalene sulfonate-type superplasticizer (BNS) during the 1980s and early 1990s [1, 2, 3] to on polycarboxylate-type SP (PC) in this decade although the studies on BNS have been continued internationally [4, 5, 6, 7, 8, 9, 10]. Many developments were tried in order to improve the slump retention ability of BNS in Japan. However, the new PC with much superior performance to keep the fluidity constant up to several hours or more has been developed and the usage of BNS has been limited in precast concrete where the slump retention was not so important. This situation limited the study on the working mechanism of slump retaining behaviors of BNS. Instead of BNS, the slump retaining mechanism of PC has been studied intensely. Because the variety of chemical structure of polycarboxylate that can be modified, many functions can be adjusted and a high dispersing performance and a good slump retaining ability have been achieved by using new PC [11, 12, 13, 14, 15, 16].

After wide applications of PC for high-strength and high-fluidity concrete [17], it became clear that controlling workability uniformly was not always easy especially at low water-to-cement ratio (W/C). For example, the use of different types and different lots of cement and aggregate can cause unexpected fluctuation of the workability of concrete. Moreover, even if the same materials were used, the workability could be changed by mixing machines, procedures and environmental conditions. The mechanism of these unexpected fluctuations has not been clarified and these phenomena have been explained as incompatibility [18, 19].

On the other hand, significant progress has been achieved in understanding the fundamental dispersing mechanism of SP. The electrostatic repulsive force and the steric hindrance effect have been shown to be fundamental dispersing mechanisms of BNS and PC, respectively [20]. In order to apply these fundamental mechanisms to control the workability of concrete and to prevent incompatibility phenomena, many researches have been carried out. Many of these studies were in simple forms of paste or mortar. It is very important to estimate the workability of concrete such as slump and it is meaningful to try to explain concrete slump.

Based on this background, in this study at first, the interaction mechanism of cement and PC is summarized based on many studies and the required factors and assumptions to be considered for the model used in the next step are discussed. After this, basic behaviors of PC are linked to concrete slump by a simple model using a Langmuir type adsorption equilibrium. Finally, this model is applied for the estimation of the slump retaining behavior of PC with different adsorption abilities when several kinds of cement are used.

2. CONSIDERING FACTORS

The fundamental dispersing mechanism of PC has been established by several studies [20, 21, 22]. The final goal of the study on the working mechanism is the estimation of the workability of concrete based on several material characteristics such as cement, aggregate, SP, mix proportion and mixing procedures by using this fundamental mechanism. In this chapter, in order to link the steric hindrance effect of PC with the workability of concrete, some factors necessary to be considered are shown with several assumptions.

A stratified image considered in this study is shown in Figure 1. By adsorbing PC, the inter-particle potential is determined by steric hindrance effect. For the adsorption, the solution chemistry, especially sulfate ions, play an important role. In order to convert the inter-particle potential to the paste rheology, the potential is assumed to be proportional to the adsorption amount of PC per surface area of solid phase of hydrated cement (Ad/SSA) and the Ad/SSA is assumed to be proportional to the paste flow as an index of the paste rheology. For the SSA , the initial hydration of cement affects. The initial hydration of cement is affected by the cement characteristics, PC addition, mixing procedure and others. Paste rheology determines mortar rheology. Clay minerals in the fine aggregate affect the performance of PC. The mortar rheology determines the concrete rheology subject to the effect of mix proportions.

Figure 1. Conceptual diagram from the working mechanism of PC to the workability of concrete.

2.1 Inter-Particle Potential

2.1.1 Steric hindrance effect

It is assumed in general that the chemical structure of PC is a comb-type and the steric hindrance effect is attributed to the graft chains. However, it is quite difficult to analyze the actual structure of PC. As is the case for copolymers of maleic anhydride and PEG-allylether, monomers are expected to be polymerized reciprocally to form a typical comb structure and show good performance even at very low W/C. As for copolymer of acrylic acid and acrylate-Mt-PEG ester, monomers are expected to be polymerized randomly and in some synthesizing conditions, the methoxy group is debonded at the end of the PEG chain, and from this portion another trunk chain can be grown to form an irregular shape [23]. Moreover, the conformation of the adsorption is also obscure. Although a computer simulation of the adsorption of PC shows the possibility of the adsorption may be initialized at the end of a trunk chain as shown in Figure 2 [24], the final conformation of the adsorption is not clear. This ambiguity may be important only at the very low W/C below 25% because superior dispersing effect is required in these conditions. A theoretical calculation indicates that the thickness of the adsorbed layer is required to be more than 10nm for particles of 1 μm radius. This thickness corresponds to the 20-30 repetitions of unit oxyethylene of PEG chain. The PEG concentration on the surface of solid phase is the critical point.

Figure 2. Simulation of the adsorption of PC

The first assumption is that the steric hindrance effect is proportional to the adsorption amount of PC in specific conditions. Required conditions of this assumption are the following: copolymers having carboxylic groups for the adsorption, W/C of paste higher than 30%, graft chain of PC longer than 20 repetitions of unit oxyethylene, and the adsorption amount is against the surface area of solid phase not against the mass of it.

2.1.2 Adsorption

There are two important factors that have not been recognized clearly for the adsorption of SP. One is the surface area of the solid phase and the other is the competitive adsorption equilibrium of SP with anions. The adsorption of PC on hydrated cement usually occurs in a Langmuir-type. However, hydrated cement is composed of multi phases. PC has been thought to be adsorbed on C_3A more than calcium silicates as well as BNS [3]. It is not the adsorption amount per mass of clinker minerals which is the important parameter but the adsorption amount per surface area of hydrates. C_3A cannot be an unhydrated phase in water but changes into some hydrates with larger surface area than originally. Besides, the adsorption of SP is not so strong. It was demonstrated the adsorption is reversible depending on the chemical composition of the aqueous phase [16]. Therefore, it is important to pay attention for the solution chemistry.

Considering these points, the adsorption isotherms of PC on typical hydrates were examined as shown in Figures 3 and 4 [25].

Figure 3. Adsorption isotherm of PC on AFt.

Figure 4. Saturated adsorption amount of PC [25].

As a result, the saturated adsorption amount per *SSA* of ettringite (AFt) is larger than those of other phases such as C-S-H, gypsum, portlandite, and calcite. This indicates that the initial hydrate of C_3A is important for the *Ad/SSA*. PC shows a Langmuir type adsorption isotherm for AFt, C-S-H, gypsum, and calcite. As for portlandite, PC shows a Freundlich type adsorption isotherm and when the dosage of PC is very high, *Ad/SSA* of portlandite will be close to that of AFt. It assumed the competitive adsorption between PC and SO_4^{2-} , *Ad/SSA* can be expressed by a function including parameters of PC concentration $[PC]$ and SO_4^{2-} concentration $[SO_4^{2-}]$ as shown in Equation (1).

$$N_{PC} = \frac{N_i \cdot K_{PC} \cdot [PC]}{1 + K_{PC} \cdot [PC] + K_{SO} \cdot [SO_4^{2-}]} \quad (1)$$

where N_{PC} is the number of adsorbed PC on the surface of solid i , N_i is the number of adsorption site on the surface of solid i corresponding to the saturated adsorption amount of PC, K_{PC} is the constant of adsorption equilibrium of PC, K_{SO} is the constant of adsorption equilibrium of sulfate ion.

In Equation (1), N_i is assumed as constant even when $[SO_4^{2-}]$ is changed in this study. There is a possibility that N_i is dependant on $[SO_4^{2-}]$. The adsorption site of PC is Ca adsorbed on the hydrate and the Ca density is believed to be affected by $[SO_4^{2-}]$ in a coexisting aqueous phase [26]. For the accurate discussion on this possibility, more data are needed. The second assumption is that *Ad/SSA* can be calculated by Equation (1).

2.1.3 Solution Chemistry

The steric hindrance effect by PEG is assumed not to be affected by ionic strength in aqueous phase and the electrostatic potential of BNS is assumed to be affected significantly in many cases. As for the later, besides the effect of ionic strength, the adsorption amount plays an important role. When NaCl is added to cement paste containing as much as 2M BNS, the adsorption amount is almost constant and the fluidity shows only a slight decrease. When Na_2SO_4 is added to cement paste with as much as 0.1M BNS, the adsorption amount and the fluidity decrease significantly [27].

In the case of PC, apart from the effect on the adsorption amount, there are two possibilities of the effect of solution chemistry; the shrinkage of PEG [28] and the shrinkage of trunk chain [12, 16]. A direct measurement of the steric size of PEG and PC in aqueous solutions by using a light scattering method shows that the size of PEG is independent of the ionic strength and that the size of trunk chain decreased in high ionic strength conditions [16]. The shrinkage of trunk chains may be caused by the reduction of electrostatic repulsive force among carboxylic groups in a trunk chain. This

result indicates that the dispersing performance of PC is almost constant as long as Ad/SSA is constant. However, a slight decrease of the performance of PC with the increase of ionic strength is observed experimentally even when the adsorption amount was constant [29]. This is thought to be the reduction of adsorbed area that one molecule of PC covers because the spread of trunk chain decreases.

The most important effect of solution chemistry is the behavior affecting the adsorption of PC. It has demonstrated that the adsorption of SP whether SP is PC or BNS, is in adsorption equilibrium. The adsorbing portion of PC is the carboxylic groups and they are adsorbed on calcium sites of cement hydrates competitively with anions showing affinity to calcium such as sulfate ion, carbonate ion, phosphate ion. The third assumption is the effect of solution chemistry only for the adsorption of PC.

2.2 Particle Dispersing Effect and Fluidity

2.2.1 Inter-Particle Potential and Paste Rheology

The main dispersing effects of particles by SP are electrostatic repulsive forces and steric hindrance effects. Presently, there is only one example that the inter-particle potential is converted to the paste rheology theoretically. That is HI theory estimating the plastic viscosity from the electrostatic potential [30]. In other cases, there is no theoretical method estimating the rheology of paste from the inter-particle potential. Therefore, in this study, the particle dispersing effect of SP is assumed to be proportional to Ad/SSA and Ad/SSA is proportional to the paste fluidity (the fourth assumption). Proportion constants are different for different kinds of SP or different mix proportions.

2.2.2 Specific Surface Area

Because cement shows hydration activity, SSA after the hydration and its time change should be considered. Moreover, SP affects the hydration of cement. Every SP shows affinity with Ca^{2+} and SP reduces Ca^{2+} concentration $[Ca^{2+}]$. The initial hydration of C_3A is restrained by the formation of Ca-S-Al-O-H hydrates. In this process, the supply of Ca^{2+} and SO_4^{2-} is very important. If the $[Ca^{2+}]$ decreases, the hydration of C_3A is not restrained effectively and as a result more hydrates such as Aft will be formed and SSA increases. This effect is significant in the case of very low f-CaO in cement [31].

In the case of BNS, hydration processes of cement are completely different depending on the timing of addition [16]. By delayed addition, the increase of SSA is restricted and this seems to result in a good fluidity retention. In the case of PC, the number of carboxylic group per mass of PC is the critical point [23]. When a PC showing higher adsorbing ability that is not affected by SO_4^{2-} is used or the PC dosage is very high at very low W/C, more carboxylic groups reduce $[Ca^{2+}]$ more and this results in the increase of SSA . From this evidence, the delayed addition of PC is very effective in the case of very low W/C conditions.

Moreover, aggregates affect the hydration of cement by the mixing effect [32]. The effect can be evaluated by the SSA of solid phase of the paste in mortar and concrete. Although clay minerals also affect the adsorption of PC [33], because the relationship between the PC adsorption by clay minerals and the fluidity is obscure, this effect is neglected in this study (the fifth assumption).

2.2.3 The mechanism of time change of paste flow

The time change of paste flow is assumed to be determined by the change of Ad/SSA (the sixth assumption). As shown in Figure 5, Ad/SSA can be changed by the change of SSA and $[SO_4^{2-}]$. SSA increases with the progress of cement hydration and reduces Ad/SSA . $[SO_4^{2-}]$ decreases with the progress of cement hydration and raises Ad/SSA . By the balance of these two effects, the change of Ad/SSA with time is determined. SSA and $[SO_4^{2-}]$ are regarded as given parameters for every experiment because the estimation of these parameters from basic characteristics of cement and mix

proportions are quite difficult (the seventh assumption).

Figure 5. Fundamental concept of the working mechanism of the time change of paste fluidity containing PC.

2.3 The Workability of Concrete and the Fluidity of Paste

As an index of the workability of concrete, slump is considered in this study. By affecting the dispersion of cement particles, PC changes the paste flow. In order to explain the concrete slump by the working mechanism of PC, the required condition is that the concrete slump is governed by the paste flow (the eighth assumption). This condition is usually achieved in well-proportioned concrete. Of course, the characteristics of aggregate and mix proportion affect the relationship between the paste fluidity and the concrete slump. Proper proportioning of concrete is thought to be very important for the durability of concrete structures by eliminating by defects in the concrete placing process.

3. EXPLANATION OF CONCRETE SLUMP BY THE WORKING MECHANISM OF PC

Satisfying the eight assumptions mentioned above, concrete slump is determined by paste flow, paste flow is determined by Ad/SSA , Ad/SSA is determined by the adsorption isotherm of PC. In other words, by using several parameters describing the adsorption isotherm of PC, it is possible to estimate the concrete slump. Hereafter, a model estimating concrete slump is proposed. In this example, nine kinds of NPC from different plants satisfying the JIS standard were used. The difference of concrete slump by the difference of cement characteristics and the changes of slumps with time elapse are explained by the model. Finally, based on the model, the performances of several PC having different adsorbing abilities are estimated.

3.1 Experiments

In order to reproduce incompatibility phenomena, W/C was set as low as 37.5%. Maximum aggregate size was 20 mm, the unit cement content was 400kg/m^3 , the air content was 4.5–1.0%, and the dosage of PC was 0.8 mass% of cement. PC used was commercial one and the solid concentration was 25.8%. The length of PEG was 23-repetition of oxyethylene.

Cement and aggregate for 30l of concrete were put in a pan-type mixer of 50l-capacity and mixed for 30s. Water containing PC was added and mixed for 90s. The mortar in the mixed concrete was extracted by wet screening with a sieve of 5mm opening. Cement paste was mixed for 3min with a Hobart mixer. The change of fluidity with time elapse was evaluated by the wet screened (WS) mortar.

Concrete slump was measured according to JIS A 1101. Mortar flow was measured according to JIS R 5201 without drops. The bottom radius of a cone was 10cm. Paste flow was measured according to JASS 15M103. A pipe of 50mm radius and 51mm height was used.

The analysis of paste was carried out as follows. Because *SSA* of concrete is mainly determined by the fine particles such as cement hydrate, the paste was separated by a sieve of 63 μm opening from the WS mortar from the concrete and the *SSA* was measured by one point BET method using N_2 gas adsorption. The aqueous phase was separated by a centrifugal separator from WS mortar. The adsorption amount of PC was estimated by comparing the PC concentration by a total carbon analyzer in the mixing water and in the extracted solution from paste of each age. The $[\text{SO}_4^{2-}]$ was measured by an ion chromatograph.

3.2 Relationship between Concrete Slump - Mortar Flow - Paste Flow

The relationship between the concrete slump and the paste flow just after mixing is shown in Figure 6.

Figure 6. Concrete slump and paste flow.

The paste flow shows a good correlation with the concrete slump in this case and the concrete slump can be considered to be determined by the paste flow. The relationship between the concrete slump and wet screened (WS) mortar just after mixing and at one hour after mixing is shown in Figure 7. There is a good correlation between them. Hereafter, WS mortar flow is discussed. In Figure 8, the changes of WS mortar flow are shown. Initial flow is different from cement to cement. The flow decreases with time in all cement.

Figure 7. Concrete slump and WS mortar flow. Figure 8. Change of WS mortar flow with time.

3.3 Analysis of WS Mortar Flow by the Working Mechanism of PC

Based on the working mechanism of PC, *Ad/SSA* is expected to show a correlation with WS mortar flow. The *SSA* just after mixing was in a range from 1.64 to 1.78 m^2/g depending on the kinds of cement used. The *SSA* increased to a range from 1.81 to 2.01 m^2/g after 2 hours. PC adsorption ratio was in a range from 67 to 76% just after mixing and increased in a range from 74 to 83%. $[\text{SO}_4^{2-}]$ was in a range from 60 to 95 mM and decreased to a range from 44 to 76 mM. Based on these data, *Ad/SSA* was calculated and the relationship with the WS mortar flow is shown in

Figure 9. Ad/SSA is almost independent of time elapse and no clear relationship with MS mortar flow is obtained.

Figure 9. Ad/SSA and WS mortar flow.

Sugamata *et al.* [34] suggested a good relationship between the PC remained in the aqueous phase and the fluidity for a specific combination of PC and cement. The relationships in this study were examined and the result is shown in Figure 10. Although there are positive relationships for all kinds of cement, the relationships are different significantly from cement to cement.

Figure 10. $[PC]$ and WS mortar flow.

Why was no clear relationship observed between Ad/SSA and the WS mortar flow? One possible explanation is a wrong assumption. For the calculation of Ad/SSA , the values used of SSA were from the N_2 gas adsorption test. In this method, it is presumed that the PC adsorption is similar to the adsorption of N_2 gas. As described in the section 2.1.2, the adsorption amount of PC is different for each solid phase. Aft adsorbs PC three times more than C-S-H. This means that the SSA of each phase is important for the calculation of Ad/SSA . However, it is difficult to estimate the SSA of each phase in cement paste.

This problem can be avoided by using Equation (1) and the mass reservation equation for added PC, Equation (2).

$$Dos = [PC] \times W + N_{PC} \times N_i \quad (2)$$

where Dos is the added amount of PC and W is the water amount. N_{PC} and N_i correspond to Ad/SSA and SSA respectively. Dos can be separated to the amount of PC remaining in the aqueous phase: $[PC] \times W$ and the amount of PC adsorbed on the solid phase: $N_{PC} \times N_i$. By using Equation (2), an

unknown parameter N_i in Equation (1) can be eliminated. Finally, Ad/SSA can be calculated from only two parameters, $[PC]$ and $[SO_4^{2-}]$.

As for the K_{PC} and K_{SO} , both constants were calculated by a minimum least square method for the isotherm of Aft. In this calculation, because the significant hydrate phase for the PC adsorption is thought to be Aft, it is assumed that Aft is the only solid phase adsorbing PC. By using these constants and the experimental data of $[PC]$ and $[SO_4^{2-}]$, Ad/SSA was calculated from Eqs. (1) and (2). The relationship between the estimated Ad/SSA and the WS mortar flow is shown in Figure 11. Compared with Figure 9, each line becomes closer. Although there is some room to improve, the whole trend of MS mortar flow can be explained by this method.

Figure 11. Estimated Ad/SSA and WS mortar flow.

4. AN APPLICATION OF THE MODEL FOR VARIOUS TYPES OF PC

By using the proposed model, the performances of various types of PC can be simulated. In this simulation, several types of PC with higher adsorbing ability and lower adsorbing ability are examined because one of the important characteristics of PC is the adsorbing ability [23]. As a standard PC, the PC used in the section 3.3 is used (PC1). PC with the higher adsorbing ability is relatively free from the effect of SO_4^{2-} and *vice versa*. On the other hand, PC with the higher adsorbing ability has poorer fluidity retaining ability and *vice versa*. PC with the higher adsorbing ability (PC2) and lower adsorbing ability (PC3) are simulated by changing K_{PC} five times higher and one-fifth lower, respectively, based on the experimental data [24]. Cements used are selected to have different content of alkaline sulfate. PC shows better initial fluidity but larger fluidity loss for cement with higher alkaline sulfate and *vice versa*.

From the results mentioned in 3.0, there are correlations between Ad/SSA and the WS mortar flow, and between the WS mortar flow and the slump of original concrete. Therefore, the concrete slump is expected to be estimated by Ad/SSA . In this estimation, three parameters, N_i , $[PC]$, and $[SO_4^{2-}]$ are used. In this case, by using Equation (2), $[PC]$ is eliminated. From several kinds of cement in the section 3, three kinds of cement showing different behaviors are selected. The dosage of each PC is adjusted to show the slump of 20cm for NPC3.

The slump retention of each combination of PC and cement is shown in Figure 12. The expected behaviors of PC are successfully demonstrated by this model. PC2 shows less variation of initial slumps and larger slump losses and PC3 shows larger variation of initial slumps and good slump retention behaviors.

Figure 12. Estimated dispersing behaviors of various types of PC for different kinds of cement based on the working mechanism of PC.

5. SUBJECTS FOR THE FUTURE STUDY

In this study, the simulation of the performance of PC in concrete has been demonstrated by using several experimental data. It is ideal to estimate the workability of concrete or the slump from the characteristics of materials and mixing conditions. For this goal, the estimation of the time changes of SSA and $[SO_4^{2-}]$ of cement paste is inevitable. The contribution ratio of each of the mineral and gel phases to SSA and the PC adsorption is also important. These parameters are affected by many factors such as cement characteristics, mix proportion, types of SP, dosage of SP, adding method, mixing procedure and mixing temperature. Therefore, every effect of all factors is required for perfect estimation of the performance of PC. Although some of them have been clarified to some degree, much research is still necessary. As for BNS, a similar approach for the estimation of the performance of BNS is possible and it will be published in another report [34].

6. CONCLUSIONS

Based on the working mechanisms of PC clarified presently, a model using limited factors of cement paste have been proposed to explain the concrete slump with several assumptions. The model was also applied to estimate the behaviors of several kinds of PC with different adsorbing abilities.

- In order to link the most fundamental working mechanism of PC to the concrete slumps, several assumptions are necessary: 1) Proportional relationship between the steric hindrance effect and the adsorption amount of PC per surface area, Ad/SSA , 2) Expression of Ad/SSA by the Langmuir type equation including two parameters $[PC]$ and $[SO_4^{2-}]$, 3) Limited effect of solution chemistry on the adsorption equilibrium of PC, 4) Proportional relationship between Ad/SSA and paste flow, 5) No effect of clay minerals, 6) Obedience of the change of paste flow with time on the change of Ad/SSA , 7) Give data of $[PC]$ and $[SO_4^{2-}]$, and 8) Governance of concrete slump by the paste flow.
- On these assumptions, Ad/SSA is estimated from the measured $[PC]$ and $[SO_4^{2-}]$ in the aqueous phase of concrete with nine kinds of cement from different plants and a model using these parameters is proposed. The model successfully explains the WS mortar flows from concrete.
- The proposed model is applied to simulate the behaviors of various kinds of PC with different adsorbing abilities by changing adsorption coefficients of PC five times higher or one-fifth lower than a commercial PC. The simulation estimates the typical behaviors of PC that the PC with higher adsorbing ability shows less fluctuation of slumps by the difference of cement characteristics just after mixing although it shows larger slump losses. Conversely, although the

PC with lower adsorbing ability shows more fluctuation of slumps just after mixing, it shows excellent slump retentions.

ACKNOWLEDGEMENTS

Concrete experiments were carried out by Mr. S. Shirokuni, Mr. K. Toriiminami and other members of the Concrete Laboratory of Kawara Taiheiyo Cement Corp. The chemical analyses were carried out by Mr. H. Ozu and Ms. M. Yano of Research & Development Center, Taiheiyo Cement Corp. The authors wish to express our gratitude for their cooperation.

ABSTRACT

We report new experimental data on the system calcium hydroxide-calcium sulphate-alkali sulphate-water over the temperature range 5° – 30°C. Experiments have been performed using either potassium or sodium as the alkali metal, and results for the pure system at 30°C are in very good accord with those of Hansen and Pressler (1947). The principal solid phases present are portlandite, gypsum and syngenite. Conductimetric measurements show that, in the “admixture-free” system, equilibrium is usually obtained within only a few tens of minutes. The solubility product of syngenite decreases with decreasing temperature, while those of portlandite and of gypsum increase, displacing the intersections between the solubility isotherms. In the presence of organic admixtures of the type generally used as “superplasticizers” (SP) in Portland cement concretes, some minor changes in apparent solubility products are observed that can be attributed to weak complexation of calcium ions and/or the neutralisation of hydroxide ions by the SP molecules.

1. INTRODUCTION

There is great interest in understanding the mechanisms by which high-range water-reducing admixtures, commonly known as superplasticizers (SP), are able to “improve concrete rheology” (i.e., to reduce the effective viscosity of fresh concrete at constant mix composition.) It is now well-established that SPs function by adsorption onto the surfaces of the particles in concrete, producing repulsive forces, which can be either electrostatic or steric in nature [1]. These repulsive forces can greatly reduce the tendency of cement grains and other fine particles in the concrete to flocculate, giving a suspension which is much better dispersed than the SP-free system. However, we still do not know exactly how typical SPs are adsorbed on the surfaces of cement grains, and how the performance of a given SP is related to its chemical composition. There are also important unanswered questions regarding the effectiveness of specific cement-SP combinations, since no two cements or SPs are identical: some couples work better than others for certain types of concrete.

In order to better understand cement-SP interactions, we must be able to model the chemistry of the aqueous phase in fresh concrete, or at least the equivalent liquid extracted from cement pastes or mortars which are believed to simulate the chemistry of fresh concrete. It has been known for many years that, in the admixture-free cement-water system, the aqueous phase contains principally alkali metal (potassium and sodium) ions, calcium ions, sulphate ions and hydroxide ions [2]. Other species, such as silicate, aluminate, iron compounds, etc., are present at much lower concentrations, except in very unusual circumstances. In many respects, the system can be regarded as a perturbed lime-gypsum solution, that is, it is close to equilibrium with crystalline portlandite and gypsum.

In practice, it is usually slightly supersaturated relative to one or both of these phases [3]. The main independent variable is thus the amount of soluble alkali in the cement. Portland cement clinkers can contain alkali sulphates at levels of up to about 2% by mass, and these highly soluble salts dissolve very rapidly when the cement is mixed with water. Some additional alkali may also be released into solution at early ages (as hydroxide) by the hydration of the aluminates phases. The amount of soluble alkali, and its potassium/sodium ratio, is a characteristic of a particular cement.

In order to determine exactly how an organic additive, such as a SP, perturbs the composition of the aqueous phase in cement systems, it is not sufficient simply to run a control mix with no admixture. This is because such admixtures can influence both the equilibrium parameters and the kinetics of cement hydration; and, in studying fresh concrete, we are dealing with a reacting system far from equilibrium, in which many reactions occur simultaneously, several of which may be perturbed by the presence of the additive. Ideally, we should first study reference systems in which a true chemical equilibrium can be obtained, in order to obtain the influence of the additive on the equilibrium system, before studying the reacting system. We have chosen to do this by starting with the simple portlandite-gypsum system. The compositions of alkali solutions in equilibrium with portlandite and gypsum at 25°C and 30°C were established by Hansen and Pressler (H&P) over 55 years ago [4], but, as far as we are aware, no study has yet been made on how this system responds to perturbation by water-soluble organic polymers.

2. EXPERIMENTAL

In the present study, we chose to work at 30°C, 20°C and 5°C. 30°C was chosen so as to have data in common with those of H&P, 20°C was chosen because it is commonly used as a standard in lab experiments on cement and concrete, and 5°C was chosen a “practical” lower limit. We chose to use solid alkali sulphates as the source of alkalis, since they are easier to weigh in air than the hydroxides used by H&P; thus, we approached equilibrium from a different direction. We also chose a set of commercial superplasticizers that span the range of types commonly used in concrete.

For each equilibrium assemblage, we generally began by adding 6.75g of reagent-grade calcium hydroxide (portlandite) and 0.75g of reagent grade calcium sulphate dihydrate (gypsum) to 75ml of either de-ionised water or prepared solution in a 100ml Pyrex flask (which minimised the dead volume once the flask was sealed with a glass stopper). The prepared solutions contained dissolved superplasticizers, or alkali sulphates, or both, in order to give the desired initial concentrations of alkali metal ions and superplasticizers in the liquid phase. In no case did the amount of alkali sulphate or SP added approach the titration capacity of the 6.75 g of portlandite, thus ensuring that there was always some solid portlandite and gypsum present. [Note: since the alkali was provided as a sulphate, the ratio of solid portlandite/gypsum in the equilibrium mixtures decreased with increasing alkali concentration, but in cases where significant amounts of syngenite formed gypsum too was consumed, and in these cases more than 0.75g was used.] The sealed flasks were immersed in water baths controlled to within $\pm 0.1^\circ\text{C}$ and agitated gently for at least 48 hours. In order to be able to follow the approach to equilibrium, the conductivities of the solutions were measured frequently, and were observed to approach steady-state values very rapidly (within a few minutes) in most cases, although some SPs appeared to retard this process slightly. Nevertheless, in order to be absolutely sure of equilibrium, we held all of the suspensions at the desired temperature for at least 48 hours before filtering and analysing any of the mixtures.

The suspensions were allowed to settle for a short period before samples of the supernatant were taken and filtered rapidly under an elevated pressure of nitrogen (to avoid carbonation). The resulting filtrate samples were weighed and immediately titrated with 0.1N HCl to pH 7.0, to stabilise them against carbonation and to obtain an estimate of the hydroxide concentration. The stabilised solutions were analysed for sodium and potassium by flame photometry, for calcium by

complexometry, and for sulphate by turbidimetric titration against a solution of BaCl_2 . All three techniques were conducted following the procedures of EN 196, and the typical coefficients of variation (in-lab repeatability) were conservatively assumed to be 1.3% for the alkali metals, 1.2% for calcium and 2% for sulphate (by taking the higher of either the typical values quoted in the European norm or those obtained in our own calibrations). We also conservatively assumed a coefficient of variation of 5% for hydroxide. (Note: A second series of solutions, including those prepared at 5°C, was analysed slightly differently, and no hydroxide titrations were done on them.)

Four different commercial SPs were chosen for this study; one was of the MSFC class, (a modified melamine sulfonate formaldehyde condensate containing sulphanilic groups,) and the other three were members of the “PCP” class (comb polymers based on polycarboxylic acid polyoxyethylene esters.) The dosages used were based on the concentrations that were found to be necessary to give about the same initial slump in typical superplasticised concretes. In a few cases, the liquid phase was analysed for total SP by the total organic carbon method (TOC), conducted by an outside laboratory following the EN 1484 procedure, with a typical coefficient of variation of 2%.

3. RESULTS

3.1 Equilibrium in the absence of superplasticizers

All of the results obtained at 20°C are shown in Figure 1, and the results obtained at 5°C and 30°C are shown in Figure 2. The ‘2nd series’ results in these figures were obtained by a different operator than the first series, but there is reasonably good agreement, as can be seen in the graphs. (Note that the results shown in figure 2 are all 2nd series except for those with Na at 30°C.)

Figure 1. Results at 20°C

Also included in Figure 1 are a set of data obtained in the absence of portlandite, i.e. for the simple equilibrium between gypsum and potassium sulphate at 20°C. As expected, they show lower calcium concentrations and higher sulphate concentrations than the solutions in simultaneous equilibrium with portlandite at equivalent alkali concentrations.

Figure 2. Results at 5° and 30° C

Table 1 gives the concentrations measured in the first series of experiments, without organic admixtures. (Note: In this case, Na^+ concentrations were not measured but rather assumed constant in the runs with added K_2SO_4 , and vice-versa for K^+ in the runs with added Na_2SO_4 .) The data at the highest sodium concentrations show a rather poor anion/cation balance, but are still within the probable range of error quoted for our analytical methods. Below $[\text{R}_2\text{O}] = 200\text{mM}$, they generally show good agreement (at 30°C) with the data obtained by H&P [4], and there is also relatively little difference between our data obtained at 20°C and their data obtained at 25°C. However, at higher alkali concentrations there are some differences, which can be ascribed to two different effects:

- (1) The formation of syngenite, ($\text{K}_2\text{SO}_4\text{-CaSO}_4\text{-H}_2\text{O}$), in the system with $\text{R}=\text{K}$. This was also observed in H&P's work. The onset of syngenite formation leads to decreases in potassium, calcium and sulphate concentrations below the portlandite-gypsum equilibrium curves, and this onset occurs at lower K_2O concentrations at 20°C than at 30°C. The effect of syngenite formation at 20°C can clearly be seen in Figure 1 for the second series of data with potassium. Similar results were obtained in the first series but we found that the amount of gypsum used in the initial mixtures had been set too low to compensate for syngenite formation, and it was increased in the 2nd series to ensure that there was always some residual gypsum at equilibrium. (Note: We also observed that the onset of syngenite formation occurred at lower alkali concentrations as the temperature decreased, but did not attempt to locate the invariant point precisely in the experiments reported here.)
- (2) Anhydrite formation. There is also a divergence in the results at the highest sodium concentrations; H&P's final data point at 30°C and $[\text{Na}_2\text{O}] = 375\text{ mM}$ gives much lower concentrations of both calcium and sulphate ions than our data, and there is little reason to believe that any double salt (sodium-calcium-sulphate) forms at this sodium concentration.

This result supports the hypothesis of Gartner *et al* [6], who suggested that anhydrite may have formed in H&P's experiments at high sodium concentrations, because the alkali would decrease the activity of water in the system relative to the alkali-free system, and thus should lower the temperature of the gypsum-anhydrite equilibrium point, which is close to 40°C in the absence of other salts. There was no evidence for anhydrite formation (checked by IR analysis of the solid residue) in any of our experiments; however, the rates of nucleation, growth and dissolution of

anhydrite are known to be very slow relative to other calcium sulphates, and they may thus, under these conditions, be sensitive to the presence of anhydrite nuclei in some sources of gypsum [7].

The data for the SP-free solutions at 20°C were used to calculate simple ionic solubility products for the compositions Ca(OH)₂, CaSO₄ and K₂Ca(SO₄)₂, based on the simplifying assumption that the solutions contained only the simple ions K⁺, Na⁺, Ca⁺⁺, OH⁻ and SO₄⁼. Results are shown in Figure 3. The first two of these three simple ionic solubility products represent the saturation values for portlandite and for gypsum, respectively, given that we had deliberately made sure that excess of these two solids was always present. The third solubility product represents the saturation values for syngenite, which is known to form at potassium sulphate concentrations of above about 165 mM at 20°C in the simple K₂SO₄-CaSO₄ system [5]. This product is only shown for the three solutions with values of [K₂O] well above 200mM, and formation of syngenite in these three mixes was confirmed by IR and DTA analyses of the filtered solids. Simple ionic products are, of course, not expected to be constant with varying ionic strength. All of the observed simple ionic solubility products increased with increasing alkali concentration, as would be expected, since the activity coefficients of all of the ions decreased with increasing ionic strength over the range of interest.

At first sight it seems surprising that the portlandite ionic product shows a smaller dependence than that of gypsum on alkali concentration. However, this is probably due to the two moles of water included in each mole of gypsum, because the activity of water decreases as alkali concentration increases, (which should then require an increase in the simple ionic solubility product to compensate). The syngenite solubility product shows by far the greatest alkali concentration dependence, which is not surprising since it is a quintuple ionic product, and the simple molecular formula of the solid phase also contains one molecule of water.

Figure 3. Simple ionic solubility products at 20°C as a function of alkali metal concentration.

3.2 Equilibrium in the presence of superplasticizers

The compositions of Na₂SO₄ solutions equilibrated with portlandite and gypsum in the presence of the four SPs are summarised in Table 2. Apart from the small increases in [Na⁺] observed with added SPs, due to the presence of sodium as the principal cation in all of the SPs, there is clearly relatively little change in the overall solution compositions due to the presence of SPs at the dosages used here. This result can be seen more clearly in the effects of SP addition on the simple ionic solubility products for portlandite and gypsum, shown in Figures 4 and 5, respectively. [Note: In the presence of SPs, hydroxide ion concentrations were estimated based on a calculation for electrical neutrality, deliberately neglecting the anionic nature of the SP. The results were generally close to those obtained by the titration of the solutions to pH 7 but presumably contains some error due to the influence of the SP on the charge balance. Estimated errors in the ionic products are shown on the graphs.]

Generally, we observed that all four SPs, at the dosages used here, increased the simple portlandite solubility product by about 30-50% over the whole range of alkali concentrations used, but increased the simple gypsum solubility product by only 20-30%. There are several possible explanations for such increases, the most likely ones being (a) the decrease in activity coefficients due to the ionic strength increase caused by the large polyanionic SP molecules, (b) the partial neutralisation of hydroxide ions by the SP, and (c) weak complexation of calcium ions by the polymers. If calcium ion complexation were the whole explanation, the portlandite and gypsum solubility products should both have been influenced in exactly the same proportions. However, the possible errors in estimation of hydroxide ion concentration make it impossible to say if this was or was not truly the case; partial neutralisation of hydroxide by organic admixture could lead to significant errors in the calculated ionic products. Very similar results to those given above were also obtained with Na₂SO₄ at 30°C, and also with K₂SO₄ at 20°C at concentrations below the syngenite precipitation point. Thus, it can be assumed that, under conditions typical of fresh Portland cement concrete, most common SPs have only a minor influence on the “effective solubility product” of gypsum and portlandite, and thus on the ionic equilibria in the liquid phase.

Figure 5. Portlandite ionic product as function of alkali concentration and SP additions

Figure 6. SP adsorption by portlandite-gypsum mix in Na_2SO_4 solutions at 20°C

The amounts of SP adsorbed by the residual solid phases at equilibrium were estimated from their reduced TOC concentrations, as given in Table 2. The degrees of adsorption were quite significant, as shown in Figure 6, despite the relatively high water/solids ratio used. It is notable that all of the SPs showed partial adsorption on the solids in the suspensions, with the strongest adsorption (66%) occurring for MSFC in the absence of additional alkali sulphate. This suggests that MSFC is probably adsorbed significantly by portlandite. The other three SPs showed weaker adsorption but a similar trend towards less adsorption with increasing sulphate concentration. [Note: it should be remembered that the proportion of gypsum in the residual solid phases also increased with increasing sulphate concentration due to the way that the solutions were prepared].

4. CONCLUSIONS

- We have extended the data of Hansen and Pressler [4] to 5° and 20°C, and obtained indirect evidence that anhydrite may have formed in their experiments with high sodium concentrations at 30°C. Our experimental techniques are also confirmed by good agreement with their results. There is indirect evidence that the invariant point syngenite-gypsum-portlandite occurs at a K₂O concentration of about 200 mM at 20°C and at lower K₂O concentrations as the temperature decreases, but we did not attempt to measure it precisely in these experiments.
- Both MSFC-type and PCP-type superplasticizers, at concentrations typical of those found in the aqueous phase of superplasticised Portland cement concretes, show only minor effects on the equilibrium solubility products of portlandite or gypsum in alkali solutions. The principal effect observed is a slight increase in the apparent solubility products of both solid phases, which can be interpreted as being due to either weak calcium ion chelation by the dissolved polymers, or to a decrease in ionic activity coefficients, or both.
- Weak adsorption on the residual solid phases (a portlandite-gypsum mixture) was observed for all of the SPs tested. This was especially notable at low sulphate concentrations, from which it is deduced that the adsorption probably occurs mainly onto the surface of portlandite, which was the preponderant solid phase in the residue after equilibrium in those cases. This adsorption was significantly stronger for MSFC-type than for PCP-type SP polymers. However, the adsorptions observed for all of the SPs tested were relatively small compared to those typically observed in Portland cement pastes at early ages, (when very little portlandite is present). This implies that portlandite is not the principal SP-adsorbing phase in hydrating Portland cements.

ACKNOWLEDGEMENTS

We would like to give special thanks to Thierry Rouillon for his contribution to the experimental work.

ABSTRACT

According to hydration reaction mechanism of conventional expansive additives, a material design for expansive additives with excellent expansive properties was proposed. In conventional CSA type expansive additives, by considering that expansion action of free-lime can be understood as an initial reaction of free-lime and then on gradual reaction of hauyne, and that more effective expansion action could be effected through the action of free-lime at a time showing its stronger plastic properties, a CSA type expansive additive containing excess free-lime (H-CSA) was proposed. By increasing free-lime content with high hydration activity the reaction of hauyne is accelerated, and H-CSA could more increase whole of reaction rate on the expansive additive than CSA. As a result of confirming the expansion characteristics using mortar, it was found that H-CSA showed larger expansion and better expansion characteristics on using blast furnace slag cement than those of conventional CSA. From the discussion on the role of hauyne in H-CSA based on the comparative study for the expansion properties obtained by free lime-anhydrite based expansive additives, it is showed that free lime solely contributes to its expansion in a system with free lime-anhydrite based expansive additive, but that ettringite generated from hauyne as a base material also contributes to the expansion mechanism for H-CSA.

1. INTRODUCTION

Crack prevention and bending capacity enhancement for reinforced concrete structures is important from the viewpoints of safety, durability and appearance of concrete structures, and further advancement in the technology of expansive additives, which can improve the problems mentioned above, is expected. In recent years, in order to enhance the performance of concrete, highly flowable concrete or high strength and highly durable concrete, which are not affected by construction workmanship and have superior durability, have been developed. For these kinds of concrete, it has been learned that in addition to the change in dimensions caused by drying, which was conventionally considered to be the cause of concrete cracking, autogenous shrinkage accompanied with hardening by hydration causes significantly large changes in the dimensions [1]. It is further pointed out that the effects of expansive additives was not fully realised due to a significantly low water to powder ratio made possible by various admixtures, and that the expansive force was decreased especially when ground granulated blast furnace slag was added [2][3]. At present, it is being considered whether the design method should be transferred to a performance-based design, and it is expected that even for evaluating the effect of cracking on the durability, performance-based design, which requires quantitative clearness, will be applied in the near future. In this case, the reduction of cracks would become an urgent issue even for ordinary concrete. In order to use expansive additives widely in general, concrete is necessary to achieve a smaller addition rate than the present one and accordingly to reduce its economic impact. Thus for achieving high performance of concrete and for responding to the new design method, development

of a new expansive additive having superior expansive properties is highly needed. The authors have been investigating quantitatively the hydration of expansive additives used conventionally [4][5][6][7]. In this paper, based on this mechanism of hydration, the material design of a new expansive additive having superior expansive properties to conventional types is proposed.

2. HYDRATION MECHANISM OF CONVENTIONAL EXPANSIVE ADDITIVES[5],[6]

2.1 Reaction rate of compounds and changes in phase composition due to hydration

A calcium sulfo-aluminate based expansive additive (called CSA hereinafter) available on the market as a representative of the conventional expansive additives, was investigated through experiments. C_3A was synthetically produced from reagents, calcium carbonate and aluminum oxide. The gypsum used was that of the reagent grade chemical. CSA consists of free lime, hauyne, and anhydrite. The chemical composition of the CSA is shown in Table-1. The Mechanism of hydration is assumed for a case when 10 mass % of CSA is added to Portland cement containing 10 mass % of C_3A with addition of two thirds mole of gypsum to the C_3A amount. Therefore, the mixture proportion of C_3A , gypsum, and expansive additive is, 41.24 mass % of C_3A , 17.53 mass % of gypsum, and 41.24 mass % of expansive additive.

Table 1. Chemical Composition and Physical Properties of CSA

Expansive additive	Chemical composition (mass %)								Density (g/cm ³)	Baine (cm ² /g)
	Ig.loss	SiO ₂	Fe ₂ O ₃	Al ₂ O ₃	CaO	MgO	SO ₃	R ₂ O		
CSA	1.1	1.2	0.6	16.1	51.3	1.1	27.5	0.1	2.86	3010

Figure 1. Reaction rate of compounds in CSA

Figure 2. Composition change of C_3A -gypsum- CSA system due to hydration

Figure 1 shows the reaction rate of free lime, hauyne, and anhydrite in CSA. From the figure, free lime and anhydrite in CSA react at early stage, and hauyne reacts slowly at later ages. Changes in the phase composition accompanied by the hydration of C_3A -2/3 mole gypsum-CSA system are shown in Figure 2. The main hydration product is ettringite, but calcium hydroxide is also produced. The mole ratio between SO_3/Al_2O_3 is 1.1, and although it is close to the stoichiometric SO_3/Al_2O_3 mole ratio in mono-sulfate hydrate, a large amount of ettringite is produced. This is because the anhydrite in CSA rapidly reacts at initial hydration stages, which hinders the hydration of C_3A . Production of calcium hydroxide observed, is due to the fact that free lime rapidly reacts at early stages, and hauyne reacts subsequently. Therefore, it is true that the expansion mechanism of CSA-type expansive additive is mostly due to ettringite, however, the material design inevitably utilizes the expansion due to free lime.

3. MATERIAL DESIGN OF EXPANSIVE ADDITIVE WITH EXCELLENT EXPANSION PROPERTIES

3.1 Method of material design

The concept of an expansive additive having excellent expansive properties, properties such as exhibiting performance equivalent to that of a conventional expansive additive but at a lower addition rate, and its expansive properties not being inhibited by blast furnace slag, was already pointed out. It is then necessary to consider how to design the material of an expansive additive having these superior expansive properties. Relevant parameters shall be considered as follows. The first, two parameters are considered for material design of the expansive additive exhibiting performance equivalent to that of a conventional expansive at a lower addition rate, as follows.

3.1.1 Timing of expansion

In the relationship between the strength development of cement matrix and the time at which the expansive additive becomes effective, the moment at which the reaction of expansive additive commences for achieving the most effective expansion shall be considered.

3.1.2 The reaction rate shall be increased at the period when it can provide expansion effectively

If the period in which expansion can be provided effectively is known, the reaction rate of the expansive additive should be increased in this period.

Figure 3 schematically shows the strength development of cement matrix and timing of expansion. In the fresh state of the first period (plastic deformation can take place), effective expansion cannot be expected to occur, and on the other hand, in the fourth period when sufficient strength is developed and it starts to become brittle, expansion would lead to failure. Therefore the period in which effective expansion can be provided is considered to exist between these periods. This period is designated as the effective expansion period hereinafter. This effective expansion period is further divided into the second period in which the plastic property is dominant, and the third period in which solid properties increase.

Figure 3. Strength development of cement matrix and timing of expansion

If the additive were designed to react in the second period showing rather plastic properties, even a small stress would generate large expansion. However, if it were designed to react in the third period showing more solid properties, a large stress would be required. Among CSA constituents, free lime and hauyne, which become the base materials for the expansive hydration products such as calcium hydroxide and ettringite, are taken into consideration together with their reactivity. The CSA hydration mechanism is such that free lime reacts at initial stages and hauyne reacts slowly at later stages, as mentioned before (Figure 1). Therefore it can be assumed that free lime reacts mainly in the second period, and that hauyne reacts mainly in the third period. In order to design an expansive additive having superior expansive properties, an effective means for material design is considered to be increasing the amount of free lime content as long as it does not cause an abnormal set. In this regard, the contents of hauyne and anhydrite shall also be reduced. However, as it is known that C_3A in cement also generates a large amount of ettringite by reacting with anhydrite (refer to Figure 2), reducing the amount of hauyne in the material design is considered to be rather appropriate. By this, free lime itself can contribute to the expansion, and in addition, the content of free lime with high hydration activity becomes large, and thus the reaction of hauyne is accelerated,

and expansive properties are expected to be improved. Next, is considered how to avoid the negative effects of blast furnace slag. The reason why conventional CSA is significantly affected by blast furnace slag is considered as follows. Free lime, hauyne, and anhydrite, which are the compounds composing CSA, are all known as activators of blast furnace slag [8][9][10]. It is estimated that since these compounds are consumed by blast furnace slag, expansion originally due to CSA is not exhibited. In order to utilize an expansion mechanism due to ettringite, concentration of hydroxide ions and the $\text{SO}_3/\text{Al}_2\text{O}_3$ mole ratio have become extremely important parameters of the system [11]. However, in a system where blast furnace slag co-exists, the hydroxide ions become few, and as the blast furnace slag contains a large amount of Al_2O_3 , the mole ratio $\text{SO}_3/\text{Al}_2\text{O}_3$ also becomes small. Therefore, it is considered that the expansion mechanism does not work normally. In order not to be affected easily by blast furnace slag, it is important to let the expansive additive react before the reaction of blast furnace slag, and an effective method shall be that most of the expansion is designed to be caused by free lime, which has high hydration activity and reacts at early ages. As shown above, a material design method to develop expansion equivalent to that of a conventional expansive additive at a lower addition rate, and a material design method that is not affected easily by blast furnace slag, are considered basically to be compatible.

3.2 Determination of composition and synthesizing expansive additive

Now that the principle of material design is fixed, the composition of a new CSA-based expansive additive can be determined. When determining the composition of compounds, a clinker of expansive material is synthesized by using the reagent of raw material, and the content of free lime is increased as much as possible without causing abnormal set or abrupt decrease in flowability, and then the amount of hauyne and gypsum anhydrite is conditioned to obtain the optimum composition.

Figure 4 shows the composition of the new expansive additive and those of conventional CSA-based expansive additives in a triangle phase diagram of $\text{CaO}-\text{Al}_2\text{O}_3-\text{SO}_3$. The first CSA-based expansive additive, recognized as the origin of the expansive additive, was developed by Poliet et chausson company in France in the 1930's [12]. This CSA-based expansive additive is estimated to be composed of approximately 70% hauyne and 30% anhydrite, and it had been used as an additive at about 20% to 30% to Portland cement. The CSA-based expansive additive developed by Klein in America in the 1960's [13], was actually composed of free lime and hauyne, and it had also been used as an additive of 20 to 30 mass % to Portland cement.

Figure 4. Composition of expansive additives in the triangle phase diagram of $\text{CaO}-\text{Al}_2\text{O}_3-\text{SO}_3$ system

Subsequently, based on an idea that expansion could be effectively provided if a unhydrous composition of ettringite were taken as an initial composition, a CSA-based expansive additive consisting of free lime, hauyne, and anhydrite was invented in Japan [14]. This CSA-based expansive additive has been used for over 30 years as an additive of 10 to 15 mass % to Portland cement. The new CSA-based expansive additive proposed by this research (abbreviated as H-CSA hereinafter) is regarded as one in which the CaO content was increased compared to the CSA composition currently used.

Next H-CSA was synthesized by using industrial raw material. The Raw material conditioned to a designated proportion was burned to synthesize in a rotary kiln at 1400°C. The chemical composition and physical properties of the H-CSA are shown in Table 2, and compounds and compositions of the H-CSA calculated based on the chemical composition compared to that of conventional CSA are shown in Figure 5. The amount of free lime in H-CSA is significantly larger compared to that of CSA, and its hauyne and anhydrite contents are smaller, and the amount of hauyne is especially small.

Figure 5. Compounds composition of H-CSA

Table 2. Chemical composition and physical properties of H-CSA

Expansive additive	Chemical composition (mass %)								Density (g/cm ³)	Brain (cm ² /g)
	Ig. loss	SiO ₂	Fe ₂ O ₃	Al ₂ O ₃	CaO	MgO	SO ₃	R ₂ O		
H-CSA	0.9	1.4	0.5	8.4	68.8	1.2	17.7	0.1	3.04	2970

4. HYDRATION AND EXPANSIVE PROPERTIES OF A NEW EXPANSIVE ADDITIVE

4.1 Hydration reaction

Figure 6 shows the reaction rate of hauyne and expansive additive. The rate of reaction for hauyne in H-CSA is accelerated compared to that in CSA. It is considered that by increasing significantly the content of free lime, which has a high hydration activity, the hydration of hauyne is accelerated. It is also revealed that the reaction rate of the expansive additive in total is accelerated for H-CSA compared to the case for CSA. This is because the free lime content of high hydration activity is significantly increased, and resultantly the reaction of hauyne is accelerated. In this manner, the reaction of the expansive additive in total was able to be accelerated by increasing the free lime content and decreasing the content of hauyne. As the reaction of the expansive additive is considered to be controlled at early stages, it is expected to exhibit superior expansion performance and not to be easily affected by blast furnace slag. Figure 7 shows changes in phase composition obtained by the quantitative research on the hydration of a C₃A-gypsum-H-CSA system by the same method as reported in the previous paper [5].

Figure 6. Reaction rate of hauyne and expansive additive

Figure 7. Composition change of C₃A-gypsum- H-CSA system by hydration

In the system added with H-CSA, a large amount of free lime produces a large amount of calcium hydroxide together with a significant amount of ettringite. In the hydration of the C_3A -gypsum-CSA system shown in Figure 2, most of the expansion was attributed to ettringite, whereas in the C_3A -gypsum-H-CSA system, free lime and ettringite equally contribute to the expansion.

4.2 Expansive properties

Performance evaluation of the expansive additive was carried out in a mortar. The mix proportion of the mortar was a water binder ratio of 50%, and the proportion of binder and sand was 1:3. The expansive additive was added by inner proportion to the binder consisting of cement and the expansive additive. The expansion rate measured was the expansion rate with uni-axial restraint in accordance with JIS A 6202. Specimens were demoulded at age one day, and cured in water at 20°C for 6 days until age 7 days. Measurement was carried out at days 1, 3 and 7. Figure 8 shows the relationship between the dosage of the expansive additive and the expansion rate at age 7 days. For all cases, the expansion rate increases with increasing dosage. For H-CSA, the required expansion rate is obtained with a smaller dosage than that for CSA. In the case that CSA is used for BB, the expansion rate did not become significantly large with increasing dosage. On the other hand, H-CSA exhibited about the same expansion rate in both cases of OPC and BB. Normally, when conventional CSA is used for OPC in order for compensation of drying shrinkage or introduction of some chemical prestress, the standard addition rate is about 10 mass %. However, when CSA is used for BB for the same purpose, an additional rate of about 14 mass % is required. Whereas for H-CSA, the required expansion rate can be achieved by adding 5 mass % of it to any type of cement, and it is capable of reducing the economical load significantly. This economical effect is considered to be a considerable difference for OPC, but it counts more significantly for BB. Figure 9 shows the period in which expansion developed due to expansive additives used for OPC. In the figure, the rate of expansion at a certain age is expressed as the ratio to the expansion rate (maximum expansion rate) at age 7 days (designated as E_t/E_{7d} hereinafter). However, as E_t/E_{7d} varies according to the dosage of expansive additives, it is shown by the average E_t/E_{7d} obtained for each dosage. The period in which expansion develops for H-CSA is shown to be earlier than that for CSA. It is closely related to the reaction rate of the expansive additive shown in Figure 6. As discussed in the previous chapter, expansion properties are largely affected by the period in which expansion develops, and it is confirmed that expansion performance can be enhanced by shifting the expansion period earlier. It is also confirmed that with early expansion this is not affected much by ground granulated blast furnace slag and expansion performance can be easily obtained even with blast furnace cement.

Figure 8. Relationship between addition rate of expansive additive and expansion at 7 days

Figure 9. E_t/E_{7d} expansion ratio

4.3 Role of hauyne in H-CSA

H-CSA has a high free lime content, and its content is higher than that of the lime-based expansive additive available on the market. As a lower hauyne content is adopted, it is important to clarify the difference from the lime-based expansive additive, including that from the free lime-anhydrite based expansive additive proposed in the past [15][16]. This is done by focusing on the role of hauyne in H-CSA. Three types of free lime-anhydrite based expansive additives of which the contents of free lime and anhydrite vary, were prepared and these expansive performance were examined in comparison with H-CSA. Figure 10 shows the relationship between the free lime content for cement and the expansion rate.

It is confirmed that the expansive performance obtained by free lime-anhydrite based expansive additives was higher than that solely by free lime, which coincides with the conclusions of former studies. Even at various addition rates of free lime and anhydrite (30:70, 50:50, 70:30), it is known that a linear relationship appears when sorted by the addition rate of free lime to the mortar. On the other hand, the expansion rate for H-CSA is shown to be higher than that for free lime-anhydrite based expansive additives. It is because not only free lime contributes to the expansion for H-CSA, but ettringite generated from hauyne as base material also makes a contribution.

Figure 10. Relationship between addition rate of free-lime and expansion at 7 days

5. CONCLUSIONS

The following conclusions were drawn from the experimental results and discussions in this research.

Considering that expansion due to free lime can inevitably be counted based on the fact that free lime reacts initially and hauyne reacts slowly and later in a system with a CSA based expansive additive, and that expansion can be effectively provided by free lime which reacts in a period in which plastic properties are relatively dominant, a CSA based expansive additive containing a large amount of free lime (H-CSA) is proposed.

By increasing the free lime content of high hydration activity, and by the resultant accelerated reaction of hauyne, the reaction of a H-CSA expansive additive in total was able to take place earlier than that with CSA. In this expansive additive, free lime and ettringite evenly contribute to the expansion mechanism.

From the results of expansion performance examined with mortar, H-CSA exhibited a higher rate of expansion compared with conventional CSA, and also exhibited good expansive performance even with blast furnace slag cement.

From the discussion on the role of hauyne in H-CSA based on the comparative study for the expansion properties obtained by free lime-anhydrite based expansive additives, it is revealed that free lime solely contributes to its expansion in a system with free lime-anhydrite based expansive additive, but that ettringite generated from hauyne as a base material also contributes to the expansion mechanism for H-CSA.

ABSTRACT

FGD-gypsum cement pastes exhibit a thixotropic rheological behaviour; their flow curves derive from the down-curve of the second hysteresis cycle drawn after mixing according to the procedure proposed by the Authors, and are of shear-thinning type that may be very satisfactorily described by the Papo-Piani model, whose parameters for physical consistency have also been fully demonstrated. Cement slurries prepared with FGD-gypsum show lower viscosity values than the pastes made with an ordinary Portland cement with the same Blaine number. Finally, the tests performed in dynamic mode permitted the structure evolution of paste from mixing to the initial setting by using non-destructive measurements to be followed; in particular, the dynamic viscosity-time transient behaviour resembles that of apparent viscosity-time transient behaviour already noticed by the Authors for ordinary Portland cement pastes as well as for gypsum-free cement pastes.

1. INTRODUCTION

In recent years FGD-gypsum, resulting from the desulphurizing of flue gases of coal burning power stations using the limestone washing method, has been widely used in the cement industry as a cement setting regulator.

Our tests showed that the heat-affected loss of water processes, which take place partly also in production cement mills, and in relation to this the dissolving properties (solubility, rate of dissolving) of *calcium sulphate dehydrate* constituting the main component of FGD-gypsum differ somewhat from those of the natural limestone. This provided a justification to investigate in depth the rheological and setting properties of cement pastes made with FGD-gypsum addition.

Understanding cement paste rheological properties is of importance in order to develop a useful tool for controlling cement production, for collecting further information on the chemistry of cement, as well as in the preparation of cement suspensions for special applications, such as injections in loose soils. Moreover, a knowledge of fresh cement paste rheology may contribute to a better understanding of the flow behaviour of mortars and concrete.

Fresh cement pastes are highly concentrated suspensions; their rheological behaviour is generally very complex, it being dependent on several factors of different natures, such as physical factors (the water/cement ratio, the cement grain shape and size, etc.), chemical and mineralogical factors (the cement composition and its structural modifications due to hydration processes, etc.), mixing

conditions (the type and rate of stirrer, the stirring time, etc.), measurement conditions (the measuring instruments, the experimental procedures, etc.), presence of additives (water reducing agents).

A lot of work on cement rheology is available in the scientific literature; here mention is made of the most recent studies (1-5). The present paper is aimed at investigating the rheological and setting characteristics of fresh cement pastes prepared with FGD-gypsum addition; moreover, their rheological properties will be compared with those of an ordinary Portland cement paste with the same Blaine number and prepared at the same water/cement ratio as the FGD-gypsum cement investigated.

2. EXPERIMENTAL

Materials employed

A cement with a specific surface of $\sim 340 \text{ m}^2/\text{kg}$ (Blaine number) made in a production mill with FGD-gypsum addition was used as the testing material. FGD-gypsum was added into the mill in such a quantity that the SO_3 content of the cement produced should be $\sim 3.5\%$. The $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ content of the FGD-gypsum was 95.5%. Cement pastes were prepared with a vane stirrer (Ultra-Turrax T50, Janke & Kunkel, IKA-Labortechnik) according to ASTM C305; deionized water was used; water/cement ratio was in the range 0.34 to 0.42. Water/cement ratios lower than 0.32 were not taken into consideration owing to the very high viscosity of samples.

Apparatus and experimental procedure

Rheological measurements were carried out using the rate controlled coaxial cylinder viscometer Rotovisko-Haake 20, system M5-Osc., measuring device MV2P with serrated surfaces. The temperature was kept strictly constant at $25 \pm 0.1^\circ\text{C}$. The tests were accomplished under both continuous and oscillatory flow conditions. The following rheological procedures were applied:

1) Continuous flow conditions: Tests under variable shear rate (hysteresis cycles). A first hysteresis cycle was drawn immediately after mixing; changes in shear rate were made at the constant shear acceleration of 2.9 s^{-2} ; the maximum shear rate reached was 352 s^{-1} . The same sample was subjected to a second hysteresis cycle 1 min after the previous one. The down curves of the second hysteresis loop have been utilized as flow curves for the cement pastes examined.

1) Oscillatory flow conditions:

A 0.1 to 1 Hz frequency sweep with 0.2 rad constant strain was applied, after determining the region of linear viscoelastic behaviour by means of a strain sweep at a 0.1 Hz constant frequency. A time sweep with a 0.1 Hz frequency was also applied in order to study the setting evolution of pastes.

3. RESULTS AND DISCUSSION

3.1 Continuous flow conditions

According to Procedure a) two hysteresis cycles were drawn after sample preparation. The first cycle shows a shape similar to that already described in a previous paper (6): the down-curve lies on the lower shear stress side than the upper one, i.e. structure breaks down during the test. The second hysteresis loop presents both up- and down-curves of a shear-thinning type and the rheological behaviour is strictly thixotropic. The thixotropic behaviour of FGD-gypsum cement pastes will be studied in depth in a further work.

Fig. 1 reports the shear stress vs. shear rate flow curves derived from the down-curve of the second hysteresis loop obtained for the cement pastes investigated in the present work. All the cement pastes tested exhibit a rheological behaviour of shear-thinning type; a yield stress is also evident. Among the rheological models which correlate shear stress with shear rate, the following equations,

which have already been applied both to cement pastes (7) and to ceramic powder suspensions (8), were tested:

The Casson model $\tau = \tau_o + \eta_\infty \dot{\gamma} + 2[\tau_o \eta_\infty]^{1/2} \dot{\gamma}^{1/2}$ (1)

The Generalized Casson model $\tau^n = \tau_o^n + [\eta_\infty \dot{\gamma}]^n$ (2)

The Herschel-Bulkley model $\tau = \tau_o + K \dot{\gamma}^n$ (3)

The Papo-Piani model: $\tau = \tau_o + \eta_\infty \dot{\gamma} + K \dot{\gamma}^n$ (4)

All the models considered gave a distinct fit, as can be seen from an examination of both standard deviation estimates (STD) and determination coefficient values (COD), which are reported in Table 1, even if, from this point of view, a slightly superior fit was achieved by applying the Papo-Piani model, whose parameter values are shown in Fig. 2.

Table 1. Standard deviation estimates (STD) and determination coefficient values (COD) for the models investigated.						
		W/C				
		0.32	0.34	0.36	0.38	0.40
Eqn. 1	STD	2.59	2.99	3.08	2.12	1.91
	COD	0.998	0.997	0.996	0.998	0.998
Eqn. 2	STD	2.64	2.24	2.28	1.87	1.52
	COD	0.998	0.998	0.998	0.998	0.999
Eqn. 3	STD	2.71	2.41	2.39	1.95	1.63
	COD	0.998	0.998	0.998	0.998	0.999
Eqn. 4	STD	2.68	2.01	2.14	1.84	1.45
	COD	0.998	0.999	0.998	0.998	0.999

The physical consistency of the parameter values of Eqn. (4) may be evaluated by fitting the τ_o values with solid volume fraction by means of the following equation:

$$\tau_o = K[(\Phi - \Phi_o)/(\Phi_m - \Phi)]^m \quad (5)$$

where Φ_o is the volume fraction corresponding to transition from the newtonian or shear-thinning behaviour to the plastic one and Φ_m is the maximum volume fraction, i.e. that corresponding to the maximum particle packing in quiet conditions. A very satisfactory τ_o - Φ correlation was found (see Figure 3); the fitting gave the following parameter values: $K=50$; $\Phi_o=0.44$; $\Phi_m=0.53$; $m=0.5$ (COD=0.997). Full agreement has been found between the Φ_m values calculated by means of Eqn. (5) and those determined experimentally by centrifugation ($\Phi_{m,exp}=0.54$). Lower values of Φ_o with respect to the volume fraction of random particle packing Φ_{rp} , calculated equal to 0.64 in (9) for suspensions of monomodal non-interactive hard spheres, denote the presence of strong attractive forces among particles, i.e. the formation of flocs and/or clusters. The size distribution of the cement particles used being not monomodal, the Φ_{rp} should be slightly higher than 0.64. This means that the formation of a three-dimensional network may be expected at solid volume fractions considerably lower than $\Phi_{rp}=0.64$.

Finally, from the comparison between the flow curve of the 0.32 w/c FGD-gypsum cement paste and that determined in a previous paper (10) for an ordinary Portland cement paste with the same Blaine specific surface (see Figure 1), the results show that the cement paste investigated in this work exhibits lower viscosity values than those presented by Portland cement; hence a higher workability may be expected from FGD-gypsum cement mixes.

Figure 1. Shear stress (τ) vs. shear rate ($\dot{\gamma}$) flow curves for the cement pastes investigated.

Figure 2. Variation of the parameter values of Eqn. (4) with water/cement ratio.

Figure 3. Yield stress (τ_0) vs. solid volume fraction (Φ): comparison between the data calculated with Eqn. (4) and those determined with Eqn. (5) [continuous line].

3.2 Oscillatory flow conditions

Dynamic flow tests were undertaken in order to add further information on the FGD-gypsum cement paste rheological behaviour as well as on the structure evolution of paste from mixing to the initial setting time by using non-destructive measurements (2,11). As far as the dynamic viscosity vs. angular velocity (frequency) flow curves are concerned, a monotonic decrease of dynamic viscosity with angular velocity is noticed, as can be expected, for all the cement pastes examined and for any water/cement ratios explored (see Figure 4).

As regards the mechanical spectra, i.e. the variation of both storage or elastic modulus G' and loss modulus G'' with angular velocity, it can be noted that G' and G'' moduli have parallel evolution vs. frequency; in particular G'' is always higher than G' for all the cement pastes examined and for any water/cement ratios investigated (see Figure 5); this means that the viscous component of complex modulus G^* always predominates over the elastic one; in addition, no transition from sol-like to gel-like behaviour is noticeable when decreasing the water/cement ratio: the paste always exhibits a liquid-like behaviour within the whole frequency range. This confirms that a satisfactory workability of the pastes formulated with FGD-gypsum may be expected also on the basis of the oscillatory flow tests results.

Figure 4. Dynamic viscosity (η') vs. angular velocity (ω) for the cement pastes investigated [0.2 rad of constant strain].

Figure 5. Storage (G') and loss (G'') moduli variation with angular velocity (ω) for the 0.34 and 0.40 w/c cement pastes investigated [0.2 rad of constant strain].

The time sweep results are useful for describing the setting evolution of paste. Fig. 6 reports an example of dynamic viscosity-time transient behaviour. The dynamic viscosity-time trend resembles that of apparent viscosity with time already observed by the Authors for ordinary Portland cement pastes and also for gypsum-free cement pastes. (6, 11). It is evinced that FGD-gypsum cement pastes undergo a breakdown of their structure immediately after mixing, and also when subjected to dynamic tests at very low frequency: this is made evident by the initial η' decay with time down to a minimum value, that implies an equilibrium condition where floc aggregation and disaggregation balance; the lower the water/cement ratio, the greater is the amplitude of structure breakdown. After reaching the equilibrium condition, dynamic viscosity increases with time up to a maximum, sometimes nearly constant value; a further η' decay with time occurs and a second minimum is made evident. Then, dynamic viscosity rises again with time as the hydration reaction goes on. The same trend is observed for storage and loss moduli variation with time.

Figure 6. Dynamic viscosity (η') – time (t) transient behaviour for the 0.32 w/c cement paste investigated [0.2 rad of constant strain; 0.1 Hz of frequency].

4. CONCLUSIONS

FGD-gypsum cement pastes exhibit a thixotropic rheological behaviour; their flow curves, derived from the down-curve of the second hysteresis cycle drawn after mixing according to the procedure proposed by the Authors, are of shear-thinning type and may be very satisfactorily described by the Papo-Piani model, whose parameters for physical consistency have also been fully demonstrated. Cement slurries prepared with FGD-gypsum show lower viscosity values than the pastes made with an ordinary Portland cement with the same Blaine number. Finally, the tests performed in dynamic mode permitted the structure evolution of paste from mixing to the initial setting time to be followed by using non-destructive measurements; in particular, the dynamic viscosity-time transient behaviour resembles that of apparent viscosity-time transient behaviour already noticed by the Authors for ordinary Portland cement pastes and also for gypsum-free cement pastes.

RECENT ADVANCES ON THE FORMATION OF HYDRATED PHASES AND MICROPOROSITY IN METAKAOLIN-BLENDED PASTES CURED AT HIGH TEMPERATURE

ABSTRACT

Due to its high pozzolanic activity, metakaolin (MK) is compared with silica fume. However, this material presents particularly important differences in its chemical composition as well as hydrated phases. Different factors can affect the reaction kinetics and the amounts of the hydrated phases produced during the pozzolanic reaction. Among them, curing temperature is the most important factor on the stability of phases and transformation process.

The current paper shows the results of an investigation focussing on the effect of MK on the reaction kinetics and microporosity of MK blended pastes. Pastes containing 0%, 10%, 20% and 25% of MK were prepared at a constant water/binder ratio of 0.55 and cured at 60°C for hydration periods of 3, 9 and 34 days.

In the current research, the results show important differences compared with data previously reported by other researchers. In a MK/lime matrix cured at 60°C, C_2ASH_8 , C_4AH_{13} and hydrogarnet were the main hydrated phases, while in a MK-blended cement cured at the same conditions, the C_2ASH_8 (stratlingite) was the only hydrated phase from the pozzolanic reaction. From DTA and XRD, data also reveal an important fact, there is no evidence of the presence of hydrogarnet in MK- blended cement pastes.

The MK blended cement pastes demonstrated an important decrease of the partial porosity (in the interval 1-0,1 μm). At 3 days of curing, porosity values were reduced by between 75% and 86% with respect to the control paste. Therefore, the presence of MK in blended cement pastes was associated with neither a reduction of volume nor a considerable increase of its porosity, due to a possible instability of hydrated phases formed at high curing temperature.

1. INTRODUCTION

In recent decades, pozzolanic materials have been used in different aspects of construction, mainly for their influence on the microstructure and durability of blended cement concrete.

In most cases, mortars and concretes containing material with pozzolanic characteristics have porosity values equal to or superior to that of an OPC matrix [1]. This evolution of the porosity depends on the characteristics of pozzolanic materials, such as fineness, mineralogy, loss of ignition, chemical composition and water/binder ratio used. However, it is well known that the critical factor affecting the performance and durability of concrete structures is pore size distribution, rather than the total porosity.

Nowadays, thermally activated kaolinite (metakaolin) is one of the most studied pozzolanic materials because it is very abundant in tropical and subtropical regions, and which do not require the energy necessary to manufacture clinker.

Due to its high pozzolanic activity, metakaolin is often compared with silica fume [2]. However, this material presents particularly important differences in its chemical composition as well as hydrated phases. Different factors can affect the reaction kinetics and the amounts of the hydrated phases produced during the pozzolanic reaction. Among them, curing temperature is the most important factor [2-4].

When MK reacts with calcium hydroxide, cementitious products are formed. It has been reported that CSH, C_2ASH_8 and C_4AH_{13} are the most important hydrated phases at 20°C of curing temperature. In the literature, Khabit and Wild [5] and, Frías et al [6-7] reported a refinement of the pore structure and an increase of total intruded pore volume in MK-blended pastes cured at 20°C.

Many previous researchers have showed the positive effect of MK in the incorporation of blended cement pastes (or mortars or concretes) [8-12]. BB. Sabir et al [13] reported that the MK alters the pore structure in cement paste, mortar and concrete and greatly improves the resistance to the transportation of water and diffusion of harmful ions which lead to degradation of the matrix.

In spite of excellent qualities shown by MK as pozzolanic material, its use is in part conditioned by a generalised idea about a possible conversion of some metastables hexagonal hydrates (C_2ASH_8 and C_4AH_{13}) to stable cubic phase (siliceous hydrogarnet with variable composition, $C_3AS_zH_{6-2z}$), when samples are submitted to high curing temperatures. [14]. This phenomenon may lead to a negative influence on the performance of MK blended matrixes, mainly on durability.

In recent works Cabrera and M. Frías [3] and, Frías et al [15] reported that the hydrogarnet can be formed from a direct pozzolanic reaction in MK-lime systems at 60°C and not from a conversion reaction.

Due to the importance that this fact can have on the durability of cementitious materials, as mentioned above, it is necessary to have a better knowledge of the evolution, development and stability phases, with special attention to the formation of a hydrogarnet phase in MK blended cement pastes.

The present paper forms part of an experimental study about the reaction kinetics in MK blended cement pastes cured at 60°C. The results of this study show the latest advances in this field.

2. EXPERIMENTAL PART

2.1 Materials

A commercial metakaolin was used in the present work. MK has the $SiO_2 + Al_2O_3$ content above 92%. It also presents as a product of low crystallinity. Quartz and mica (mainly muscovite) were identified as unique crystalline impurities present. A value of 15.5 m²/g of specific surface and 130 Å of average pore diameter were obtained using BET techniques.

A commercial white Portland cement available in UK was also used for this study. The BET surface area of cement was 1.04 m²/g. XRD patterns and chemical compositions for MK and white cement are given in Figure 1 and Table 1.

Figure 1. XRD patterns of MK and cement

Table 1. Chemical composition of cement and MK

Oxides (%)	Cement	Metakaolin
SiO ₂	20.4	51.6
Al ₂ O ₃	5.02	41.3
Fe ₂ O ₃	2.92	4.64
CaO	64.25	0.09
MgO	2.83	0.16
S ₂ O ₃	2.62	-
Na ₂ O + K ₂ O	1.23	0.07
TiO ₂	0.21	0.08
L.O.I.	0.7	0.6

2.2 Preparation of specimens and curing

Four different pastes were prepared. White OPC was partially replaced with 0, 10, 20 and 25% of MK. The water/binder ratio was 0.55 by weight.

In all cases, mixtures were placed in plastic airtight containers and then left in a water bath at a temperature of 60°C. Different hydration times were applied: 30 hours, 3 days, 9 days and 34 days for MK-blended cements. After the predetermined curing time, the hydration reaction was stopped using two different methods, depending on the parameter to be studied:

- Vacuum oven method. The samples were left at 50°C and 1 bar. After 3 days a constant mass was detected. This method was used for mercury porosity tests (MIP).
- Microwave method. This procedure was good and quick to dry the samples. Further information can be found in a previous paper [3]. This method was used for DTA and TG tests.

Differential Thermal Analysis (DTA) and X-ray Diffraction (XRD) techniques were used to provide information about the effect of temperature on the pozzolanic reaction kinetics in different matrixes.

3. RESULTS AND DISCUSSION

The effect of temperature on the reaction kinetics in MK-blended cement pastes is clearly identified in Figure 2.

Figure 2. DTA thermograms for MK/cement pastes at 60°C

Figure 2 shows the evolution of hydrated phases with the curing time for the cement pastes containing between 0 and 25% of MK. These DTA curves illustrate that the main hydrates in white cement were: CSH and CH (portlandite). However, in MK-blended cement pastes an endothermic

peak also appeared at about 170-175 °C, which was attributed to the C_2ASH_8 phase [3]. The CH concentration decreases with the curing time and with the amount of MK incorporated.

An important aspect obtained from the DTA curves was the absence of compounds, such as: C_4AH_{13} and hydrogarnet, the main phases detected in MK/lime systems cured at 60°C [15]. A detailed observation of MK blended cement pastes, mainly 10% of MK, showed the presence of a weak endothermic peak, which was situated at 300°C. This peak might be assigned to the hydrogarnet phase. The intensity of this peak did not vary with the hydration time.

The XRD patterns for all mixtures with MK are very similar, showing that the crystalline compounds were C_3S , C_2S , CH and traces of calcium aluminium oxide carbonate hydrate (peaks at 10.9 and 21.8 2 θ). The gehlenite hydrate does not appear as crystalline compound. Figure 3 shows the XRD patterns corresponding to the pastes with 20% of MK.

In this particular case, a weak crystalline peak is easily detected at 17.5 2 θ . This fact confirms the presence of traces of hydrogarnet above 30 hours of hydration in blended cement pastes, mainly with 20% of MK. Hydrogarnet was not detected as crystalline phase in the rest of the blended pastes.

From these results, it is important to note that there is practically no hydrogarnet obtained from the pozzolanic reaction in MK blended cement pastes cured at high curing temperatures and in the conditions tested here. This means there is no conversion reaction from metastable hexagonal phases to the stable cubic phase.

The absence of the stable cubic phase (hydrogarnet) in MK blended cement pastes at 60°C of curing temperature might be related to the different phenomena, which could be compatible at the same time: absence of conversion reaction, an insufficiency of calcium hydroxide to form hydrogarnet, presence of activators from cement, decrease of solubility of CH due to the presence of alkalis, etc.

This fact is a very important aspect from the engineering point of view since the incorporation of MK in the development of new blended matrices (mortars and/or concretes) does not have associated a conversion phenomenon and therefore, a loss of performances and durability.

These findings are totally in agreement with the results obtained from porosity data. Figure 4 shows the total and partial porosity for the four samples studied.

Figure 3. XRD patterns for MK cement pastes (20%) versus hydration time.

The total porosity values for the MK blended cement pastes were very similar to those obtained for the control pastes; except for the case of 10% of MK, a light decrease of total porosity is observed for all ages. The positive effect of the incorporation of MK in the development of blended pastes cured at 60°C is clearly observed on the porous structure. Pore diameters between 1 and 0.1 μm showed an important decrease of the partial porosity. At 3 days of curing, a reduction was detected of porosity values between 75% and 86% with respect to the control paste.

New studies have been performed at longer curing times in order to confirm the non-formation of hydrogarnet in MK-blended cement pastes cured at high temperatures.

Figure 4. Evolution of porosity versus hydration time

4. CONCLUSIONS

The main conclusions derived from current study may be summarised as follows:

- The reaction kinetics of the pozzolanic reaction between MK and calcium hydroxide is closely related to the curing temperature. At 60°C of curing, MK-blended cement pastes showed different kinetics to that obtained in MK-lime systems
- From STA and XRD data, the stratlingite (C_2ASH_8) was detected as unique non crystalline compound from pozzolanic reaction between MK and the lime liberated by cement in MK-blended cement pastes cured at 60°C of curing temperature. There was no evidence of the formation of C_4AH_{13} and hydrogarnet (only traces in some cases).
- The absence of the hydrogarnet phase in MK blended cement pastes suggest that these blended cements will not experience a degradation process and therefore, a loss of performance and durability during its service life due to the conversion reaction.
- The incorporation of MK in the manufacture of blended cement pastes cured at 60° C had a positive effect on the porous structure. A very important pore refinement phenomenon was detected between 1 and 0,1 μm .

A COMPARISON BETWEEN TRADITIONAL AND MICROWAVE DRYING METHODS OF CEMENT PASTE

Julian Rivera¹, M^o Isabel Sánchez de Rojas², and Moises Frías³

Instituto de Ciencias de la Construcción Eduardo Torroja, Madrid, España.
E-mail: ¹Julianrl@ietcc.csic.es, ² mfrias@ietcc.csic.es and ³ srojas@ietcc.csic.es

ABSTRACT

The aim of this research is to study the viability of using the microwave oven technique as an alternative method to stop the hydration reaction of the cement paste.

In order to determine the effectiveness of this dried method, it has been compared and evaluated with other traditional dried methods (Propan-2-ol, 105°C oven and 50° C vacuum-oven).

To determinate how the different drying methods stop the cement hydration reaction, the hydration degree of the cement paste is used, which is calculated by mean of the amount of $\text{Ca}(\text{OH})_2$ (CH) and the amount of chemically combined water (CW) by Thermal-analysis Technique. Differential Thermal-Analysis (DTA) also is used since it gives very high quality information about the evolution of the compounds in the cement paste.

This research shows the microwave oven is a very effective technique capable of stopping the hydrated reaction of the cement paste quicker than other traditional methods without damaging the cement hydrated compounds.

1. INTRODUCTION

Cement hydration is a complex dissolution-precipitation process in which various hydration reactions proceed simultaneously at differing rates and influence each other. The dissolution of anhydrous phases enables the formation of compounds whose solubilities are lower than those of the anhydrous clinker minerals, thus leading to the precipitation of colloidal and crystalline hydrates that form the hardened paste [1].

A large number of studies about cement hydration or their constituent phases confirm the need to remove the free water from the sample after a specified curing time to stop the hydration reactions and to render the material less susceptible to carbonation, since it eliminates the water which dissolves the CO_2 [2].

The method used to dry the samples is very important. Insufficient drying may not effectively remove the physically bound water, but too severe a drying might dehydrate the chemically-bound water from the hydrated products.

Some papers don't give any specifications of the drying methods used, and the use of different drying methods can give different results. So, it is absolutely necessary to know the drying methods used in each research project.

Furthermore, considering the fact that both chemical and mechanical properties in the cement paste change the most during the earlier part of temporal evolution of the solid-liquid system (1 day), it is necessary to quickly find a drying method capable of eliminating the free water from the cement paste, in order to determine the exact time when the hydration reaction has been stopped.

This research studies how a microwave oven stops the cement hydration, and whether it produces any damage to the different hydrated components of the cement.

2. METHODOLOGY

2.1 Propan-2-ol method

Solvent exchange techniques have been used to preserve the existing structure of the cement paste by replacement of water with a liquid of lower surface tension, since hardened cement paste is extremely sensitive to heat drying methods.

The samples, in which the free water fraction was removed by grinding the material with acetone or alcohol, filtering it, washing it on the filter with additional acetone and ethyl-ether and finally drying in air [3] [4], in vacuum for 24h [5] or at 45°C [6], are very gentle procedures employed to preserve the Aft and Afm phases, which are decomposed if more drastic water removed methods are employed.

On the other hand, soaking or grinding in polar organic liquids, such as methanol, propan-2-ol or acetone, should be used only in situations where it will not invalidate the subsequent test. Organic substances can be completely removed from C₃S pastes only by drastic procedures that seriously alter the material. Their presence is especially undesirable if any form of thermal analysis is to be carried out, since on heating they react with Calcium Silicate Hydrated (CSH) to give CO₂ [7].

Some workers consider that primary aliphatic alcohol alters structures of C₃S or cement pastes or of synthetic CSH preparations and it has also been claimed that methanol reacts with CH at ordinary temperatures, giving calcium methoxide [8].

For some procedures, such as XRD, the presence of organic material may not matter, but even here; the possibility of decomposing or altering hydrated aluminate phases must be considered [2].

Finally, Propan-2-ol was chosen for this work on the basis of previous studies [9] [10] [11]. Their studies have indicated minimal chemical and physical interference with the hydration products of cement during solvent replacement (methanol and acetone react with the products of hydration, in particular calcium hydroxide).

The samples were soaked in alcohol for 5 minutes and later were washed 3 times with more alcohol, finally they were placed into a vacuum-desiccator over silica gel. The filter used was one vacuum-filter. The samples were in contact with the alcohol for a short time to avoid all problems shown previously.

2.2 105°C oven method

This method consists of heating the sample at 105°C for 24h in a very low relative humidity atmosphere (<15%). All the samples are ground into 0.5cm diameter particles.

It is a drastic method, which can partially dehydrate the Calcium silicate hydrate (CSH) and, with cement pastes can also decompose crystalline hydrated calcium aluminates or aluminate sulfate phases.

2.3 50°C vacuum oven method

This method is based in the elimination of the free water by heating the sample up to 50°C for 3 days in a vacuum oven.

Although the temperature used is very low, this method can harm some cement compounds as the ettringite, which is decomposed over 60°C or even at a lower temperature in very dry conditions.

2.4 Microwave oven method

A microwave is a kind of electromagnetic radiation with a wavelength range between 1mm-1m. In order words, it is an ultra high frequency radio, characterized by a fast heating rate, even dewatering and high-energy efficiency, stopping the cement hydration reaction at a determinate age. The equipment used was a 700 w conventional microwave.

To work with this non-traditional drying method, there was a need to prepare and develop an experimental method:

First of all, to avoid possible interference in the results, the sample weights were always the same (5g) and the particle sizes were lower than 0.5cm.

Secondly, the minimum time was calculated to completely dry the samples. To calculate this time several samples of cement paste (water/cement ratio = 0.4) and with different curing times (1h, 3h, 24h y 28 days), were dried for different times.

These samples were kept inside the microwave for 3, 5, 6, 7 and 8 minutes. The lost weight of the samples was calculated as a percentage, taking account of the 100% of the samples and the weight of the dried sample.

Finally, these results are compared with the results obtained by heating the samples up to 105°C and 50°C -Table 1.

Table 1. % free water obtained in a cement paste cured to different ages with different dry methods

Methods	Microwave					105°C	50°C
Curing (h)	3 min	5 min	6 min	7min	8 min	24 h	72 h
1	89,4	92,6	92,7	92,8	93	93	92,7
3	38	39	39,1	39,3	39,4	38,7	37,9
24	28	28,8	28,9	29	29	28,94	29
672	21	21,8	22,2	22,4	22,5	21,23	19,5

The minimum time needed to completely dry the samples was 5 minutes. The microwave oven temperature was checked with a digital thermometer, being 105°C.

3. MATERIAL AND SAMPLES PREPARATION

The cement used was an ordinary Portland cement (OPC) CEM I 45.2 R supplied by Castle Cement (England). It complies with the requirement of UNE 80301:1996 [12].

The pastes were mixed at water/cement ratio of 0.4 by hand mixing for 2 minutes. Distilled water was used and the pastes made. They were cured in a fog room (RH 95%) kept at 20°C until required for testing. At the age of testing (3, 6, 8, 10, 15, 20h and 1, 3, 7, 28 days) the samples were taken out of the curing room, ground to under 50mm and dried with the different methods.

The dried samples were sieved on a 0.75mm sieve and kept in sealed glass bottles and placed in a desiccator containing silica gel. At the convenient times they were taken from the desiccator and transferred to the test equipment.

4. EXPERIMENTAL

The hydration degree of the paste, which is calculated by a mean of the amount of Ca(OH)_2 (CH) and the amount of chemically combined water (CW) by the thermo-analysis technique, is used to determine how the microwave method stops the cement hydration reaction in comparison with the other methods.

Moreover, this research takes into account another technique, Differential Thermo-Analysis (DTA), which gives better quality information about the evolution of the compounds in the cement paste.

4.1 Thermogravimetry (TG)

The study of the TG curve is based in three specific areas:

- 1.- Lost weight from 400°-500°C (aprox.) corresponding to the CH decomposition (table 2).
- 2.- Lost weight from 600°- 700°C (aprox) corresponding to the CaCO_3 (table 2).
- 3.- Combined water is considered to the lost weight between 20°C to 400°C [14] [15] (table 3).

The Tables 2 and 3 also show the total percentage of CH in the samples, which has been calculated taking account of the correction of CaCO_3 formed [13], and the hydration degree of the paste. These values are calculated considering the amount of CH and CW as 100% of a hydrated paste, when the samples have been cured under 20°C and HR 95% conditions for one year.

Table 2. Total amount of Ca(OH)_2 in the samples dried with different drying methods

The samples dried with alcohol are not absolutely dry, so that it is not possible to calculate the CW formed in these samples.

Finally, the hydration degree is shown in figures 1-3.

These results show that, up to 15h of curing, the samples dried in microwave oven and alcohol have a lower amount of CH than the other methods, but after 15 h curing all the dried methods show very similar hydration degree with a difference of 3 %.

The samples dried in 105°C oven have the largest amount of CH at all the curing times, though the difference is very small. These differences are very clear at ages less than 10h, which can indicate that this method produces a little acceleration process in the cement hydration.

Figure 1. Hydration degree obtained by the calculated amount of Ca(OH)_2 in the samples dried with the different methods.

Figure 2. Hydration degree obtained by the calculated amount of CW in the samples dried with the different methods

When the hydration degrees of the same samples are studied taking account different hydrated compounds, the evolution of CW degree is very related to the degree of CH evolution, but in these cases this evolution shows small differences.

The CW microwave values obtained are lower than the 50°C oven, at curing time less than 8 h, due to the microwave oven drying the samples quicker. But this difference starts to increase after 20h of curing, fact does not happen in the CH degree evolution, where these values are very similar.

Microwave results are lower than the samples dried to 105°C at ages less than 8 hours, but afterwards the 105°C samples have a lower amount of CW. This evolution is very different to CH degree evolution, where the 105°C method shows the highest values.

This is due to the fact that the microwave and 105°C oven are drying methods more drastic than the 50°C. So, this different evolution between CH and CW degree evolution is due to microwave and 105°C partially dehydrating the CW.

It only occurs after 24h curing, because at very early curing times the amount of free water in the samples is enough to avoid an extra heating of the samples, but when the curing time increases the amount of free water decreases, and the sample is more sensitive to the heat, the CW being the more sensitive compounds.

In both cases, it is observed that the microwave oven methods eliminate the water more quickly than the other studied methods

4.2 Differential Thermal Analysis (DTA)

The most representative of the DTA diagrams (figure 3 - 10) is:

a) At early ages (< 24h), the dried samples in 50°C vacuum oven present a wide band situated in 120°C, whereas in the dried samples in microwave and 105°C oven, this band appears divided into two bands; one is situated at 100°C and the second at 160°C.

The dried samples in alcohol present a very sharp band in 89°-90°C due to the free water non-evaporation in the samples. At later ages (>24h) the 160°C band starts to be observed in the 50°C dried samples, even in the alcohol dried samples where the free-water band almost hides it.

These bands are mainly due to the formation of CSH, which main bands are situated between 100°-230°C [16] [17]. But this band can be also formed for other endothermic bands due to different cement compounds such as ettringite (120-145°C), gypsum (145°C-160°C) and monosulphate (130°-190°), but their effects are very small, due to:

1. The amount of these compounds is very small in an Ordinary Cement Portland [18].
2. The only compound formed in the hydration cement that starts from the beginning of hydration and lasts and increases its amount until the hydration ends is the CSH gel.

b) Around 450°C there is a very sharp endothermic band due to lost water of the CH. This band increases its intensity and it shifts its position up to highest temperatures when the curing time increases too, due to the largest amount of CH.

The reasons for 105°C and microwave oven dried samples showing two bands are due to these methods eliminating more combined water than the 50°C method. The bands which intensity is reduced for these methods are situated under 120°C (aprox), so that this water is due mainly to free water situated in pores between 10^{-4} - 10^{-5} m (100°C) and 10^{-6} - 10^{-8} m (120°C) and interlayer water of the silicates [19] [20].

This decrease of the band can also due to the ettringite decomposition. But this decrease cannot be easily related with the ettringite since all these methods (microwave, 105°C and 50°C) destroy the ettringite to a greater or lesser degree. These samples were studied by X-ray Diffraction (XRD), where there goes not appear to be any ettringite peak, except a very small peak in the sample dried with alcohol and by Infrared (IR), where the diagrams don't show any difference among the different samples (Julián Rivera, thesis), (21).

5. CONCLUSIONS

The microwave oven is a very fast drying method, which is indicated to dry the cement paste with more accurate timing than other methods. But this accuracy is only discernible at very early ages (< 24h) where the cement hydration reaction is more intensive.

The microwave and 105°C methods are more drastic than the 50°C and alcohol methods, producing at larger dehydration of the cement paste. Although, under these study conditions the microwave method is less aggressive than the 105°C method.

This dehydration produced by the microwave method increases when the curing time increases, so it is very important to control the time and the temperature inside the microwave oven to avoid bigger dehydration.

The 105°C method accelerates the cement hydration, giving different hydration degrees.

EXPLANATION OF LONG-TERM COMPRESSIVE STRENGTH OF CONCRETE CAUSED BY THE SET ACCELERATOR CALCIUM NITRATE

Harald Justnes

SINTEF Civil and Environmental Engineering, Cement and Concrete,
7465 Trondheim, Norway. E-mail: harald.justnes@civil.sintef.no

ABSTRACT

Calcium nitrate (CN) is used worldwide as an admixture for concrete, in particular for applications utilising its properties as set accelerator. However, CN also enhances the long-term compressive strength of concrete. This strength enhancing property should not be utilised before the reason for it is understood.

Concrete (low alkali portland cement, 4 % silica fume and $w/(c+s) = 0.45$) with additions of 2 % of the set accelerator calcium nitrate (CN) was shown to exhibit a long-term compressive strength increase relative to reference. The strength was also measured on equivalent paste cubes of 50 mm with and without 2% CN of cement weight. Thus, the strength increase could not be due to improvement of aggregate/binder interface alone. The paste was also subjected to detailed investigations by NMR, MIP, DTA/TG and SEM.

As an overall conclusion, the long-term strength increase of concrete caused by the addition of 2 % calcium nitrate to the fresh mix seems to be due to lower porosity of the binder only observable by gentle drying techniques (i.e. water replacement by ethanol followed by drying at 50°C).

1. INTRODUCTION

During the later years of research on calcium nitrate as a concrete admixture, particularly as a set accelerator, substantial long-term strength increase has been observed. The possible causes for this have recently been discussed [1, 2] based on non-systematic observations over several years. The present study, on the other hand, is the first attempt at a systematic study of the phenomenon, making concrete specimen and paste specimen of identical binder composition with and without 2% dry calcium nitrate of the cement weight. This dosage was chosen since previous data showed that there was no extra strength gain at even higher dosages for the low alkali type cement used.

2. EXPERIMENTAL

2.1 Components

Norwegian high strength Portland cement (ENV 197/1 CEM I 52.5 R-LA) produced by Norcem, Brevik, was used. The cement conformed to the requirements given in ENV 197/1 and had the following properties: Characteristic compressive strength in plastic mortar: $\sigma_{c,1} = 18.8$ MPa, $\sigma_{c,7} = 44.6$ MPa and $\sigma_{c,28} = 58.3$ MPa. Specific surface according to Blaine was 366 m²/kg. The cement showed no sign of false setting and the content of C₃A was 5.3 % according to Bogue calculations.

The silica fume was delivered by Fesil, Lilleby, Norway, and had specific surface 22.1 m²/g as measured by BET and consisted of 94.7% SiO₂.

Limestone filler was delivered by Franzefoss, Norway, while Årdal aggregate was supplied by Norstone AS, Norway.

A granulated, technical quality calcium nitrate (CN) was used that may be expressed as $x\text{NH}_4\text{NO}_3 \cdot y\text{Ca}(\text{NO}_3)_2 \cdot z\text{H}_2\text{O}$, with $x = 0.092$, $y = 0.500$ and $z = 0.826$. In other words it consisted of 19.00 % Ca^{2+} , 1.57 % NH_4^+ , 64.68 % NO_3^- and 14.10 % H_2O . The manufacturer was Norsk Hydro, Porsgrunn, Norway.

2.2 Concrete

The concrete mixes with recipes as given in Table 1 were tested with respect to workability in terms of slump and spread, air content, fresh density and compressive cube strength at a number of ages (samples made and stored for up to 10 years). Experimental details are found in the next section. Furthermore, the concrete quality was characterised by a capillary suction technique as described in section 2.2.2 after 28 days curing at 90% RH and 20 °C. Cubes of 15 mm were also cut from the specimen and prepared for analysis by scanning electron microscopy (SEM) in order to spot possible differences in transition zones between aggregate and binder.

Table 1. Concrete recipes

Components	Mix 1 (reference)	Mix 2 (2% CN)
CEM I 52.5 R-LA	13,300 g	13,300 g
50% silica fume slurry (E8)	1,060 g	1,060 g
Årdal sand 0-8 mm	36,798 g	36,798 g
Årdal crushed gravel 8-11 mm	14,700 g	14,700 g
Årdal crushed gravel 11-16 mm	14,700 g	14,700 g
40 % SP (Mighty 150)	0.168 g	0.250 g
50 % dissolved CN	-	530 g
Deionised Water	4,696 g	4,432 g

The recipes in Table 1 translate into a composition of 4% dry silica fume of cement weight, $w/c = 0.46$ and $w/(c+s) = 0.44$.

2.2.1 Fresh concrete properties and compressive strength of hardened concrete

Measurements of slump, spread, apparent density and air content were performed according to methods given in the Norwegian Standards NS 3662 (ISO 4109), NS 3664 (ISO 9812), NS 3660 (ISO 6276) and NS 3659 (ISO 4848), respectively. Compressive strength was determined after storage at +20°C in air of 100 % relative humidity as a mean of 3 tests per mix and testing age. 100-mm cubes were used as test specimens. Moulding and testing were performed according to the specifications given in Norwegian Standards NS 3669 and NS 3668 (ISO 4012), respectively.

2.2.2 Capillary suction

Six 20 mm slices were cut from the middle of each of epoxy coated concrete $\phi 100 \cdot 200$ mm cylinders. The method recommends 105°C drying before capillary suction measurements. After drying, the discs are placed on a grating 1 mm below the water surface in a covered box. The increase in weight as the specimen suck water is monitored for 4 days and plotted versus square root of time. The results from the capillary suction test can be expressed by means of linear regression analyses of two lines. The first line represents the value until the waterfront reaches the top of the specimen and the second, nearly horizontal, line the suction thereafter. The crossing between the two straight lines is calculated and expressed by the water absorption value (Q_{cap}) and time for exposure (t_{cap}). These values can be used to calculate the capillary coefficient, k , and the resistance coefficient, m [1]. The procedure consists of 6 important steps for the specimen:

1. Drying to constant weight.
2. Capillary suction for 4 days with weight monitoring.
3. Water saturation by submersion 3 days in water at 1 atm.
4. Pressure saturation by submersion 3 days in water at 80 atm.
5. The outer volume is recorded by differential weighing of the specimen under water and saturated surface dry in air according to the principle of Archimedes.
6. Drying the specimen to constant weight at 105°C.

From these 6 steps, one can calculate the initial moisture content, total porosity (ϵ_{tot}), the capillary porosity (ϵ_{cap}), the air volume (ϵ_{air}), the average density of the concrete solids (ρ_{sol}) and the dry density of the concrete (ρ_{dry}). A more detailed procedure with formulas is given elsewhere [1].

2.2.3 SEM/EDX

The samples for SEM/EDX were cut into slices with 15 mm diameter and thickness 3 mm and cast in epoxy after drying at 105°C, plane polished and coated with a carbon layer in vacuum in order to conduct electrons. The samples were inspected by SEM (Scanning Electron Microscopy) in the BEI (Backscattered Electron Images) modus. For some images, spot-analyses of chemical elements were recorded by EDX (Energy Dispersive Analyses of X-rays) in order to explain details.

2.3 Cement paste

The cement paste samples were subjected to detailed investigation by the following methods:

- MIP/HeP (Mercury Intrusion Porosimetry/Helium pycnometry)
- ^{29}Si MAS (Magic Angle Spinning) NMR (Nuclear Magnetic Resonance).
- DTA/TG (Differential thermal analysis/Thermogravimetry)
- SEM/EDX (Scanning Electron Microscopy/ Energy Dispersive analyses of X-rays)

2.3.1 MIP/HeP

The samples for MIP/HeP (Mercury Intrusion Porosimetry/Helium Pycnometry) were crushed into bits of about 5 mm and stored in excess ethanol for two months to exchange the free water with ethanol. The selected samples were dried at only 50°C to prevent distortion of the pore structure before the MIP experiments were carried out with the Carlo Erba Porosimeter (Model 2000). This porosimeter records the pore size (radii) distribution of the sample between 50 and 500,000 Å, assuming spherical pores. The density of solid material, ρ_s , was determined by Micrometrics AccuPyc 1330 He-pycnometer, while the particle density, ρ_p , was determined by Carlo Erba Macropores Unit 120. The accuracy of total porosity is within ± 0.5 units and the density within ± 0.01 units.

2.3.2 ^{29}Si MAS NMR

The samples intended for NMR (Nuclear Magnetic Resonance) were crushed and dried at 105°C. The solid-state ^{29}Si MAS (Magic Angle Spinning) NMR spectra were recorded on a Varian INOVA 300 Spectrometer at the Department of Chemistry, University of Aarhus, Denmark. The single pulse MAS NMR experiments employed high-power ^1H decoupling ($\gamma B_1/2\pi = 36$ kHz) and an observed pulse width of 4.5 μs (45° flip angle). The spinning speed was about 7 kHz and the relaxation delay 60 s. Chemical shift values were calibrated prior to the experiments and given relative to TMS (trimethylsilane). Since the active silicon isotope ^{29}Si only has a natural abundance of 4.5 %, each spectrum shown under results is really an average of more than 1,000 scans to obtain satisfactory signal to noise ratio. The accuracy of the chemical shifts is ± 0.1 ppm.

2.3.3 DTA/TG

The samples for DTA/TG (Differential Thermal Analysis/Thermo Gravimetry) were crushed to a fine powder and dried at 105°C (i.e. to remove adsorbed water). The DTA/TG experiments were carried out at a NETZSCH 409 STA with a heating rate of 10 °C/min until 1000°C and nitrogen as a carrier

gas. The sample (≈ 150 mg) was contained in an alumina crucible and alumina powder was used as a reference. The accuracy of the temperature determined for thermal decompositions was within $\pm 2^\circ\text{C}$, while the accuracy of the mass losses was within ± 0.3 mg.

3. RESULTS AND DISCUSSION

3.1 Concrete

3.1.1 Fresh properties and compressive strength

The fresh properties of the concrete are given in Table 2, while the compressive strength development is listed in Table 3. The reason for the higher dosage of SP (see Table 1) for concrete with CN, was to obtain roughly equal spread.

Table 2. Fresh properties of concrete with and without 2% CN

Fresh properties	0% CN	2% CN
Slump (mm)	170	160
Spread (mm)	443	438
Air (vol%)	1.5	1.6
Density (kg/m^3)	2420	2415

Table 3. Cube mass, m (g), and compressive strength, σ_c (MPa), for concrete without and with 2% CN. Average with standard deviation for 3 parallels.

	0 % CN		2 % CN	
Curing time	m (g)	σ_c (MPa)	m (g)	σ_c (MPa)
8 hours	2465 ± 13	5.9 ± 0.2	2439 ± 8	7.5 ± 0.1
1 day	2456 ± 7	30.9 ± 0.5	2437 ± 11	28.4 ± 0.6
28 days	2449 ± 13	71.1 ± 1.7	2446 ± 5	81.4 ± 1.5
90 days	2458 ± 18	76.6 ± 0.5	2448 ± 9	86.0 ± 1.6
365 days	2465 ± 15	83.1 ± 1.1	2454 ± 6	91.4 ± 0.7

3.1.2 Capillary suction test

The average capillary suction profiles for 6 parallel discs sawn from cylinders of concrete without and with 2% CN are compared in Figure 1, while the results derived from the test are listed in Table 4. As seen from Table 4, the total porosity for the concrete is not significantly different for the two mixes and can thus not explain the increase in compressive strength brought about by the 2% CN addition. However, the k and m values in Table 4 and the profiles of Figure 1 reveal that the concrete with CN absorb water with a slower rate (k) than the reference and that the time for the water front to reach the top (m) is somewhat longer.

Table 4. Concrete properties derived from the capillary suction test for concrete without and with 2 % CN. Average values with standard deviations for 6 parallel discs.

Properties	0% CN	2% CN
Air content, ε_{air} (vol%)	1.3 ± 0.1	1.4 ± 0.1
Capillary porosity, ε_{cap} (vol%)	13.0 ± 0.7	12.8 ± 1.0
Dry density, ρ_{dry} (kg/m^3)	2295 ± 21	2299 ± 26
Solid density, ρ_{sol} (kg/m^3)	2678 ± 5	2679 ± 6
k ($\text{g/m}^2 \cdot \sqrt{\text{s}}$)	18.2	15.5
m ($10^6 \cdot \text{s/m}^2$)	46.6	58.4

Figure 1. Average capillary suction profiles for concrete without and with 2% CN

Since 105°C may coarsen the porosity, prolonged drying at 50°C was tried out first followed by the normal procedure of 105°C drying used in a former study [1, 2]. However, both drying procedures gave about the same result, [1,2] and the concrete based on low alkali cement and 2% CN had actually marginally higher porosity than its reference.

3.1.3 SEM/EDX

An overview of concretes without CN and with 2 % CN are shown in the upper and lower part of Figure 2, respectively. The binder is the more porous part with black holes (i.e. “Hadley grains” = dissolved cement grain), while the aggregate appears smoother (less pores) even though it contains domains of different chemical composition appearing in different shades of grey.

There is no sign of different porosity in the transition zone between aggregate and binder in the two photos of Figure 2. The only marginal difference may be that there seems to be a slightly higher amount of “Hadley grains” in the concrete with 2% CN (right photo of Figure 2). The irregular, bright grains distributed throughout in both cases are unreacted cement grains and the amount seems to be about equal in both cases.

Figure 2. BEI overview of concrete without CN (left image) and with 2% CN (right image).

3.2 Paste

The results from the different investigations of the paste specimen (i.e. containing all the ingredients as for the concrete, except sand and gravel) are reported and discussed in the following sub-sections.

3.2.1 Compressive strength

Testing compressive strength of paste samples is difficult, since the chemical shrinkage of the binder is higher per volume unit than for concrete where the binder is “diluted” by aggregate and where the shrinkage also is restrained by aggregate. Paste samples are thus likely to show a too low strength since they may contain a number of microcracks. This tendency is limited by using smaller samples (often down to 20 mm), but in this case 50 mm cubic specimens were used. However, immediately after setting (i.e. stiffening) the moulds were submersed in water so that the empty contraction pores formed by the chemical shrinkage could be filled with water and less strain formed by water menisci in the pores.

First 4 series with 0 and 2% CN and without and with 20% limestone filler to dilute the cement were made. However, there were too few parallels so it was difficult to draw a conclusion even though the tendency was that samples with 2% CN had higher strength than the reference without. Therefore, new series of plain paste without and with 2% CN were made with 9 parallels and the compressive strength was 69 ± 3 and 74 ± 4 MPa, respectively. The increase in compressive strength both for paste and concrete when CN is added, indicates that it cannot be explained by improved interface between aggregate and binder, but rather by physical or chemical changes of the binder itself.

3.2.2 MIP/HeP

The 4 series with 0 and 2% CN and without and with 20% limestone filler were subjected to pore size distribution (MIP) and total porosity (HeP) studies. Since a recent study [3] has demonstrated that drying at 105°C may substantially alter the pore structure by coarsening the CSH-gel, a very gentle treatment was chosen. First the water in about 5 mm pieces of sample was exchanged with ethanol over a period of 2 months. The ethanol was in great excess and changed several times during the period. Finally, the sample pieces weighing about 1.5 g were dried only at 50°C rather than the usual 105°C prior to the MIP/HeP study. The specific surface; S_g (m^2/g), particle density; ρ_p (kg/m^3), solid density; ρ_s (kg/m^3), specific pore volume; V_g (m^3/kg), specific particle volume; V_p (m^3/kg), mercury accessible porosity; $\varepsilon_{Hg} = 100\% \cdot V_g/V_p$ (%), and helium accessible porosity; $\varepsilon_{He} = 100\% \cdot (1 - \rho_p/\rho_s)$, are listed in Table 5 for the 4 paste mixes. The pore size distribution for neat pastes and pastes with 20% limestone filler are plotted in Figure 3.

The results in Table 5 show that the addition of 2 % CN leads to a substantial decrease of the total porosity. Since the difference in mercury and helium accessible porosity is about the same, the difference lies in pore sizes accessible to mercury. The pore size distributions plotted in Figure 3 show that the pore entry size for mercury is shifted from about 20 nm to 10 nm when 2 % CN is included in the mix.

Note that the pore size distributions from MIP really represent pore entries. In the case of for instance coarse “Hadley grains” (irregular holes) embedded in a gel with small pores (as seen in Figure 2), the pores around such a hole will be misinterpreted as high in numbers since the mercury will flow through them and into the larger hole. This is a serious drawback to the MIP method and the effect is often nicknamed the “ink-bottle” effect.

Table 5. Results from porosity studies of pastes

CN	0 %	2 %	0 %	2 %
Limestone filler	0 %	0 %	20 %	20 %
m (g)	1.66	1.39	1.65	1.32
S_g (m ² /g)	26.46	28.57	22.58	21.83
ρ_p (kg/m ³)	1,648	1,674	1,726	1,787
ρ_s (kg/m ³)	2,127	2,067	2,196	2,142
V_g (10 ⁻³ ·m ³ /kg)	0.1282	0.1029	0.1108	0.0768
V_p (10 ⁻³ ·m ³ /kg)	0.6068	0.5974	0.5794	0.5596
ϵ_{Hg} (%)	21.1	17.2	19.1	13.7
ϵ_{He} (%)	22.5	19.0	21.4	16.6

Figure 3. Pore size distribution of paste without and with 2% CN (left) and paste with 20% limestone filler and without and with 2% CN (right).

3.2.3 DTA/TG

The thermogravimetry curves of paste without and with 2 % CN showed only marginal differences between the two samples. The total weight loss at 105°C is somewhat higher for the reference (23.25 %) than for the mix with 2% CN (23.01 %). If chemically bound water is 25% for 100% hydration, the mass losses give a degree of hydration of 93.0 % for the reference and 92.0% for the mix with 2 % CN. However, if anything, this should contribute to an opposite effect on strength than observed.

A sharp mass loss in the range 470-520°C is due to the thermal decomposition of calcium hydroxide. The difference is negligible and the mass loss of water corresponds to a content of calcium hydroxide relative to the paste at 105°C of 11.5% for the reference and 12.0% for the paste with 2% CN. Properly hydrated cement paste without silica fume should have in the order of 25% calcium hydroxide, so about half the content is consumed in the pozzolanic reaction of the 4% silica fume added.

3.2.4 ²⁹Si MAS NMR

The interpretation of ²⁹Si NMR spectra is described in detail elsewhere [4]. The ²⁹Si MAS NMR spectra of cement paste without and with 2% CN are shown in Figure 4. Contributions from unreacted alite and belite are peaks at -67 and -76 ppm, respectively, and the relative intensity from this “doublet” Q⁰ is 28.8 and 27.2 for paste without and with 2% CN, respectively, corresponding to the degree of hydration for the silicate minerals of 70.0 and 71.7 % (remembering the 4 % silica fume that has fully reacted). The end group of the silicate anion in the CSH gel (Q¹) at -80 ppm has relative intensity 37.6 and 43.5 % for paste without and with 2% CN, while the mid group (Q²) at -85 ppm has intensity 30.4 and 26.3 %. There is also a signal from a mid-group in the silicate anion bridged to

an AlO_4 -tetrahedron, $\text{Q}^2(1\text{Al})$, at -82 ppm with respective intensities of 3.3 and 2.9 %. If the latter is included in the calculation of the average polysilicate anion length, values of 3.8 and 2.2 are obtained for the paste without and with 2% CN, respectively. This is in contradiction to Justnes and Nygaard [4] who observed a slight elongation of the average polysilicate anion when 5.26 % CN was added to paste of OPC (+17%) and SRPC (+5%). However, bot cement types and dosage were quite different.

Figure 4. Experimental (upper) and deconvoluted (lower) ^{29}Si MAS NMR spectra of cement paste without (left) and with 2% CN (right).

3.2.5 SEM/EDX

An overview of cement paste without and with 2% CN is depicted in Figure 5, while enlarged images are reproduced in Figure 6. The bright grains evenly distributed in the images of Figure 5 are unreacted cement grains embedded in the dark grey amorphous CSH binder. The lighter grey, irregular areas are calcium hydroxide (CH). These should not be confused with rounded, non-dispersed silica fume agglomerates (some are marked with SF in the images as examples). The only difference between the two samples as seen from the images in Figures 5 and 6 is perhaps that calcium hydroxide seems to appear in somewhat larger cluster in the paste with 2% CN. This may be understood by slightly lower solubility of calcium hydroxide in the paste with CN due to the common ion effect (i.e. Ca^{2+}).

Figure 5. BEI overview of cement paste without (left image) and with 2 % CN (right image).

Figure 6. BEI of cement paste without (left image) and with 2 % CN (right image).

4. CONCLUSIONS

The compressive strength of concrete was about 10 MPa higher than the reference at both 28 and 90 days when 2 % calcium nitrate (CN) was added to the fresh mix. Extra specimens are stored at 20°C and 100% RH to see if the strength enhancement prevails for up to 10 years.

The capillary suction test showed that concrete without and with 2% CN had no significant difference in total porosity. However, the water suction rate was somewhat slower (-17%) and the time required for the water to reach the top of the specimen was somewhat longer (+25%) when 2 % CN was added. This could indicate finer capillaries or capillaries partly segmented to a higher degree. Note that specimens were dried at 105°C prior to the capillary suction test.

SEM/EDX of concrete did not reveal any striking differences. The aggregate/binder interface was about the same. There appeared to be marginally more “Hadley grains” (i.e. irregular holes) in the binder of the concrete with 2% CN.

The compressive strength of binder without aggregate (i.e. paste) was about 5 MPa higher than the reference when 2 % CN was included in the recipe. Although the standard deviation was high, it is significant and points to the fact that aggregate/binder interface improvement alone cannot explain the strength increase.

The paste specimens for porosity investigations were treated with a gentle ethanol/water exchange and drying at only 50°C. The total porosity was then significantly less ($\approx 30\%$) when 2 % CN was included, and the majority of the pore entry sizes was reduced from ≈ 20 nm to ≈ 10 nm.

No significant difference in chemically bound water, calcium hydroxide content or degree of hydration of paste without and with 2 % CN was observed by thermal analysis. ^{29}Si MAS NMR showed a significantly lower chain length of the linear polysilicate anions of the CSH gel when 2 % CN was included, which may be explained by a higher Ca/Si molar ratio of the CSH gel. SEM/EDX of the pastes indicates that calcium hydroxide may be in the form of larger clusters when CN is included, which may be understood by calcium hydroxide solubility suppression due to the common ion effect of Ca^{2+} .

As an overall conclusion, the long-term strength increase of concrete caused by the addition of 2 % calcium nitrate to the fresh mix seems to be due to lower porosity of the binder only observable by gentle drying techniques.

ABSTRACT

The recycling and re-valuation process of waste products involves studies leading to deep knowledge of them and finding applications for their intended use.

In this work, the utilisation of waste products from calcined clay as a pozzolanic material in cement manufacture is studied. One of the first materials used as pozzolan in history was thermal treated clays, material similar to the calcined clay precast elements, whose wastes are the base of this research. For this study, the materials selected are clay products, which have been rejected for various reasons: a low temperature inside the kiln, dimensional and mechanical failures and durability loss.

The kinetics of the pozzolanic reaction is investigated following chemical methods. The hydrated phases were studied by means of X-ray diffraction (XRD). Also, the mechanical properties and hydration heat are studied in the blended mortars.

The pozzolanic activity does not vary significantly for the different samples selected and, on the other hand, this activity is very similar to those products fabricated suitably. So, these ceramic materials with some anomalies due to the calcining temperature, and which are not suitable for commercialisation, can be recycled as pozzolanic materials in the manufacture of blended cements.

1. INTRODUCTION

The utilisation and revaluation of industrial by-products have to acquire greater priority in the future for various reasons: energy cost, cost of raw materials and manual labour, necessity of controlled sinks and mainly, environmental damage caused by the progressive increase of all types of wastes.

For this reason, different world-wide initiatives have appeared to control and regulate the management of industrial wastes and materials from demolition. In this way, the legal restrictions will become stricter to minimise and recycle these products. However, finding definite applications requires additional knowledge for the waste materials.

In the European Union, the amount of construction and demolition waste varies from 720 Kg/person/year in Germany and Holland to 17 Kg/person/year in Ireland and Greece, giving an EU average of 480 Kg/person/year. Nowadays, the recycled construction and demolition waste average in the EU is between 25% and 30% of production and, the rest is deposited at dumps (1). Holland (90%), Belgium (87%), Denmark (81%) are the countries which recycle most residues in Europe, whereas Spain only recycles 5%. So, The Waste National Plan [1] identifies amongst its ecological objectives the reusing of, at least, 40% in 2005 and a 60% in 2006.

In spite of the improvements in manufacturing process, factories produce significant amounts of material considered not suitable for sale, i.e. waste material. Spain produced more than 21 million tons/year of ceramic material (bricks, tiles, blocks, etc). The amount of factory rejected products depended on the type of manufacture and product requirements.

The ceramic products come from natural materials, which contain a large percentage of clayey minerals. The activation of clay is achieved by means of the dehydration process, followed by the separation of amorphous and active alumina. Clayey minerals such as Kaolinite, mormorillonite or mixtures between them become pozzolanic materials by mean of a controlled calcination process (540°C -980°C). If the clays are illites or contain large amount of vermiculite, chlorite and micas, it will be necessary to use higher temperatures for activation [2-3].

This paper studies three waste materials coming from the ceramic sector, researching their applications as pozzolanic materials. The pozzolanic reaction kinetic are studied following a chemical method, X-ray diffraction as well as hydration heat and compressive strength of blended mortars.

2. EXPERIMENTAL, RESULTS AND DISCUSSION

2.1 Materials

This work has chosen 5 ground and milled samples from two different waste ceramic materials. These samples show different particle size distributions, since they were only controlled on the 45 microns residue. Their Blaine specific area was subsequently determined in the laboratory.

The different materials used and their finenesses are shown below:

Bricks: There are three samples of waste ceramic materials produced at different temperatures:

L1: Adequate firing temperature(Blaine 6000 cm²/g u.). L2: Correct firing temperature (higher temperature) (Blaine 5500 cm²/g u.). L3: Incorrect firing temperature (lower temperature) (Blaine 5000 cm²/g u.)

Tiles: Waste materials with adequate firing temperature (one sample with two different fineness):

T1 (3500 cm²/g u. Blaine) y T2 (3200 cm²/g u. Blaine)

These materials have a chemical composition similar to other industrial by-products such as silica fume and fly ashes [4] (Table 1). All of them present a marked acid character with alumina and silica as main components and also iron oxide (about 70%); except for sample L3 which shows a high CaO content (48,11%).

Table 1. Chemical Compositions of the samples used in the study

Chemical Compositions (wt%)	L1	L2	L3	T1-T2
LOI	10,82	1,73	4,26	3,44
SiO ₂	45,18	50,53	25,97	52,88
Al ₂ O ₃	17,56	19,13	10,50	16,80
Fe ₂ O ₃	5,05	6,62	4,14	5,29
CaO	15,00	14,39	48,13	12,41
MgO	3,35	3,56	3,21	3,64
SO ₃	0,00	0,00	3,11	0,79
Na ₂ O	0,50	0,51	0,41	0,58
K ₂ O	2,63	3,13	1,20	3,10

The mineralogical composition of the samples were studied by mean of X ray Diffraction. The product L1, Figure 1, comprises quartz (Q), illite (I), calcite (C), hematite (H) and traces of montmorillonite (Mo). The product L2, Figure 2, is rich in feldspans as anorthite (An), piroxenes as augite (Au), quartz (Q) and hercynite (He). The sample L3, Figure 3, is mainly formed from calcium silicate Ca_3SiO_5 (CS) and calcium magnesium aluminum oxide silicate (CM). Samples T1 and T2 have the same composition and are very similar to the L1 sample, although T1 and T2 samples present some more crystalline compounds such as calcium aluminum oxide (CA) and augite (Au), Figure 4.

Figure 1. XRD pattern for sample L1

Figure 2. XRD pattern for sample L2

Figure 3. XRD pattern for sample L3

Figure 4. XRD pattern for samples T1 and T2

2.2 Pozzolanic Activity

In order to study the pozzolanic activity of these materials, an accelerated method was used, i.e. the material-lime reaction with time. The test consisted of putting the different pozzolanic materials in contact with a saturated lime solution at 40 ± 1 °C for 1 day, 3 days, 7 days, 28 days and 90 days. At the end of that time, the CaO concentration in the solution was established. The fixed lime (%) was obtained from the difference between the concentration in the saturated lime solution and the CaO found in the solution in contact with the sample, at the end of the given period.

The results (Figure 5) show that the brick residues have an acceptable pozzolanic activity, since at the age of 1 day, samples L1, L2 and L3 fixed 46%, 26% and 11% of lime, respectively. The mineralogical composition has a direct effect on the pozzolanic activity. However in this case, an increase of pozzolanic activity with increasing fineness is observed. This shows a very low activity due to its low fineness. Subsequently, all these samples fix about the same amount of lime, being about 50% at 3 days and 80% at 90 days, when the pozzolanic test finishes

Figure 5. Pozzolanic activity

These results show that the calcining temperature of these ceramic materials (about 900°C) is enough to activate the clays, giving pozzolanic properties.

The samples with ground ceramic tiles show similar results to the ceramic bricks, although the lower finenesses delay the beginning of the pozzolanic activity. At 7 days, the fixed lime for the T1 sample is 68%, and the low fixed lime of the T2 samples is due to the low specific surface area and is not due to the chemical and mineralogical composition, since both T1 and T2 are made with the same clay material and calcined at the same temperature.

2.3 Pozzolanic Reaction Products

The mineralogical composition of the samples, which have been submerged in lime saturated solution, for 1, 7, 28 and 90 days are studied by mean of X-ray diffraction.

The original crystalline compounds in the L1 and L2 samples are maintained during all the ages, but in the L3 sample the CS and CM reacts partially. In this sample new crystalline compounds are formed due to the reaction with the calcium hydroxide, very similar results to those obtained with fly ash [5-6]. In the sample L1 (Figure 6) calcium aluminium hydrate and more specifically C_4AH_{13} (CAH) as well as carboaluminate C_4AcH_{11} (CAc) is formed, although at early ages (24h) is observed monosulfoaluminate (C_4AsH_{12}) (CAs) is observed.

Figure 6. XRD pattern for sample L1 with lime over time

At 90 days ages, the composition progress up to formation of calcium aluminum silicate hydrate (CAS). In L2 and L3 samples (Figure 7) observe mainly the formation of C_4AcH_{11} (CAc), T1 and T2 the tendency is the same, although at 90 days the C_4AH_{13} (CAH) predominates, Figure 8.

Figure 7. XRD pattern for sample L3 with lime over time

The presence of C-S-H, cannot be confirmed by the x-ray diffractograms, because it is hidden by the main peak of calcite and other mineralogical components of the original samples.

Figure 8. XRD pattern for sample T1 with lime over time

2.4 Mixed Mortar Study

2.4.1 Hydration heat

Waste material T1 was used as the pozzolanic material. The cement is a CEM I-42,5 N, according to UNE EN 197-1:2000 standard [7] and standard sand according to EN 196-1: 1994 standard [8], with a silica content upper to 98% and with a particle size less than 2 mm.

The method given for determining heat hydration in the Spanish standard [9] is based on the Langavant Calorimeter. This semi-adiabatic method consists in quantifying the heat generated during cement hydration using a Dewar flask, or, more exactly, a thermally isolated bottle. Since the exterior conditions are very influential, the test is carried out in a climatized room at $20^{\circ}\text{C} \pm 2^{\circ}\text{C}$.

The measurements were made over five days, as is required by the standard, since the heat increase is observed to be very low at later times, and also since the relative error of the measurement increases beyond that time.

Samples analysed are:

Reference Mortar: 100 % cement

Blended mortar: cement/ceramic material (T1): 80/20

These mixed cements were used to prepare mortars, whose sand/cement proportion was 3/1 and W/C was 0.5.

The calcined clay decreases the heat developed during hydration of the mixed cement (cement/clay material: 80/20), as shown in Figure 9 and, more clearly in Figure 10.

Figure 9. Evolution of the hydration heat

Figure 10 showed the heat increase, positive or negative, developed by the mixed cements with respect to the reference cements taken as zero. As observed, fly ash and clay material present negative values in the heat of hydration test. This is in contrast to that of silica fume with higher pozzolanic activity formerly studied [10] which provokes an increase in the heat of hydration with respect to the reference cement. This increase is due to the weakly exothermal pozzolan-lime reaction, that, in the case of silica fume is able to increase the heat released.

Thus, the calcined ceramic material presents a pozzolanic activity, but the heat developed in this reaction is not able to increase the heat released in the cement hydration, decreasing this heat in a percentage similar to that of the cement substitution by the clay in the mix. So, at 24 hours, the maximum heat for mortar 80/20 is 19% less than that of the reference mortar.

Figure 10. Increase of the hydration heat

2.4.2 Mortar mechanical strengths

The mortar proportioning and mixing is done according to the EN 196-1:1994 standard [8]. The mortar composition was 3/1: sand/cement and W/C was 0.5. The ceramic waste materials used replace a 15% of cement.

The mortar produced are:

- M1: Reference Mortar (100% cement)
- M2: Mortar with product L1, replacing 15% of cement
- M3: Mortar with product L2, replacing 15% of cement
- M4: Mortar with product L3, replacing 15% of cement

The results of the flexural and compressive strength tests of the 4x4x16 specimens at 24h and 28 days are shown in the Figure 11. The flexural strengths at 24 hours do not vary significantly. At 28 days of curing, the values obtained are slightly lower than the reference mortar in all cases.

Figure 11. Mortar mechanic strengths

The compression strength results do not show important changes. For the mortars M2, M3, and M4 with a 15% of replacement, the compression strengths decrease slightly compared with the reference mortar, but those are less than the percentage of cement substitution, indicating that these materials act as pozzolanic material improving the compression strengths.

3. CONCLUSIONS

The studies carried out indicate the feasibility of using these waste materials from calcined clay as pozzolans. These results indicate that the firing temperature of these materials (around 900°C) is enough to activate the clays, giving them pozzolanic properties. The hydration products are similar to those obtained from fly ashes [5].

Mortars that have pozzolanic material incorporated in them usually increase hydration heat, with respect to the reference mortar, during the first hours of the test, depending on the pozzolanic activity of the material, because the reactions taking place with the lime also give off heat [10]. The heat developed in the cement hydration with a 20% of calcined clay is lower than that of reference cement. This is because the percentage of cement substitution counteracts the heat from the pozzolanic reaction, and the substitution effect predominates over the effect of the pozzolanic activity the cement substitution effect is stronger than the pozzolanic activity of the material.

In the mortars with a 15% replacement, the compression strengths decrease slightly compared with the reference mortar, but those are less than the percentage of cement substitution, indicating that these materials act as pozzolanic material improving compression strengths.

ABSTRACT

Clinker production presents substantial problems of atmospheric emissions, either of flow rates either for the presence of specific pollutants in the fine fraction (heavy metals and, to a lesser extent, organic compounds). The levels of particle size ranges (between 70% and 90% of particles in dry process kiln gas $<10 \cdot 10^{-6} \text{m}$) imply that global efficiency values cannot be used to estimate either of fine particle emission values or of its variations, the likely direction for any evolution in emission limits. In the range of emission limits, global efficiency values leads to uncertain operation practices to control heavy metals emission and should be replaced by fractional efficiency criteria (concerning total mass loading or a metal of concern). In this work, cascade impactors, used normally to measure the size distribution of particulate matter, are to be employed as sample preseparators. Further analysis of target elements or compounds proceed in the laboratory.

The results lead to a combination of operation variables for emission control (measurement of in-stack size distribution and electrofilter fractional efficiency) with the knowledge acquired from the distribution of heavy metals along the size distribution of emitted dust, which include: Size distributions measured at the inlet and at the outlet of a clinker dust electrofilter, analysis and physicochemical characterization of impactor stages, using AAS, ICP/OES and ICP/MS) and microscopy. The operational result is a curve of fractional efficiency of the electrofilter.

Conclusions cover the observed separation of most relevant trace metals, its usefulness as criterium to specify the raw meal (secondary fuels or feeds), and the use of fractional efficiency as the main criterium to specify and to operate a dust separation unit. Also prospects for real-time monitoring will be discussed.

1. SCOPE

Clinker production presents substantial problems of atmospheric emissions, either of flow rates or for the presence of specific pollutants in the fine fraction (heavy metals and, to a lesser extent, organic compounds). Consideration of some basic data concerning size ranges, for raw gas is particularly important for dry clinker processes. The values of size ranges between 70% and 90% of particles in dry process kiln gas $<10 \cdot 10^{-6}\text{m}$ imply that global efficiency values cannot be used to estimate either fine particle emission values or their variations, the likely direction for any evolution in emission limits. In the range of emission limits, global efficiency values leads to uncertain operational practices to control heavy metal emissions and should be replaced by fractional efficiency criteria (concerning total mass loading or a metal of concern).

1.1 Limits of HM's

The Directive on the incineration of waste (which in conjunction with the Directive 1999/31/CE on landfill disposal and Directive 96/61/EC concerning integrated pollution and prevention control, defines the main legal framework) states emission limits for cement kilns as co-incineration plants with special provisions. Strictly, any variation in material or fuel pattern could be covered by these provisions. The permit shall include emission limit values for dust, SO_2 , NO_x , VOC and metals. These limit values may be supplemented or replaced by other equivalent parameters or technical measures.

In the U.S.A., the emission limit values are established in the "40 CFR Part 63, Subpart EEE. NESHAPS: Final Standards for Hazardous Air Pollutants for Hazardous Waste Combustors. Final rule, 30 September in 1999." Table 1 summarizes the different emission limit values.

The tendency of emission limits (ELV's) has taken cognisance of the experimental knowledge about fine fractions. National ELV'S (for the kiln stack) differ not only on target metals but also in measurement conditions, methods, time interval and frequency. So, there is not yet a common language concerning trace metals emissions, which could provide a common basis for the interpretation of several sampling, analysis, and result reporting approaches.

1.2 Secondary raw materials and fuel substitutes (including typical range of concentrations for the most relevant heavy metals)

Recently, the interest and role of wastes as fuels or secondary raw materials in the cement industry is rapidly growing. Large regional discrepancies are also reported, closely related to the structure of the local market, and policies. But secondary raw material consumption in clinker production should neither be considered merely as a waste treatment option, nor as a privileged co-incineration option; it constitutes a beneficial action over the process life-cycle from other industries and also a traditional practice that contributes to lessen the depletion of natural resources. The use of trace metals as a fingerprint of maximum feed ratio for a specific type of waste is yet to be reported on.

2. EXPERIMENTAL WORK

Data presented here have been collected in a cement plant with nominal production of 2000 t of Portland clinker/day, which uses marl and limestone, and occasionally lime mud and pool rolling, and petroleum coke and tyres as fuel. In spite of the fact that particle emissions are below limits (TSP about 30 mg/Nm³), real uncertainties have been observed in the achievement of the limits in metal content. This makes it necessary to design a specific experimental program with the additional objective of correlating the dose and operational parameters with the metal emissions.

On-line methods for the measurement of aerosol chemical properties represents a serious gap in existing aerosol instrumentation. Consequently, the control of composition must be periodic and by extracting a representative sample. In this context, the continuous monitoring of PM10 as surrogate for heavy metal control has been proposed. The speciation (relevant to the environmental fate of such an emitted metal) is not generally determined. Continuous emission monitoring, most of the systems being spectroscopy-based, is so far unable to ensure plant monitoring, despite progress in this field. However, continuous emission monitoring could be considered as the up-to-date maximum achievable monitoring- technology.

In this work, cascade impactors, used normally to measure the size distribution of particulate matter, are to be employed as sample preseparators. Further analysis of target elements or compounds proceed in the laboratory. Using this kind of sampling instruments, measurements must meet two conflicting requirements. First, the isokinetic condition require a continuous adjustment of sampling velocity in the probe to match the local in-stack gas velocity. But in order to be able to obtain the particle size distribution, the cut points in each stage of the impactor must be constant over the measuring period, that is, the flow velocity through the impactor must be constant. The results here presented were obtained adjusting the flow at each point.

The size distribution of emitted particles was measured by means of the combination of a sampling train (Napp) and a cascade impactor placed in-stack. The preliminary tests to ensure isokinetic conditions were conducted following the EPA Reference Methods 1 to 5. Two cascade impactors were used in this campaign: a Dekati PM10 (3 stages and a back filter, with nominal cut diameters of 10, 2.5 and 1 µm) and a Pilat Mark III (seven stages and a backfilter), depending on the main goal of the measurement: size distribution and/or chemical analysis.

Sampling and analysis of heavy metals was conducted following the VDI3868, B. 1, 2EVDI 2268, B. 1- 4 standards, and VDZ analytical recommendations.

The size distribution (aerodynamic diameter) of particles in the gas exiting from the preheater and from the conditioning tower were measured using a Ströhlein apparatus for in-duct collection and further fractionation using a laboratory impactor. The sampling conditions (temperature and dust load) leads to unacceptable measuring errors in the case of stack sampling, and values obtained must be considered approximate.

The results lead to a combination of operation variables (measurement of in-stack size distribution and electrofilter fractional efficiency) with the knowledge acquired from the distribution of heavy metals along the size distribution of emitted dust.

3. RESULTS

Figure 1 shows the typical size distribution of particles in the raw gas. The effect of water spray in the conditioning tower is mainly concentrated in the coarse fraction. During the experimental program, only in a few cases were particles larger than 13 μm observed at the electrofilter inlet, and their presence was associated with high gas temperatures and, consequently, poor cooling efficiency by means of water addition. These approximate results are consistent with VDI (1985) figures about raw gas size distribution.

Figure 1. Particle size distribution in raw gas: $dM/d(\log D)$ versus aerodynamic diameter in μm

Figure 2. Emission size distribution (Mark III). $dM/d(\log D)$ versus aerodynamic diameter in μm

Figure 2 shows the typical size distribution measured at the clinker kiln stack in less favourable conditions, that is, when the crude mill gases are also emitted by this source. The size distribution of the puff due to the electrode and plate rapping was inferred as the difference between total or measured size distribution, and the ideal conditions (no rapping), and fitted to a log-normal distribution with $6,0 \cdot 10^{-6}$ m of median diameter with a deviation of 2,5, which is considered as a conservative hypothesis

Figure 3 shows the relative contributions of the feed and the fuels to the entry of heavy metals. The differential enrichment of the traces in the clinker kiln dust (CKD), recirculated from the hoppers of clinker kiln electrofilter are observed.

Figure 3. Relative contributions of the main streams (crude feed, petroleum coke, tyres, recirculated CKD and clinker)

Figures 4a to 4d summarize the range of concentrations (minimum and maximum for each heavy metal) along the experimental campaign. These results have been obtained by AAS, following the recommendations and methods of VDZ. In full scale processes, considerable difficulties arise in order to establish a uniform closure of mass balances due to the relative weighing precision and the mass flows of relevant trace metals, and also because of the variability along an entire operating campaign. These results lead to the identification of experimental mass balances methodology and the interpretation of individual measurements.

Figure 4a. Variability of trace metals concentration (ppm) in crude

Figure 4b. Variability of trace metals concentration (ppm) in clinker

Figure 4c. Variability of trace metals concentration (ppm) in precalcinator

Figure 4d. Variability of trace metals concentration (ppm) in CKD (ppm)

An intensive analysis and physicochemical characterization of impactor stages, using AAS, ICP/AE, S ICP/MS and microscopy was carried out to determine the usefulness of elemental analysis as the main tool to understand the environmental fate of heavy metals, and also to ascertain the possibilities of emission control under operating conditions.

The collected dust in the PM_{2.5} stage of a Dekati PM₁₀ impactor, Figure 5b, could correspond to a rather slow formation of fractal-like aggregates, whereas in Figure 5a, corresponding to the same sampling period, shows a condensate of nearly spherical geometry.

Figure 5a. SEM image of a DekatiPM10 cut corresponding to the nominal 1µm

Figure 5b. SEM image of a DekatiPM10 cut corresponding to the nominal 2.5µm

In Figure 6, two fractions of fractionated CKD are shown. These images correspond to operating conditions for mixed clinker and crude mill dust. Figure 6a presents, as typical for these conditions, a very large range of physical diameters, whereas the aerodynamic diameters are approximately the same due to the chemical composition and origin of the two components. Figure 6b shows an extreme case of this situation, in which the condensation aerosol enriched in heavy metals and their compounds behaves aerodynamically in the same manner as the lighter components.

Figure 6a. SEM image of fractionated clinker kiln dust

Figure 6b. SEM image of fractionated CKD

The fractionated CKD was also chemically analyzed after leaching with demineralized water. The analysis was for major (Ca, Al) and minor elements (S insoluble, alkalis, Mg, Fe) and for trace elements. As an example, in Figure 7 are presented the representative values for Pb and Tl (ppm on the basis of the total sample mass) in the soluble and insoluble fraction, analyzed by means of ICP/AES. The stage numbers correspond to the following intervals (calculated assuming a mean value of the relative bulk density, 1.5): 0.39-0.81, 0.81-1.67, 1.67-3.31, 3.31-6.64, 6.64-12.9, 12.9-26.45, 26.45-32 μm .

Figure 7. Behaviour against water leaching of Tl and Pb in the CKD.

In the soluble fraction, thallium exhibits a bimodal distribution with pronounced modes in stages 1 and 5. Lead in the soluble fraction appears to be less concentrated and presents maxima in stages 1 and 5. The insoluble fraction shows a very different pattern of size distributed elemental composition of Tl and Pb. Lead seems to be clearly enriched in this fraction, with maxima below stage number 3, and another local but less pronounced maximum in stage number 7. Thallium distributes rather uniformly below the stage number 4, and its less pronounced positive gradient in the stage 7 could be attributed to condensation on fractal-like structures.

Figure 8 shows the structure of control variables to maintain the emission of heavy metals under the set points fixed on administrative requirements, This nearly real-time information is used to regulate the flows in order to match with correlations obtained for each metal.

Figure 9 shows the experimentally obtained fractional efficiency curve for the electrofilter in the field campaign. There is a clear penetration window in the size range of enrichment in volatile heavy metals, due to the intrinsic operation of electrofilters. Whilst the advantages of this type of dedusting equipment are notorious in cement plants, they are not able to separate in the range about $1\ \mu\text{m}$ with the necessary efficiency to ensure compliance with ELV's of certain metals. The set points for applied voltage, which is the unique reliable control variable, should rely on experimental evidence about the behaviour of metals, which in turn depends on the feed and fuels characteristics and trace contribution.

Figure 8. Operation variables for emission control

Figure 9. Fractional efficiency of electrofilter

4. CONCLUSIONS

The observed separation of most relevant trace metals requires further explanation on the basis of local analysis and speciation. The size of phases implies limitations for the application of several techniques (IMP/MS with laser ablation, and so on). Morphological and chemical information could be used together to gain insight about the nature of fine particulate fractions of emissions from clinker kilns generally, the metals are concentrated on finer fractions, either in water- soluble and insoluble fractions. Thallium is concentrated in soluble phases.

Although, its usefulness as a criterium to specify the raw meal (secondary fuels or feeds), the best practices observed for heavy metal emission control, and the use of fractional efficiency as the main criterium to specify and to operate a dust separation unit. Also prospects for real-time monitoring will be discussed.

The design, operation and maintenance practices for emission control and compliance must be based on fractional efficiency observed for the particular feed mixture and fuels used. This fractional efficiency should be established on the basis of experimental correlations with operating variables and conditions.

A very important fraction of emissions appears in a size range that does not modify substantially the overall efficiency. So, this parameter loses its quantitative significance for ESP performance quantification. Overall efficiency explains neither the basic geometry of the electrode configuration nor the rapping sequence, nor the performance for emission control purposes.

Prospects for real time monitoring depend on the accumulation of full-scale experimental evidence of heavy metals mass flows and trajectories, depending on operating practices. This is the previous step to develop thermodynamically-based approaches, which could use the measured temperatures to predict heavy metals, their species, and behaviour. It is confirmed that ESP is not a valid subrogated for heavy metals.

ABSTRACT

Recently, soft x-ray transmission microscopy has emerged as a useful technique for the examination of cement based materials. The unique advantage of this method is that it allows for high resolution (25 nm) observation of samples under wet conditions at atmospheric pressure. Thus, hydration of cementitious materials can be followed over several hours. For this study, Portland cement was hydrated in solutions saturated with calcium hydroxide and gypsum, with and without retarders (sucrose, calcium lignosulfonate, tetrasodium pyrophosphate and sodium gluconate). The delayed growth of hydration products on the surface of cement grains was documented.

1. INTRODUCTION

While there are many microscopy techniques available for the study of cement-based materials, they all have some drawbacks. There is usually a trade-off between resolution and artifacts introduced by sample preparation. The recently adopted soft x-ray transmission microscope does not transcend this problem, but it does offer the extremely valuable and unique ability to study cement hydration in situ. High-resolution (25 nm) images are obtained in real time of wet samples at atmospheric pressure. While the water-to-cement ratio (w/c) must be high and the cement particles small, the chemistry of the solution can be easily tailored, allowing observation of the effects of chemical admixtures on hydration.

Soft x-ray microscopy has been successfully applied to the study of alkali-silica gels and tricalcium silicate (C_3S) hydration [1-4]. Research on hydration of C_3S , ordinary Portland cement (OPC), calcium aluminate cements and pozzolans is ongoing. The work presented here examines OPC hydration in the presence of chemical retarders. There are many substances that retard hydration of OPC and its constituent phases, including sugars and many other water-soluble organic substances, as well as some inorganic species. The mechanisms of retardation are in most cases not well proven, but it is believed that most retarders form complexes on the surfaces of hydrating grains or hydration products thereby inhibiting hydration [5-7]. The retarders chosen for this study were the following: sucrose, one of the strongest and most widely-used retarders; calcium lignosulfonate, a water-reducing agent (dispersant) that also acts as a retarder; plus tetrasodium pyrophosphate and sodium gluconate, ingredients in some commercial concrete admixtures. OPC was mixed in dilute

suspensions containing these retarders and the growth of hydration products was observed using a soft x-ray transmission microscope.

2. MATERIALS AND METHODS

The experiments described here were conducted using the soft x-ray transmission microscope (XM-1) located on beam line 6.1.2 of the Advanced Light Source (ALS) at the E.O. Lawrence Berkeley National Laboratory (LBNL) in Berkeley, California and operated by the Center for X-Ray Optics (CXRO). The synchrotron generates radiation with a wide spectrum of wavelengths. This radiation is filtered by a plane mirror and only that in the soft x-ray regime with wavelengths between 0.7 and 4 nm (300 to 1800 eV) is sent to a condenser zone plate, which then focuses the radiation onto the sample. X-rays transmitted through the sample are refocused with a micro zone plate onto an x-ray CCD camera (Figure 1). More detailed information on the microscope has been reported elsewhere [8,9].

Figure 1. Soft x-ray transmission microscope

The use of soft x-rays, with wavelengths more than 100 times shorter than visible light, leads to a maximum resolution of 25 nm. In these experiments, a wavelength of 2.400 nm (516.6 eV) was used. The magnification of the images is between 1600 and 2400x and remains fixed during a given session. The images have a circular field of view of approximately 10 μm in diameter. If a larger field of view is desired, several images are taken across a grid and a composite image is created by montage alignment using a custom autocorrelation process [10]. All of the images presented in this paper have been processed in this manner.

Cementitious suspensions are placed between two silicon nitride membranes and sealed into a stainless steel mounting cell prior to examination. Rubber O-rings in the sample cell prevent water loss and carbonation. In order for sufficient x-rays to be transmitted, the total thickness of the sample must not exceed 10 μm , necessitating the use of dilute suspensions of small particles. There is some risk of carbonation during the mixing, centrifugation and transfer of the sample, although we did our best to minimize exposure of the suspensions to air.

A commercial Portland cement (Lafarge) was used with a density of 3110 kg/m^3 , Blaine specific surface area of 387 m^2/kg , volume mean diameter of 12 μm and chemical composition shown in Table 1. Distilled water was boiled to remove dissolved carbon dioxide, and then cooled to room temperature. Retarders were dissolved in the prepared, room temperature water at a concentration of 1g/L. Determining an appropriate concentration of retarder was problematic because of the high water-to-cement ratio used for these studies; 1g/L enabled us to see retardation of the growth of hydration products, but may not be exactly equivalent to concentrations used in practice. The retarders used were sucrose (Fisher Scientific), an ultrafiltered calcium lignosulfonate ("Ultrazine

Ca,” Børregaard Lignotech), tetrasodium pyrophosphate decahydrate (Aldrich Chemicals) and sodium gluconate (Sigma). All solutions were then saturated with respect to calcium hydroxide and gypsum by adding 3.5 g $\text{Ca}(\text{OH})_2$ (Sigma) and 1 g $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (Sigma) per 100 mL at room temperature. The solutions were shaken vigorously in sealed, polyethylene bottles for one minute and allowed to settle overnight. On the day of testing, 14 mL of solution was pipetted from the top of the settled mixtures and placed in sealed, polystyrene containers for each sample to be studied. Care was taken not to disturb the solids at the bottom of the containers and minimize exposure of the solutions to air.

Saturation of the solutions with calcium hydroxide and gypsum was done in order to compensate for the diluteness of the final suspensions, and to ensure that the cement was hydrating in a liquid medium not too different from that typical of ordinary concrete applications. Without such an approach, we might have expected excessive dissolution of the anhydrous particles due to the high dilutions used. The pre-saturation with respect to calcium hydroxide was intended to prevent excessive dissolution of the silicate phases, and the pre-saturation with respect to gypsum was intended to prevent excessive dissolution of the aluminate phases. An excess of calcium hydroxide and gypsum were used in order to guarantee saturation because some chemical admixtures may change their solubility. Likewise, the presence of calcium hydroxide and gypsum may change the solubility of some admixtures so that the initial 1g/L concentration of the retarders listed above may not necessarily be accurate in the final solution.

Immediately before testing, 0.28 g of cement was added to 14 mL of solution ($w/c = 50$), and the mixture was shaken for approximately 15 seconds to ensure mixing. Aliquots of 2 mL were removed from these mixtures and then centrifuged briefly in order to isolate the smallest particles in the supernatant. One small drop of supernatant was then placed on the silicon nitride membrane and sealed in the sample cell for immediate observation. Mixing and imaging was always done at room temperature, $22 \pm 2^\circ\text{C}$. All of the images shown in this paper were chosen for their quality and clarity out of several showing similar phenomena.

Table 1. Chemical composition of Portland cement

Oxide Composition (% by mass)	
CaO	64.8
SiO ₂	20.7
Al ₂ O ₃	4.5
Fe ₂ O ₃	1.9
MgO	0.76
TiO ₂	0.23
P ₂ O ₅	0.15
K ₂ O	0.21
Na ₂ O	0.16
SO ₃	3.35
LOI	2.81

3. RESULTS AND DISCUSSION

3.1 Neat Portland Cement

Images from OPC hydrated in a solution saturated with calcium hydroxide and gypsum are shown in Figure 2. On all samples there is layer of finely divided hydration products with a “sheaf-of-wheat” morphology. These are believed to be a form of calcium silicate hydrate (C-S-H) [1,11]. The density and thickness of the fibers differ between samples, but these products are always immediately present (images have been taken as early as 8 minutes after mixing), and look like the initial products formed around pure C_3S particles under similar conditions [unpublished work].

Once formed, these products do not change during the first several hours. In Figures 2c and 2d, angular crystals believed to be ettringite are growing (top center). Ettringite growth has been observed in some, but not all, early age OPC samples. Note that the shadow on the bottom left of Figure 2c is an artifact of the montage alignment and does not reflect a change in the nature or volume of hydration products.

Figure 2. Three different samples of OPC hydrated in a solution saturated with calcium hydroxide and gypsum, w/c = 50, a. 28 minutes, b. 49 minutes, c. 34 minutes, d. (same location as c) 72 minutes. Scalebars = 1 μm .

3.2 Sucrose

Sucrose is well-known as a very strong retarder of cement hydration. Figure 3 shows images taken of OPC in a solution containing sucrose (1g/L). It is difficult to see if there are hydration products on the cement grains in Figure 3a or if the surfaces of the grains are simply rough. The chains of small spheres in Figure 3a are unidentified products that have apparently dissolved or dispersed in the later images. Hydration products with a sheaf-of-wheat morphology form after one hour as seen in Figure 3b. Clearly, the sucrose has delayed the formation of this type of C-S-H. Unfortunately, the resolution of these images is too low to discern whether an initial layer of hydration products forms on the hydrating grains which is later poisoned, or if the cement grains themselves are poisoned by the sucrose.

b.

c.

d.

Figure 3. OPC in solution saturated with calcium hydroxide and gypsum containing sucrose (1g/L), w/c = 50, a. 31 minutes, b. 68 minutes, c. 100 minutes, d. 130 minutes. Scalebars = 1 μ m.

Evidence of further hydration appears in Figure 3c as some of the dark solid grains have been replaced by what we call an “inner product” C-S-H. It has either lost a lot of calcium relative to the anhydrous materials or has become thinner or less dense, thus increasing its transparency to x-rays. By 2 hours, hydration has slowed again as there are no significant differences between Figures 3c and 3d. Sucrose has often been referred to as a “delayed accelerator,” meaning that after the retarding period is over, hydration proceeds more rapidly than usual [5,12]. The apparent rapid growth of this inner product as seen in Figure 3c has also been seen in samples that have been accelerated with calcium chloride [13].

As discussed in reference to accelerators [13], the “pseudomorphic” hydration that results in inner product C-S-H is essentially a leaching process, i.e. the inner product that forms is presumably calcium-poor relative to the anhydrous material. Given the high dilutions necessitated by the x-ray transmission microscopy technique, it is very possible that this leaching process is rather

exaggerated compared to what would in principle be observed in cement pastes made at the much lower water-to-cement ratios typical of concrete applications. Since it is known that calcium hydroxide is the main component that leaches out of the anhydrous grains during cement hydration, we did take the precaution of using a pre-saturated calcium hydroxide solution as the dilution medium, in order to minimize this type of artifact. Nevertheless, calcium hydroxide supersaturations of 2-3 generally occur at fairly early ages during OPC hydration [14] and we cannot preclude this possibility in our experiments, implying that the loss of calcium could still be much greater than would be expected in more concentrated suspensions. Moreover, any loss of calcium hydroxide due to carbonation, or complexation by the admixtures used, would tend to enhance the leaching effect.

3.3 Lignosulfonate

Figure 4. OPC in solution saturated with calcium hydroxide and gypsum containing calcium lignosulfonate (1g/L), w/c = 50, a. 11 minutes, b. 88 minutes, c. 162 minutes. Scalebars = 1 μ m.

Calcium lignosulfonate is a much weaker retarder than sucrose, but lignosulfonates are important commercially as the principal ingredients in many concrete admixtures sold as “water-reducing agents.” The retarding effects of lignosulfonates are often attributed to the presence of sugars in the commercial products, but even “pure” lignosulfonates have some retarding power [15]. Like sucrose, calcium lignosulfonate delays the growth of sheaf-of-wheat C-S-H; none is present in Figure 4a, but by 162 minutes (Figure 4c) the grains are almost completely covered with a thin layer of this type of product. The fibers are much smaller and finer than in the sucrose sample, but this may not be important since the morphology varies even in neat OPC samples (Figure 2). Ettringite

is also growing in this sample as seen clearly in Figure 4c. It is difficult to say whether ettringite formation has been delayed by calcium lignosulfonate as it does not appear in all samples nor does it form at a consistent time. Rapid growth of inner product C-S-H is not seen in these samples. This may be a result of the fact that lignosulfonates do not influence hydration as strongly as sucrose [15].

3.4 Phosphate

Phosphates are known to be good retarders [16] and can be used to control slump and setting times in concrete. They are weaker retarders than sucrose [15]. The results of a tetrasodium pyrophosphate addition are shown in Figure 5. Since the earliest picture was taken after 45 minutes of hydration, it is impossible to know whether the formation of sheaf-of-wheat C-S-H was delayed or if the image was simply taken too late. A similar experiment with C_3S instead of OPC showed very little sheaf-of-wheat product after 40 minutes and much more after 77 minutes, demonstrating the retarding power of phosphates (images not shown). The images in Figure 5 are similar to those with sucrose (Figure 3) in that inner product C-S-H is observed; the dark solid center of the grain visible in Figure 5a is replaced by hydration products in Figures 5b and 5c.

Figure 5. OPC in solution saturated with calcium hydroxide and gypsum containing tetrasodium pyrophosphate (1g/L), w/c = 50, a. 45 minutes, b. 94 minutes, c. 143 minutes. Scalebars = 1 μ m.

3.5 Gluconate

Gluconates are very strong retarders that are thought to delay hydration by poisoning the nuclei of some hydration products [17]. Sodium gluconate is known to strongly affect the nucleation and crystallization of gibbsite ($\text{Al}(\text{OH})_3$) [18] and may affect the formation of cement hydration products as well. The difference between the images in Figure 6 in the presence of sodium gluconate and Figures 2-5 is striking. Sheaf-of-wheat hydration products are conspicuously absent. Instead, the hydration products are globular and appear to have precipitated “homogeneously” out of the solution rather than on the surfaces of the cement grains. The apparent volume of solids increases over time, as the globular products appear to increase in size. Perhaps sodium gluconate not only delays growth by poisoning cement hydration products, but also changes the nano-structure of C-S-H.

a.

b.

c.

Figure 6. OPC in solution saturated with calcium hydroxide and gypsum containing sodium gluconate (1g/L), w/c = 50, a. 24 minutes, b. 70 minutes, c. 120 minutes. Scalebars = 1 μm .

4. CONCLUSIONS

Soft x-ray transmission microscopy is an excellent technique for continuous monitoring of the hydration of cementitious materials at early ages in dilute suspensions. High magnification images are obtained of cement grains hydrating in solutions over time. The effects of admixtures are easily studied as the chemistry of the solutions can be varied as needed.

The early hydration products of Portland cement, as seen using a soft x-ray microscope, appear as bundles of fibers, often described with the term “sheaf-of-wheat.” It is likely that these products are a form of calcium silicate hydrate. The addition of chemical retarders, including sucrose, calcium lignosulfonate, and tetrasodium pyrophosphate, delays the formation of these sheaf-of-wheat products, with the retardation time being dependent on the strength of the retarder. Sodium gluconate appears to be unique, among the retarders that we have tested, in that sheaf-of-wheat products do not form in its presence. Instead, globular products form in the solution surrounding the cement grain and grow with time.

Some retarders appear to act as “delayed accelerators” in the sense that, once the initial retardation is overcome, further “pseudomorphic” hydration apparently continues more rapidly than in the unretarded control specimens. This “pseudomorphic” hydration results in the decrease in x-ray transmission density of the material within the confines of the original anhydrous particle, leaving behind a material that we refer to as “inner product.”

ACKNOWLEDGEMENTS

We would like to gratefully acknowledge guidance and financial support for this project from Lafarge. ABSTRACT

In this paper, the formation and decomposition of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ have been researched comprehensively by using chemical reagents as the raw materials. The tested temperature range is from 900°C to 1450°C . Samples are tested by means of TG-DTA, EPMA and XRD. During the formation process of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$, aluminate minerals, such as $\text{CaO}\cdot \text{Al}_2\text{O}_3$ and $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$, are the medium states. The formation of $\text{BaO}\cdot \text{Al}_2\text{O}_3$ results from the chemical reaction between BaO and Al_2O_3 and BaO forms from the decomposition of the BaSO_4 reagent. Results state that when the temperature is more than 1360°C , $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ decomposes and new minerals will form. The decomposition solid products of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ include $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$, $\text{CaO}\cdot \text{Al}_2\text{O}_3$ and $\text{BaO}\cdot \text{Al}_2\text{O}_3$ on condition that the temperature $\geq 1360^\circ\text{C}$. The chemical equation of the decomposition may be described as follows:
$$3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4 \rightarrow 12\text{CaO}\cdot 7\text{Al}_2\text{O}_3 + \text{CaO}\cdot \text{Al}_2\text{O}_3 + \text{BaO}\cdot \text{Al}_2\text{O}_3 + \text{SO}_2\uparrow + \text{O}_2\uparrow$$

Keywords: $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$; Formation Process; Medium States; Formation Mechanism of $\text{BaO}\cdot \text{Al}_2\text{O}_3$; Decomposition Equation.

1. INTRODUCTION

Teoreanu I. reported the new mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ in 1986 and researched the formation problem of the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$. [1] And then Feng Xiuji et al studied comprehensively the crystal structure characteristics of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ and its application, such as the new type of barium-containing sulphoaluminate cement. [2,3,4] The characteristic of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at high temperatures ($>1300^\circ\text{C}$) has also been studied.[5] However, the results of the characteristics of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at high temperatures, such as the formation temperature and the decomposition temperature, are different. Meanwhile, there are many observations about the formation mechanism of the mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$ in the clinkering process of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$. In this paper, the formation process of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ has been researched and the ideal burning temperature, which could produce the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$, is decided. The stability of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at high temperature is researched through burning the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at different temperatures ($>1350^\circ\text{C}$). Meanwhile, the formation mechanism of the mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$ is discussed because of its importance for the research problem.

2. EXPERIMENT AND TEST

CaCO_3 , Al_2O_3 and BaSO_4 , which are used in the experiment, are the chemical reagents. The sieve residue of each raw material on the $80\mu\text{m}$ fine-mesh sieve is zero. According to the chemical composition of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$, the ratio of each raw material in the raw meal is calculated. The experimental raw meal is prepared after the mixed raw material is homogeneous.

The tested temperature range of the raw meal is between 900°C and 1450°C . The burned samples were tested by means of TG-DTA, EPMA and XRD.

3. RESULTS AND DISSCUSION

3.1 The Formation Process of the Mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$

The raw meal is respectively burned at the temperature 900°C , 1150°C , 1200°C , 1300°C and 1350°C and the burned sample is tested with the XRD. The test results of each sample are shown in the Figure 1.

Figure 1. XRD patterns of the raw meal of $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ burned at different temperature

From Figure 1, it can be seen that $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$ ($d=0.2680\text{nm}$, 0.4889nm , 0.3204nm), $\text{BaO}\cdot \text{Al}_2\text{O}_3$ ($d=0.3130\text{nm}$, 0.2605nm) and $\text{CaO}\cdot \text{Al}_2\text{O}_3$ ($d=0.2971\text{nm}$, 0.2514nm) exist in the burned sample. The mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ has been formed at the temperature 900°C . At the temperature 1350°C there exists only the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ and the rest of the minerals disappear in the burned sample.

From the XRD results of the burned raw meal, it could be deduced that the formation velocity of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ is lower than that of the aluminate minerals. The mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ is formed from the chemical reaction of the aluminate mineral, such as $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$ and $\text{CaO}\cdot \text{Al}_2\text{O}_3$, with the mineral BaSO_4 . The mineral $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$ and $\text{CaO}\cdot \text{Al}_2\text{O}_3$ are the median phases during the formation process of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$.

The formation mechanism of the mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$ is important for the research of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$. It will be discussed separately in part 3.3.

3.2 The Stability of the Mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at the High Temperature

3.2.1 TG-DTA analysis

The thermal result of the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ between the ambient temperature and 1450°C are shown in Figure 2. The velocity of the temperature increase is $10^\circ\text{C}/\text{min}$ during the test process.

Figure 2. TG-DTA curves of the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ between ambient and 1450°C

On the DTA curve there is an endothermic peak, which begins from the temperature 1385°C . Correspondingly, there is a mass loss on the TG curve at the same temperature. This suggests that the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ is not stable when the temperature is more than 1385°C .

3.2.2 EPMA Analysis

The pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$, clinkered at the temperature 1450°C for 300 minutes, is tested with the method of the EPMA. The content of the element S at the different planes and points of the clinkered sample is listed in Table 1. The micrograph of the plane distribution of the element S in the clinkered sample is shown in Figure 3.

Table 1. Mass fraction of the element SO_3 at the different planes and points of the burned sample

Position	Planes					Points				
No.	1	2	3	4	5	1	2	3	4	5
SO_3 (wt.%)	5.65	8.02	6.36	6.14	7.80	8.28	5.31	4.78	7.07	3.25

The content of the SO_3 in the clinkered sample is less than the theoretical content 11.31 wt.% (based on the chemical composition of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$). The distribution of the element S in the clinkered pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ is not homogeneous according to Figure 3.

Figure 3. Micrographes of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ burned at temperature 1450°C for 300 minutes and element distribution for S

The results of the EPMA test state that the decomposition of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ will form the gas phase SO_2 .

3.2.3 Burned experiment of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$

The mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ is respectively burned at the temperature 1350°C , 1360°C , 1380°C , 1400°C and 1450°C for 300 minutes. The mass loss of the burned sample is tested with the analytical balance (the precision: 0.0001g). The results are shown in Table 2.

Table 2. Mass loss of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ burned at the high temperature

Parameter	Temperature/ $^\circ\text{C}$				
	1350	1360	1380	1400	1450
Mass loss (%)	0	1.32	1.53	2.42	5.01

At the temperature 1360°C , the mass of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ has decreased. It could be deduced that the pure mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ clinkered at the temperature 1360°C has been decomposed and the gas phases SO_2 and O_2 have been formed. The decomposition temperature is lower than the test result of the TG-DTA because of the difference of the test condition.

3.2.4 XRD analysis

The XRD result of the pure mineral, which is made from the raw meal clinkered at the temperature 1350°C for 240 minutes, is shown in Figure 4. The free CaO content of the sample is zero with the alcohol-glycerol method. It is stated that the pure mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$ may be prepared on condition that the temperature is 1350°C for 240 minutes. In order to research the stability of the mineral $3\text{CaO}-3\text{Al}_2\text{O}_3-\text{BaSO}_4$, the pure mineral is clinkered at temperatures from 1350°C to 1450°C . The XRD results of the clinkered samples are shown in Figure 5.

Figure 4. XRD pattern of the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$

Figure 5. XRD patterns of $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ burned at the different temperature

There exist the minerals $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$ ($d=0.2680\text{nm}$, 0.4889nm , 0.3204nm), $\text{BaO}\cdot \text{Al}_2\text{O}_3$ ($d=0.3130\text{nm}$, 0.2605nm) and $\text{CaO}\cdot \text{Al}_2\text{O}_3$ ($d=0.2971\text{nm}$, 0.2514nm) in the clinkered pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ at a temperature of 1360°C . The characteristic peak strength of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ decreases as the clinkered temperature rises. However, the characteristic peak strength of the mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$ increases with the increase of the temperature. When the clinkered temperature reaches to 1450°C the peak strength of two minerals is approximately equal.

It could be deduced that the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ has decomposed at the temperature 1360°C . The minerals $12\text{CaO}\cdot 7\text{Al}_2\text{O}_3$, $\text{BaO}\cdot \text{Al}_2\text{O}_3$ and $\text{CaO}\cdot \text{Al}_2\text{O}_3$ are formed because of its decomposition. Based on the analysis of the other test results, the decomposition equation of the mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ may be described as follows:

It also states that the preparation condition of the pure mineral $3\text{CaO}\cdot 3\text{Al}_2\text{O}_3\cdot \text{BaSO}_4$ in the reference [1] is not suitable.

3.3 The Formation Mechanism of the Mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$

According to the thermodynamics data, the enthalpy of formation of $\text{BaO}\cdot \text{Al}_2\text{O}_3$ through the reaction of BaSO_4 with Al_2O_3 is $+27.33\text{kJ/mol}$ when the temperature is less than 1327°C . Why does the mineral $\text{BaO}\cdot \text{Al}_2\text{O}_3$ exist in the burned sample (as shown in Figure 1) when the temperature is not more than 1300°C ? Because the BaSO_4 reagent used in the experiment is not stable. In the ideal

state, BaSO_4 does not decompose at temperatures $\leq 1300^\circ\text{C}$. However, the BaSO_4 reagent (class: analytical reagent) decomposes at temperatures $\leq 1300^\circ\text{C}$ [6] and the solid decomposition product is BaO . The reaction of Al_2O_3 with BaO forms the mineral $\text{BaO-Al}_2\text{O}_3$ when the temperature is less than 1300°C . The formation process of $\text{BaO-Al}_2\text{O}_3$ is described as follows:

The former research results that show that the formation of the mineral $\text{BaO-Al}_2\text{O}_3$ results from the decomposition of $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$ at temperatures $\leq 1300^\circ\text{C}$ are not validated and acceptable.

The formation of $\text{BaO-Al}_2\text{O}_3$ results from the decomposition of the mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$ when the temperature is more than 1360°C according to the research result in the part 3.2 of the paper.

4. CONCLUSION

1. During the formation process of the mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$, $12\text{CaO-7Al}_2\text{O}_3$ and $\text{CaO-Al}_2\text{O}_3$ are the middle phases. The chemical reaction between BaSO_4 and aluminate minerals is the formation type for the mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$. The pure mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$ may be prepared on condition that the temperature is $\leq 1350^\circ\text{C}$.
2. The mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$ is stable when the temperature is not higher than 1350°C . However, when the temperature is higher than 1360°C , $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$ is decomposed and new minerals are formed. The chemical equation of the decomposition may be described as follows:

$$3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4 \rightarrow 12\text{CaO-7Al}_2\text{O}_3 + \text{CaO-Al}_2\text{O}_3 + \text{BaO-Al}_2\text{O}_3 + \text{SO}_2\uparrow + \text{O}_2\uparrow$$
3. $\text{BaO-Al}_2\text{O}_3$ forms from the chemical reaction of the raw materials at the temperature $\leq 1350^\circ\text{C}$. because of the decomposition of the chemical reagent BaSO_4 . When the temperature is higher than 1360°C ., $\text{BaO-Al}_2\text{O}_3$ is from the decomposition of the mineral $3\text{CaO-3Al}_2\text{O}_3\text{-BaSO}_4$.

ABSTRACT

The analysis of data taken from the measurements of trace elements in clinkers may lead to extremely valuable insights into the properties of raw materials and can be used to solve practical problems too: to determine the origin of the clinker (i.e. the manufacturing works). For this purpose, several hundred clinker sorts have been analysed by replicated quarterly samples, collected from factories of nine countries to determine their Mg, Sr, Ba, Mn, Ti, Zr, Zn and V content. This paper describes a soft-computing based approach where the Self-Organizing Map (SOM) is used for the extraction of knowledge from this database related to the trace element content of clinkers. The SOM is a vector quantization method which places prototype vectors (cluster centers) on a regular low-dimensional grid in an ordered fashion. Since SOM provides a compact representation of the data distribution, the typical clinkers are detected by the SOM via clustering of the data. As the typical trace element contents are arranged on a two-dimensional grid, efficient visualization can then be performed in the two-dimensional projection of the concentration variables, hence the model can be effectively used to analyze the relationships between different factories and different trace elements

1. INTRODUCTION

The trace element content of clinkers is of high scientific interest, and can be used to solve practical problems too, e.g. to determine the origin of the clinker (i.e. the manufacturing works). The first paper of similar topics was published in 1993 by Goguel and StJohn, showing the Ba, Sr and Mn concentration of portland cements in New Zealand concretes. This first attempt suggests that advanced statistical methods, called “pattern recognition” or “fingerprinting” can help qualitative identification ^[1].

For the qualitative “fingerprinting” of clinkers, obviously a set of well defined clinker samples are necessary. To obtain such informative database, a Technical Committee “QIC” (Qualitative Identification of Clinkers and Cements) has been established in 1996 (TC 180/QIC). This project enabled collection of composite average samples from 9 countries (Austria, Hungary, Portugal, South Africa, Slovakia, Slovenia, Spain, Switzerland and United Kingdom). Over 200 samples have arrived to date, and analysed to determine their Mg, Sr, Ba, Mn, Ti, Zr, Zn and V content.

Among the wide range of advanced statistical and “pattern recognition” methods, in our previous papers the analytical data were transformed by principal component analysis into a two-dimensional space and dendograms were constructed for cluster formation. The visualisation of trace element content of clinker/cement is not an easy task. At the 10th International Congress on the Chemistry of

Cement, J.H. Potgieter^[2] presented a method to construct “star plots”, where the visual impact of chemical differences are more striking. This “star plot” method has been further developed in our previous paper^[3]; to facilitate the visualisation of the trace element content a new star plotting is presented where every clinker is compared to the proposed standard.

The term knowledge discovery in databases (KDD) refers to the overall process of discovering knowledge from data. KDD has evolved from the intersection of research fields such as machine learning, pattern recognition, databases, statistics, artificial intelligence, and more recently it gets new inspirations from soft computing. KDD methods have been successfully applied for the analysis of process systems, and the results have been used for process design, process improvement, operator training, and so on^[4].

When we attempted to use standard data mining, KDD, and multivariate statistical tools for industrial problems, like extracting knowledge from large amounts of data, we realized that production systems are typically ill-defined systems, difficult to model and they have large-scale solution spaces. In these cases, precise models are impractical, too expensive, or non-existent. Furthermore, the relevant available information is usually in the form of empirical prior knowledge and input-output data representing instances of the system's behavior. Therefore, we need an approximate reasoning system capable of handling such imperfect information. Computational Intelligence (CI) and Soft Computing (SC) are recently coined terms describing the use of many emerging computing disciplines.

The aim of this paper is to show how SC can be used in finding useful patterns in data obtained by the measurement of trace element content of clinkers. Most of the SC based models can be effectively used in data mining and lend themselves to transformation into other traditional data mining or advanced SC-based model structures that allow information transfer between different models. For example, in^[5] a decision tree was mapped into a feedforward neural network. A variation of this method is given in^[6] where the decision tree was used for the input domains discretization only. Another example is that as radial basis functions (RBF) are functionally equivalent to fuzzy inference systems^[7], tools developed for the identification of RBFs can also be used to design fuzzy models. The KDD process also includes the interpretation of the mined patterns. This step involves the visualization of the extracted patterns/models, or visualization of the data given the extracted models. Among the wide range of SC tools^[8], the Self-Organizing Map (SOM) is the most applicable for this purpose^[9]. The main objective of this paper is propose a SOM based methodology that can be effectively used for the analysis of operational process data and product quality.

The SOM algorithm performs a topology preserving mapping from high dimensional space onto a two dimensional grid of neurons so that the relative distances between data points are preserved. The net roughly approximates the probability density function of the data and, thus, serves as a clustering tool^[9]. It also has the capability to generalize, i.e. the network can interpolate between previously encountered inputs. Since SOM is a special clustering tool that provides compact representation of the data distribution, it has been widely applied in the visualization of high-dimensional data. The SOM facilitates visual understanding of processes so that several variables and their interactions may be inspected simultaneously. For instance, Kassalin used the SOM to monitor the state of a power transformer and to indicate when the process was entering a non-desired state represented by a "forbidden" area on the map^[10]. Tryba and Goser^[11] applied the SOM in monitoring of a distillation process and discussed its use in chemical process control in general. Alander^[12] and Harris^[13] have used the SOM in fault detection. Since the model is trained using measurement vectors describing normal operation only, a faulty situation can be detected by monitoring the quantization error (distance between the input vector and the best matching unit (BMU)), as a large error indicates that the process is out of normal operation space.

Based on the above mentioned beneficial properties of the SOM, a new approach for the analysis and visualization of the trace element content of clinkers is proposed in this paper. The paper is organized as follows. In Section 2., the SOM is introduced. In Section 3., a detailed application study is presented. Conclusions are given in Section 4.

2. SELF-ORGANIZING MAP

Cluster analysis organizes data into groups according to similarities among them. In metric spaces, similarity is defined by means of distance based upon the length from a data vector to some prototypical object of the cluster. The prototypes are usually not known beforehand, and are sought by the clustering algorithm simultaneously with the partitioning of the data. In this paper, the clustering of the operational data is considered. Hence, the data are the measured input and output process variables, parameters of the operating conditions, and laboratory measurements of the product quality. Each observation consists of l measured variables (l measured trace element concentration in this case), grouped into an l -dimensional column vector $\mathbf{x}_i = [x_{i,1}, \dots, x_{i,l}]^T$. A set of N observations is denoted by \mathbf{X} and represented as a matrix $\mathbf{X} = [\mathbf{x}_1, \dots, \mathbf{x}_N]^T$. In pattern recognition terminology, the columns of \mathbf{X} are called patterns or objects, the rows are called the features or attributes, and \mathbf{X} is called the pattern matrix. The objective of clustering is to divide the data set \mathbf{X} into c clusters.

The SOM algorithm is a kind of clustering algorithm which performs a topology preserving mapping from high dimensional space onto map units so that relative distances between data points are preserved. The map units, or neurons, form usually a two dimensional regular lattice. Each neuron, i , of the SOM is represented by an l -dimensional weight, or model vector $\mathbf{m}_i = [m_{i,1}, \dots, m_{i,l}]^T$. These weight vectors of the SOM form a codebook and can be considered as cluster prototypes. The neurons of the map are connected to adjacent neurons by a neighborhood relation, which dictates the topology of the map. The number of the neurons determines the granularity of the mapping, which affects the accuracy and the generalization capability of the SOM.

SOM is a vector quantizer, where the weights play the role of the codebook vectors. This means, each vector represents a local neighborhood of the space, also called Voronoi cell. The response of a SOM to an input $\mathbf{x}_k = [x_{k,1}, \dots, x_{k,l}]^T$ is determined by the reference vector (weight) \mathbf{m}_{i^0} which produces the best match of the input

$$i_k^0 = \arg \min_i \|\mathbf{m}_i - \mathbf{x}_k\|$$

where i_k^0 represents the index of the Best Matching Unit (BMU) of the k -th input.

During the iterative training of SOM, the SOM forms an elastic net that folds onto the "cloud" formed by the data. The net tends to approximate the probability density of the data: the codebook vectors tend to drift there where the data are dense, while there are only a few codebook vectors where the data are sparse.

The training of SOM can be accomplished generally with a competitive learning rule as

$$\mathbf{m}_i^{(t+1)} = \mathbf{m}_i^{(t)} + \eta \Lambda_{i_k^0, i} (\mathbf{x}_k - \mathbf{m}_i^{(t)})$$

where $\Lambda_{i_k^0, i}$ is a spatial neighborhood function and η is the learning rate, and the (t) upper index denotes the iteration step. Usually, the neighborhood function is

$$\Lambda_{i_k^0, i} = \exp \left(- \frac{\| \mathbf{r}_i - \mathbf{r}_{i_k^0} \|^2}{2\sigma^{2, (t)}} \right)$$

where $\| \mathbf{r}_i - \mathbf{r}_{i_k^0} \|^2$ represents the Euclidean distance in the low dimensional output space between the i -th vector and the winner neuron (BMU), and $\sigma^{2, (t)}$ represents the time-variant width of the Gaussian function used for the representation of the neighborhood function.

There are two phases during learning. First, the algorithm should cover the full input data space and establish neighborhood relations that preserve the input data structure. This requires competition among the majority of the weights and a large learning rate such that the weights can orient themselves to preserve local relationships. Hence, in the first phase relatively large initial σ^2 is used. The second phase of learning is the convergence phase where the local detail of the input space is preserved. Hence the neighborhood function should cover just one unit and the learning rate should be also small. In order to achieve these properties, both the neighborhood function and the learning rate should be scheduled during learning [9].

3. APPLICATION TO THE FINGERPRINTING OF CLINKERS

A qualitative identification obviously requires a database, to compare the trace element content of unknown clinkers/cements with characteristic known samples. For the qualitative “fingerprinting” of clinkers, obviously a set of well defined clinker samples are necessary: composite average samples of a longer period of kiln operation. Such samples were collected quarterly, over a longer period (2-3 years) in all Hungarian cement factories. A nationwide sample collection has a limited value only; to obtain a higher area, a Technical Committee 180/QIC, (Qualitative Identification of Clinkers and Cements), was established in 1996 under the auspices of RILEM (Réunion Internationale des Laboratoires d’Essais et de Recherches sur les Matériaux et les Constructions) (TC 180/QIC). This enabled the collection of composite average samples from 8 further countries (Austria, Portugal, South Africa, Slovakia, Slovenia, Spain, Switzerland and United Kingdom). Over 200 samples have arrived to date, and been analysed. Detailed analytical data can be obtained from the author. At the request of the companies, factory and sampling data cannot be revealed, only the country and a codenumber. The details of the analytical experiments and the data are described in our previous papers ^[14, 15, 16, 17].

In this paper the Self-Organizing Map (SOM) is applied to visualize the data collected from nine countries. SOM places the prototype vectors of typical clinkers on a regular two-dimensional grid in an ordered fashion. This makes it a powerful tool for the analysis of clinkers as it maps the 6-dimensional input vector (a clinker is defined by six trace element concentration) into a two dimensional space.

A SOM consists of neurons organized on a regular two-dimensional grid. Each neuron is a 6-dimensional weight vector (prototype vector, codebook vector).

Figure 1. SOM map of trace elements of clinkers

Figure 1. represents the results of the application of SOM where a 7 times 8 grid has been used to represent the “world map” of trace elements. As the previous section showed, the neurons are connected to adjacent neurons by a neighborhood relation, which dictates the topology, or structure, of the map. Hence, the neighboring objects in the SOM have similar properties.

The trace element content of a cell in this grid can be easily seen in this figure. As can be observed, the Ba has a similar distribution to Mn and Ti is also similar to Zr. This fact is also reflected by the analysis of the correlation of the data, as the two highest correlation coefficients are the Ba-Mn (0.5769) and Ti-Zr (0.4312). Hence, SOM is an effective tool for “correlation hunting”.

The main benefit of the proposed approach can be seen from Figure 2 where the countries and factories on the world map of clinkers are depicted.

This map can be easily used to classify a clinker and analyze the similarity of clinkers produced in different factories.

Figure 2. Countries and factories on the world map of clinkers.

4. CONCLUSIONS

Quarterly average samples from 9 countries were collected over a longer period and their trace element contents (Ba, Mn, Sr, Mg; Ti, Zr; Zn and V) determined. The trace element content of clinkers can be used for the qualitative identification. The paper presented the application of Self-Organizing Maps that have been found to be particularly useful in the qualitative analysis of the trace element content of these clinkers. The proposed approach can be used to solve practical problems: to determine the origin of the clinker (i.e. the manufacturing works), to provide visual impact of chemical differences of the materials, and to detect correlation among the trace elements.

A detailed description of the tools helps the construction of the algorithms; still easier, a computer program has been written (in MATLAB[®]) and it can be downloaded from www.fmt.vein.hu/softcomp.

ACKNOWLEDGEMENT

The financial support of OTKA (Hungarian National Research Foundation), No. T026307 and No. T037600 are gratefully acknowledged. Thanks are due to the laboratories of Hungarian cement factories as well as to members of the Technical Committee „180-QIC” (Qualitative Identification of Clinkers and Cements) of RILEM (Réunion Internationale des Laboratoires d’Essais et de Recherches sur les Matériaux et les Constructions) for collecting composite average clinker samples. Janos Abonyi is grateful for the Janos Bolyai Research Fellowship of the Hungarian Academy of Science.

Ferenc D. Tamás

A native of Hungary, F. D. Tamás was born in 1928. Received his M. Eng. in Chemical Engineering at Budapest Technical University in 1951; his D. Tech. In 1951 from Veszprém University; his Candidate of Chemical Science (equivalent of Ph.D) degree and Doctor of Chemical Science (D.Sc.) degree from the Hungarian Academy of Sciences in 1968 and 1978, resp.

After receiving his M.S. he worked at universities and research institutes in Hungary. At present he is Emeritus Professor at the University of Veszprém, Faculty of Engineering, Department of Silicate- and Materials Engineering.

His career is connected to the physical chemistry and technology of silicates; fields of interest include cement chemistry (esp. trace elements in clinker and cement), materials science, silicate mineralogy, phase equilibria, testing of engineering materials and recently cement/environment interactions (use of wastes as fuels or raw materials, cement based immobilization of hazardous wastes, etc.).

Dr. Tamás is author of over 100 publications in Hungary and abroad. He is author, co-author and/or editor of 16 technical books, the most important of which is the volume "Handbook of the Silicate Industries", published in 1982, where he acted as Editor-in-Chief. His books "Mullite: Formation, Properties and Significance" (1962) and "Phase Equilibria Spatial Diagrams" (1970) were published in English too. Was Scientific Committee chairman of the series of the international Conferences on Silicate Science and Technology, Budapest and editor of their Proceedings (1961, 1964, 1967, 1970, 1973, 1977, 1981, 1985 and 1989).

Dr. Tamás has supervised research of a high number of Ph.D. students (his former students working in Hungary and abroad (Canada, U.S., Denmark, Egypt, etc.)), directed numerous research projects in Hungary and was co-principal investigator of several international research projects (U.S.A. - Hungary, Austria - Hungary. Acted as a visiting professor at several European, Israeli and American universities.

Dr. Tamás attended several international scientific meetings, gave plenary or contributory papers in practically all European countries, in the U.S.A, Canada, Australia, India and Brazil. Was invited overseas speaker at the Gordon Research Conference on "Solid/Liquid Interactions in Cement Hydration", Plymouth, NH, USA, 1996. Acted several times for the most important meeting of cement chemists, the International Cement Chemistry Congresses: was Rapporteur at the 6th, in Moscow–1974; 7th, Paris–1980; 8th, Rio de Janeiro–1986, was International Scientific Committee member and Panel coordinator of the 9th Congress, in New Delhi, India–1992. and of the 10th

Congress, in Gothenburg Sweden–1997. The next, 11th will be held in Durban, 2003; he serves as International Scientific Committee member of this congress too. Other former activities: was chairman of the waste destruction panel at the World Conference on Hazardous Wastes, Budapest, 1987, keynote speaker at the „Waste Destruction Seminar” organized by the Environmental Protection Authority, Melbourne, Australia, 1993, invited overseas speaker at the Engineering Foundation Conference, Durham, NH, USA, 1994, at the Gordon Research Conference on Chemistry & Physics of Cement-based Materials, Plymouth, NH, USA, etc.

In 1989 he has been elected Academician, International Academy of Ceramics; holds memberships in several scientific committees, both in Hungary and abroad. He is Chairman of the RILEM Technical Committee "Qualitative Identification of Clinkers and Cements", President of the Hungarian "Industry for Environment" Foundation.

Dr. Tamás is editorial board member of four scientific journals: Cement and Concrete Research, USA; Journal of Materials in Civil Engineering, USA; InterCeram, Germany; and Építőanyag (Building Materials), Hungary.

INFLUENCE OF HEAVY METALS ON THE PROPERTIES OF CEMENT AND CONCRETE - BINDING MECHANISMS AND FIXATION

ABSTRACT

The chemical composition of Portland cement mainly depends on the composition of the natural raw materials that are used for the clinker production. Beside geological variations in the raw material, the use of secondary raw materials and fuels can also influence the concentration of some minor and trace elements. Results described the potential effects of some heavy metals on clinker properties and subsequent products.

The impact of the heavy metals can vary during the life cycle of cement from the clinker production to the recycling of the building material. Different aspects are presented about the influence of heavy metals on pure clinker phases and clinker produced in the laboratory. The binding of heavy metals in cement, mortar and concrete are additional environmental aspects.

The main focus in this work was on Cr, Ni and Zn. These metals were used in different concentrations, ranging from natural concentration up to 25 000 ppm. The presented results indicate that the heavy metals can influence both the manufacturing of pure clinker phases or clinker and the hydration activity of the binder. The most decisive fact is, that the phenomena described can only be detected at concentrations many times higher than the naturally occurring concentrations of these heavy metals. Generally, up to 1 000 ppm of Cr, Ni and Zn had no or only a negligible effect, and in many cases even 5 000 ppm had no influence on the properties of clinker and cement.

The leaching procedures showed that Ni and Zn are nearly completely fixed in the hydrated cement matrix, even if the heavy metal concentration is many times higher than normal. Cr is not fixed that strongly, and the concentration of Cr during the leaching rises in proportion to the total amount of Cr in the cement. The leaching test with concrete blocks produced with industrial cements showed that the concentration of leached heavy metals is much lower than the limits for drinking water.

1. INTRODUCTION

The main and minor components of Portland cements (CaO, SiO₂, Al₂O₃, Fe₂O₃, MgO, SO₃, K₂O etc.) are responsible for the basic properties of the cements. Cements also contain trace elements (mainly heavy metal oxides). With more frequent use of alternative fuels and due to geologically caused fluctuations of the concentration of trace elements in the raw material and fuels, increased concentrations of heavy metals can occur from time to time. The aim of this project was to investigate potential effects of Cr, Ni and Zn on clinker and its subsequent products, including environmental aspects.

The level in Portland cement clinker ranges from around 10 to 90 ppm for Cr, 10 to 50 ppm for Ni and 28 to 350 ppm for Zn [1], but also higher concentrations have been reported [2]. In order to measure underlying effects, the samples were doped with much higher concentrations of heavy metals than are normally present in industrial clinker.

1.1 Pure and doped C_3S , C_3A and C_4AF

Portland cement clinker is a multi-phase product. During the production different clinker phases are formed. There are several chemical reactions going on at the same time, which can influence each other. Such a complicated system is a difficult basis for fundamental research about the influence of heavy metals on the formation of clinker and the reaction of cement. Therefore the pure clinker phases were for fundamental research.

To pure clinker phases C_3A , C_4AF , C_3S and C_3S with 1 wt.-% of free lime, heavy metal oxides in concentrations of 200, 1 000, 5 000 and 25 000 ppm were added (in some cases up to 50 000 ppm, in each case relative to the heavy metal). The treated samples were fired several times. The production of pure phases and sample preparation is described in detail elsewhere [3, 4].

1.1.1 Unhydrated pure clinker phases

The influence of heavy metal oxides on the stability and modification of pure phases was investigated. In most samples the heavy metals were trapped almost quantitatively, only from the C_3S -samples about 25 % of Zn evaporated. The changes of free lime with the addition of heavy metals were monitored by the Franke wet chemical method. Fairly high changes in free lime content with heavy metal addition were only found with the clinker mineral C_3S shown in Figure 1. Even if there are no clear stoichiometric correlations, the results indicate that Cr is incorporated into the lattice instead of Si, and Ni and Zn are incorporated instead of Ca. Very high intakes of Cr stabilize C_2S , hence C_3S decomposes to give C_2S with Cr and free lime. The findings confirm the results of other reports [5, 6, 7, 8, 9].

Data obtained by X-ray diffraction (XRD) revealed that different polymorphs of C_3S could be stabilized by the intake of heavy metal oxides. But only above 5 000 ppm could a clear change of the modification be registered. The results for very high intakes are shown in Figure 2. These results largely confirm earlier investigations [7, 8, 10, 11].

1.1.2 Hydration of pure clinker phases

The early hydration kinetics of samples that were ground to the same fineness was investigated by heat flow calorimetry. Detectable differences only occurred above addition levels of 5 000 ppm.

Examples for hydration curves of samples with very high intakes are illustrated in Figure 3.

Figure 1. Free lime in samples with and without heavy metals; a) made from C_3S with 0.3 wt.-% free lime, b) made from C_3S with 1.1 wt.-% free lime

Figure 2. XRDs of pure C_3S and C_3S with 25 000 ppm of heavy metal; modification: pure $C_3S \rightarrow T_1$; $Cr \rightarrow T_2 + C_2S + CaO_{free}$; $Ni \rightarrow T_2$; $Zn \rightarrow M_2$

Figure 3. Heat flow calorimetry of control and samples with 25 000 ppm of heavy metals

Figure 4. Hydration products of a) pure C_3A and b) C_3A with 25 000 ppm Cr; plates with high Cr content, octahedron with low Cr content

The hydration products were analysed by XRD and scanning electron microscopy (SEM). Some pictures of the hydration products are given in Figure 4. The composition of different products could be detected by energy-dispersive X-ray fluorescence analysis (EDX).

From the hydration of pure phases and samples with heavy metals or higher concentrations of free lime it can be concluded that:

- Cr accelerates the hydration of C_3S .
- the acceleration of samples with Ni is because of higher concentrations of free lime.
- Zn retards the hydration of C_3S ; in the hydration product $Ca[Zn(OH)_3]_2 \cdot 2H_2O$ could be analysed [12, 13, 14].
- the heavy metals are enriched in C-S-H products, the concentration of heavy metals in portlandite is below the detection limit of EDX.
- well crystallized areas of portlandite and C-S-H are smaller in the samples with Ni or Cr than in the control and somewhat larger in the samples with Zn.
- C_3A is retarded by Cr and Zn, while Ni does not influence the hydration characteristic.
- the morphology of hydration products of C_3A are not changed by Ni and Zn, but Cr does sharply influence the morphology (Figure 4).
- Cr suppresses the hydration of C_4AF nearly completely at 25 000 ppm, but at lower concentrations this effect is greatly reduced; Ni and Zn have virtually no effect.

2. PURE AND DOPED CLINKER

The clinker phases have a mutual effect on one another during production and subsequent hydration. Thus the actual effect of the heavy metals on the product properties has to be examined in the clinker and cement. In order to measure the influence of heavy metals on real clinker and cement, three different raw materials were chosen. The composition of these raw materials is given in Table 1. The samples were taken from industrial raw meal for the production of clinker for ordinary Portland cement (PC), high sulphate resisting Portland cement (SRPC) and white Portland cement (WPC). Different amounts of heavy metal oxides were added to the raw material to give 200, 1 000, 5 000 and 25 000 ppm in the final clinker respectively (in each case relative to the heavy metal). The burning conditions for the three series of samples were chosen to give a content of free lime between 1.0 and 1.3 wt.% for the pure raw meal of PC, SRPC and WPC (Table 1).

Table 1. Composition of raw materials for clinker production and burning conditions

Material (wt.%)	PC	SRPC	WPC
SiO ₂	14.1	13.0	14.4
Al ₂ O ₃	3.5	2.5	2.7
Fe ₂ O ₃	2.2	4.9	0.1
CaO	41.3	42.2	44.7
MgO	1.7	1.2	0.3
K ₂ O	1.1	0.4	0.2
SO ₃	0.6	0.1	0.7
Cr (ppm)	51	46	12
Ni (ppm)	55	15	5
Zn (ppm)	88	111	48
Specific surface (m ² /cm ³)	1.71	2.06	3.19
Burning conditions			
Temperature (°C)	1400	1450	1550
Time (min)	60	70	180

2.1. Unhydrated clinker

The analysis of Cr, Ni and Zn in the clinker showed that the concentration did not differ much from the amount predicted by calculations based on concentrations in the raw material and the ignition loss. Only Zn evaporated from the samples in amounts of 15-25 %. The Zn losses in the clinker presumably occur because the heavy metal reacts with secondary constituents in the raw meal and forms compounds, which are more volatile.

Figure 5. Left: PC clinker with 25 000 ppm of Cr; Right: PC clinker with 25 000 ppm of Ni

As predicted from results with pure clinker phases, no changes in the clinker could be detected up to 1 000 ppm of heavy metals and even 5 000 ppm had only a negligible influence. The clinker was analysed for free lime and polished clinker sections were analysed by light microscopy, SEM and EDX. Compared to the control the content of free lime is lower for all samples with added heavy metals in all concentrations, except for the samples with 25 000 ppm of Cr. This result confirms that

alite is destabilized by very high concentrations of Cr. On the other hand, low concentrations of all heavy metals react as mineralising agent. By means of SEM and EDX in the PC clinker with Cr, a new phase was found which had the approximate composition of $K_2Cr_2O_7$. In the two other clinkers with lower concentrations of K, this compound could not be detected. In all three clinkers the concentration of Cr was especially high in belite (up to 5.6 wt.-%) and very often CaO_{free} was found in direct contact with belite, which is not normal for a sufficiently well burned clinker (see Figure 5). In the PC and SRPC clinker with Ni, a new phase with the composition $MgNiO_2$ was formed, and is shown in Figure 5. Because of the lower content of Mg this compound could not be detected in the WPC clinker and the Ni was mainly incorporated into the interstitial phase. The formation of $MgNiO_2$ could be verified by the results of XRD. Recently the formation of this compound was also reported by Lopez [15]. In all three clinkers the highest concentrations of Zn were found in the interstitial phase.

2.2 Hydration of cements

Taking into consideration the sensitivity of measurement, a concentration of up to 1 000 ppm of heavy metals does not have any effect on the hydration of cement. This is the same result as in the investigation of pure clinker phases. Even at concentrations of 5 000 ppm of heavy metals, the early hydration is only slightly accelerated (Figure 6). This might be a result of a higher number of crystal defects in alite. A concentration of 25 000 ppm Cr accelerates the hydration, Ni has no effect and Zn gives a strong retardation, which is caused by a surface passivation of the hydration product of incorporated Zn. The compound $MgNiO_2$ was not attacked during the hydration process. An important result is the preferred incorporation of the heavy metals into the C-S-H phases and not into the portlandite, which could be proved by SEM combined with EDX. This causes a good fixation of the heavy metals in the hydration products.

Figure 6. Hydration of SRPC with 25 000 ppm (left) and 5 000 ppm (right) of heavy metals

Results of the physical properties of the samples showed a good correspondence between flexural strength, compressive strength and dynamic modulus of elasticity. Concentrations of up to 1 000 ppm of heavy metals have no influence on the strength. Figure 7 shows the compressive strength of SRPC-mortar with 5 000 and 25 000 ppm of heavy metals after 1, 7 and 28 days. Except for the PC-sample with Cr, 5 000 ppm of heavy metals caused a slight increase in strength. An intake of 25 000 ppm Cr always results in a decrease of strength. This is due to the high content of free lime with corresponding expansion phenomena and the lower content of alite. The influence of Ni at this concentration is different. Zn induces an increased strength after 7 and 28 days apart from a lower strength in the early period of hydration. More details about the influence of heavy metals on the formation of clinker and hydration of cement are given elsewhere [16, 17].

Figure 7. Compressive strength of control and samples with 5 000 and 25 000 ppm of heavy metals.

3. FIXATION OF HEAVY METALS

During the project the fixation of heavy metals in the building material cement and its following products was analysed by three different procedures. For that purpose cements were produced from three different industrial raw meals (PC, SRPC and WPC). Before burning the raw meals were doped with heavy metal oxides in different concentrations (aim: 200 – 5 000 ppm in the cement).

The investigation of the wash-out of cements showed, that even very high intakes of Ni and Zn did only result in metal concentrations in the leachates within the range of the detection limit. On the one hand this extreme low solubility is brought about by the high pH, which causes precipitation of heavy metal hydroxides of these metals. Additionally it is due to the high concentrations of different ions in the solution that lead to a more complete precipitation by reactions that are not yet known. Cr, however is washed-out from the cement very quickly and it remains in solution even at high pH [18]. The rate of the washed-out Cr compared to the absolute Cr depends on the type of cement and not on the absolute content of Cr in the cement. The rate of washed-out Cr was about 25 % for the PC-cement, 2 % for SRPC-cement and 1 % for WPC-cement (Table 2).

Table 2. Concentration of Cr in the cements and leachates from the wash-out procedure and the DEV-S4 procedure

sample	cement	wash-out of cements		leaching of mortars (DEV-S4)	
	[ppm]	leachate [ppm]	leaching [%]	leachate [ppm]	leaching [%]
PC control	81	3,7	18,3	0,033	1,77
PC all 200	216	10,8	20,1	0,107	2,19
PC all 500	460	37,4	32,5	0,293	2,80
PC all 1000	924	67,1	29,0	0,600	2,86
PC Cr 500	491	26,8	21,8	0,360	3,22
PC Cr 5000	5063	309,8	24,5	3,077	2,67
SRPC control	94	0,27	1,1	0,026	1,19
SRPC all 500	526	2,55	1,9	0,296	2,47
WPC control	41	0,10	1,0	0,012	1,32
WPC all 500	536	0,80	0,6	0,256	2,10

The tank leaching test for standard prisms (aggregate-cement-ratio= 3:1, water- cement-ratio= 0.5), that will probably become the basis for a planned European Standard was used to simulate the period of using the building material [19, 20]. After the storage of the mortar under water at a liquid-solid-ratio of 5, the concentration of Ni and Zn in the leachates was below detection limit. Even at 5 000 ppm of heavy metal in the cement the concentration of heavy metal in the leachate was insignificant. On the one hand this is brought about by high pH in the solution and it is also due to an incorporation of the metals in the C-S-H-phases. The analysis of Cr in the leachates again

shows that this element is much more soluble. In this project the diffusion control of the leaching was confirmed. Figure 8 shows exemplary graphs of the total amount of Cr that was leached from two cement mortars. The leaching of Cr from mortar is < 1 % after 56 days and it is nearly independent of the composition of the cement. If the leaching mechanism does not change in the cause of time, an extrapolation gives a leaching rate of < 3 % after 10 years (see Table 3).

Figure 8. Sum of leached Cr in the leachates of tank leaching test in [ppb]; a) control PC (81 ppm Cr in the cement); b) PC Cr 500 (491 ppm Cr in the cement)

The leaching with the DEV-S4 procedure was done to simulate the period of demolition and recycling and in part as an availability test. In this test 100 g of the material is crushed <10 mm and shaken with 1l of water for 24 h. The concentrations of Ni and Zn in the leachates are again very low, even with very high intakes of heavy metals. The average leaching rate of Cr from PC-mortar was about 2.6 % and it was independent of the absolute content of Cr. The leaching rate from SRPC- and WPC-mortar was similar (see Table 2).

Table 3. Leaching with tank leaching test after 14 d and 56 d and some extrapolations

	Measured leaching rate [%]		extrapolated leaching rate [%]		
	14 d	56 d	6 month	1 year	10 years
PC control	0,52	0,74	1,13	1,29	1,88
PC all 200	0,46	0,68			
PC all 500	0,50	0,77	1,24	1,45	2,30
PC all 1000	0,44	0,69			
PC Cr 500	0,55	0,83			
PC Cr 5000	0,56	0,82	1,39	1,63	2,59
Ø PC	0,51	0,76			
SRPC control	0,35	0,43			
SRPC all 500	0,60	0,76			
WPC control	0,48	0,60			
WPC all 500	0,88	1,09			

4. CONCLUSION

The results of this study show that the heavy metals Cr, Ni and Zn can influence both, the manufacturing of pure clinker phases respectively clinker and the hydration activity of the binder. But the most decisive fact is that these influences can only be detected at concentrations many times higher than the naturally occurring concentrations of these heavy metals. The investigation of the binding mechanisms showed that the leaching of Ni and Zn under usual environmental conditions is insignificant, even if the heavy metal concentration is higher than normal. The leaching of Cr is much easier. The concentration of Cr in the leachates rises in proportion to the total amount of Cr in the cement.

Curriculum Vitae

Surname	Stephan
First name	Dietmar
Birthday	29 th of October 1968

Professional training

1985 - 1988	Apprenticeship as a chemical laboratory worker
-------------	--

University

1990 - 1996	Study of Chemistry at the University of Siegen Main focus: Building and materials chemistry Diploma thesis: Formulation of recipes for restoring of bricks with slurries and sandstone with repair mortar.
9/1994 - 4/1995	Study of Chemistry at the Bristol University (GB)

PhD-thesis

8/1996 - 10/1999	PhD-thesis in the group of Prof. Dr. D. Knöfel at the University of Siegen: Chromium, Nickel and Zinc in clinker and cement – incorporation, influence on properties and leaching-
------------------	--

Professional Career

11/1999 - 10/2000	Engineer-In-Training program at Heidelberg Cement
11/2000 - 12/2001	Senior Scientist Cement Chemistry at Heidelberg Cement Technology Center
Since 1/2002	Qualified as a university lecturer at the Technical University of Munich, Institute for Construction Chemicals Main focus: Interaction of inorganic binder with construction chemicals.

POZZOLANIC REACTION OF FLY ASH CEMENT SYSTEM

ABSTRACT

An increase of compressive strength and durability of concrete containing fly ash is well known as the effect of pozzolanic reaction. However, the specific mechanisms of pozzolanic reaction, which affect these properties of concrete, are not clearly understood.

The aim of this study is to determine the effect of the pozzolanic reaction of fly ash on properties of hardened paste; such as combined water, calcium hydroxide, pore distribution and BET specific surface area. In this study a quantitative investigation on the reaction ratio as a criterion of pozzolanic reaction is conducted. The reaction ratio of fly ash is important in this study. The reaction ratio of fly ash is calculated by determining the levels of insoluble residue in the specimen at several ages.

Firstly, the effects of the water/powder ratio, mixing ratio of fly ash and curing temperature on the pozzolanic reaction of fly ash in cement paste are investigated. Evidentially these conditions have an affect on the pozzolanic reaction speed of fly ash.

Secondly, the effects of the pozzolanic reaction on the microstructure in the cement paste are determined. There had been no study that has tried to clarify pozzolanic reaction with a quantitative approach.

As a result of this experiment, the effect of the pozzolanic reaction on many properties of the cement paste can be described as a function of the reaction ratio of fly ash.

1. INTRODUCTION

The progress of pozzolanic reactions in hardened cement mixtures containing fly ash is sometimes discussed in relation to the compressive strength [1]. Specifically, the reaction quantity is indirectly estimated from the quantity of calcium hydroxide formed in the hardened cement mixture [2], [3]. Although many studies on the effects of pozzolanic reaction on concrete have been done, the effects of absolute quantity of pozzolanic reaction are still unclear. The effect appears to vary in each experiment because the pozzolanic reaction is affected by the chemical composition of fly ash, mixture proportions of concrete and curing conditions. Furthermore evaluations of the durability of concrete in each study were carried out with different pozzolanic reaction ratios.

As a result of our study [4], the pozzolanic reaction ratio of fly ash was determined to be influenced by the curing temperature, ratio of water to cementitious material, and the replacement dosage of fly ash. The pozzolanic reaction ratio of fly ash was calculated by determining the levels of insoluble residue in the acid. A simple constant pozzolanic reaction model can be derived for this reaction [5]. Mixtures of moderate heat cement containing fly ash were investigated using the same method. The microstructure of the paste was compared with concrete [6].

The purpose of this study is to clarify the effect of the pozzolanic reaction on properties of hardened paste; such as combined water, calcium hydroxide, pore distribution and BET specific surface area. Also the quantitative change of these properties of hardened paste accompanied with increasing pozzolanic reaction ratio of fly ash is evaluated. Quantitative study of the effects of pozzolanic reaction helps clarify the mechanism of pozzolanic reaction.

If the chemical function of pozzolanic reaction adjusting on curing condition, mixture proportion or age changes, it is expected that the correlation between pozzolanic reaction ratio and the quantitative effects of pozzolanic reaction on hardened paste will be weak. However, results from this experiment showed a strong correlation, whereby the function of pozzolanic reaction is almost constant. It was verified that the effect of condition differences were only observed as a pozzolanic reaction speed difference.

This information about the pozzolanic reaction mechanism contributes to the rational use of industrial by-products as a concrete material.

2. MATERIALS AND EXPERIMENTAL METHODS

2.1 Materials

As listed in Table 1, ordinary Portland cement and fly ash produced at the Hekinan Power Plant (Japan) were used. In addition, the paste of calcium hydroxide (CH) reagent containing fly ash at the same plant is also produced. The specific gravity and Blaine specific surface area of each material are shown in Table 1. The chemical composition of cement and fly ash are shown in Table 2. The glass phase of fly ash determined by XRD with internal standard is 65.8 %.

Table 1. Physical Properties of Materials

Materials	Specific gravity (g/cm ³)	Blaine specific surface area (cm ² /g)
Ordinary Portland cement	3.14	3370
Calcium hydroxide	2.23	—
Fly ash	2.33	4000

Table 2. Chemical Composition of Used Cement and Fly Ash

Materials	Chemical composition (% by mass)											L. O. I. (%)
	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	FCaO	MgO	Na ₂ O	K ₂ O	TiO ₂	SO ₃	C	
Cement	20.8	4.7	2.9	64.7	-	1.7	0.4	0.4	0.3	2.0	-	1.7
Fly ash	54.4	31.1	4.6	4.4	0.1	0.8	0.6	0.8	1.4	0.4	1.3	1.4

2.2 Paste Specimens

The mixture proportions of cement paste containing fly ash are shown in Table 3. Two different W/P(water/powder) ratios of 30% and 50% are considered in the present study. Fly ash is substituted for cement by weight.

Table 3. Mixture Proportions of Cement Paste with Fly Ash

Curing temperature	W/P (%) P: powder	W/C (%)	Replacement dosage of Fly ash (% by mass)	Mixture proportions (% by mass)		
				Water	Cement	Fly ash
20°C 40°C	30	30.0	0	23.1	76.9	0
		33.3	10	23.1	69.2	7.7
		37.5	20	23.1	61.5	15.4
		50.0	40	23.1	46.2	30.8
		75.0	60	23.1	30.8	46.2
20°C 40°C 65°C (2 days) --> 20°C	50	50.0	0	33.3	66.7	0
		55.6	10	33.3	60.0	6.7
		62.5	20	33.3	53.3	13.3
		83.3	40	33.3	40.0	26.7
		125.0	60	33.3	26.7	40.0

The powder and water are mixed for 3 minutes at low speed using a Hobart mixer at 20°C room temperature. A test piece for each age is molded in a 100ml plastic bottle, which is then sealed. Specimens are cured at 3 different temperatures of 20°C, 40°C, and 65°C. The temperature of 65°C imitates the steam curing state. The specimens that are cured at 65°C are kept for 2 days before decreasing the temperature to 20°C.

The CH paste is prepared similarly. The mixture proportion is shown in Table 4.

Test specimens are prepared by cutting off a 7-mm cube out of each molded sample with a diamond cutter at a specified age. The hydration reaction is then stopped by dipping the cube samples in acetone and drying them by D-drying method under 5×10^{-4} mmHg vapor pressure. If necessary, test specimens are ground.

Table 4. Mixture Proportions of Calcium Hydroxide Paste with Fly Ash

Curing temperature	W/P (%)	Replacement dosage of Fly ash (% by mass)	Mixture proportions (% by mass)		
			Water	Ca(OH) ₂	Fly ash
20°C, 40°C	50	60	33.3	26.7	40.0

2.3 Experimental Methods

2.3.1 Loss on ignition

The ignition loss and combined water of D-dried sample are determined at a temperature of 950°C.

2.3.2 Content of calcium hydroxide

CH amount in D-dried sample is determined by differential scanning calorimetry. In order to eliminate the variation of sample weight due to combined water with different age, the combined water content is compensated for with the ignition loss value. Content of CH percentage then is indexed to the weight of the specimen without combined water.

2.3.3 Pozzolanic Reaction Ratio of Fly Ash

The insoluble residue of D-dried sample is determined according to JIS R 5202 standard. The sample is in hydrochloric acid (1+1) and sodium carbonate solution, then neutralized using hydrochloric acid, and insoluble residue is filtrated. The residue is ignited and its mass is weighed. The pozzolanic reaction ratio of fly ash is calculated using equations (1) and (2).

$$b_d = (f_r * f_i - a_d) / (f_r * f_i / 100) \quad (1)$$

$$a_d = a_d' / (1 - IG_d / 100) \quad (2)$$

- b_d : The pozzolanic reaction ratio per 1g of fly ash after d days that is determined from insoluble residue (%)
- a_d : The insoluble residue that compensated for combined water of the hardened paste after d days (%)
- a_d' : The insoluble residue of the hardened paste after d days (%)
- f_r : The replacement dosage of fly ash
(example: 0.4 for 40% of replacement dosage)
- f_i : The insoluble residue of unhydrated fly ash (%)
- IG_d : The ignition loss of the hardened paste after d days (%)

For example, the values needed for the calculation of the reaction ratio are shown in Table 5. In the case of CH paste, an equation of (3) is used instead of the equation (1).

$$b_d = (f_r * f_i - k * a_d) / (f_r * f_i / 100) \quad (3)$$

$$k = (1 - 18 / 74 * (1 - f_r)) \quad (4)$$

k: Dehydrate of CH

Table 5. Example Values Needed for the Calculation of Pozzolanic Reaction ratios of Fly Ash
(Curing temperature = 40°C, W/P= 50%, FA=40%, Age = 1 year)

	Insoluble residue (% by mass)	L.O.I. (% by mass)	Insoluble residue compensated for combined water (% by mass)
Unhydrated fly ash	$f_i = 83.9$	—	—
Hydrated sample (Age d days)	a_d' : $a_{365'} = 18.60$	IG_d : $IG_{365} = 17.09$	$a_d = a_d' / (1 - IG_d / 100)$: $a_{365} = 22.43$
Replacement dosage of fly ash : f_r (by mass)	$f_r = FA / (Cement + FA) = 0.4$		
Reacted ratio of fly ash : b_d (% by mass)	$b_{365} = (f_r * f_i - a_{365}) / (f_r * f_i / 100) = 33.2$		

2.3.4 BET specific surface area of hardened paste

D-dried cubic sample is crushed with a hammer into 1mm size grains. Approximately 1g of grains with size between 0.6mm and 1.0mm are sieved out to be used for determining BET specific surface area. Microstructure in the sample remains in each grain due to the coarse crush. BET specific surface area increases with the degree of crush. But the effect of crush is reduced with the selection of specific grain sizes.

BET specific surface area is then determined by 1point method with nitrogen gas.

2.3.5 Pore Structure of hardened paste

Pore structure of hardened paste is determined with mercury intrusion porosimetry. Approximately 6g of D-dried cubic samples are used for each measurement. Pore distribution of the diameter from 60 micrometer to 3nm in paste specimen is determined.

2.3.6 BEI and SEI observation

Secondary electron image (SEI) of hardened cement paste is observed by FE-SEM. The back scattered electron image (BEI) is observed by EPMA and applying the accelerating voltage of 15 kV.

3. EXPERIMENTAL RESULTS AND DISCUSSION

3.1 The Pozzolanic Reaction Ratio of Fly Ash

Figure 1. Effect of fly ash replacement dosage in cement paste on reaction ratio of fly ash determined from insoluble residue.

Figure 2. Effect of curing temperature and water powder ratio on pozzolanic reaction ratio of fly ash in cement paste.

The pozzolanic reaction ratio of fly ash determined from the insoluble residue of the hardened cement paste with different fly ash replacement dosages is shown on Figure 1. For 40°C curing temperature and 50% W/P, the reaction ratio per 1 g of fly ash reduces as the replacement dosage increases. The pozzolanic reaction is active until the age of 91 days. After this age, the reaction becomes slow. When fly ash dosage was 10%, the reaction ratio of fly ash at 1 year of age almost reached glass phase content of fly ash.

The pozzolanic reaction ratio of fly ash in cement paste with 40% fly ash is shown on Figure 2. The reaction ratios of fly ash at 7 days are 0 and 13% when samples are cured at 20 and 40°C, respectively. There is a big difference in the reaction ratio at early periods. The reaction ratio at 1 year increases with increasing curing temperature and W/P.

3.2 Combined Water of Pozzolanic Reaction

The relation between the reaction ratio of fly ash and combined water of hardened paste is investigated. Combined water due to fly ash is calculated with equation (5).

$$Wf_d = (Wr_d - W0_d * (1 - f_r)) / f_r$$

Wf_d : The difference of combined water result from 1g of fly ash at d days (%)

Wr_d : The combined water of hardened paste with fly ash replacement dosage f_r at d days (%)

$W0_d$: The combined water of hardened paste without fly ash of each W/P and curing condition at d days (%)

f_r : The replacement dosage of fly ash

Figure 3. Effect of pozzolanic reaction of fly ash on combined water.

Effect of the pozzolanic reaction of fly ash on combined water is shown on Figure 3. Each legend includes 2 different curing temperatures, 2 different water/powder ratios at different ages. These conditions are shown in Table 3. Combined water of cement paste due to fly ash (W_{fd}) increases along with the reaction ratio of fly ash increasing. Fly ash contributed to the acceleration of cement hydration when cement was only replaced with fly ash, which did not react. If 100g of fly ash reacts 100%, combined water increases 15.6g.

3.3 Consumption of Calcium Hydroxide due to Pozzolanic Reaction

The amount of CH consumed due to the pozzolanic reaction is shown in Figure 4. The relations between CH consumption and amount the reaction ratio of fly ash are shown in Figure 5. Value of various water/powder ratios, fly ash replacement dosages and ages are plotted in Figure 5. In addition, the values for CH paste of 5 ages at 2 different curing temperatures and 5 ages in CH paste are also plotted in Figure 5. The quantities of fly ash reacted and the reaction ratios in cement paste in Figure 1 and Figure 2 are different with given the mixture proportions and curing conditions. However, when these two conditions can be ignored in Figure 5, one can see that CH is consumed in proportion to the reaction ratio. The produced quantity of CH increases 0.051 g for every 1 g of fly ash substituted for cement in the cement paste. This is because the W/C is increased.

Regardless of the replacement dosage of fly ash, W/P, curing temperature, and test age, the CH is consumed at a rate of 8.04 mg per 1% of reaction ratio for each 1g of fly ash. This constant consumption of CH means that Ca/Si mole ratio in C-S-H formed by the pozzolanic reaction of fly ash is unchanged.

Figure 4. Relationship between fly ash replacement dosage and the amount of $\text{Ca}(\text{OH})_2$ consumed by pozzolanic reactions.

Figure 5. Effect of pozzolanic reaction of fly ash in cement paste and in $\text{Ca}(\text{OH})_2$ paste on the amount of $\text{Ca}(\text{OH})_2$ consumed, as determined through DSC thermal analysis.

The slope of the consumption line of CH paste on Figure 5 is different from the slope of the cement paste. In the case of CH paste, CH is more consumed than in the cement paste. This may be due to the difference of pH condition in the paste. The relationship between pH and C-S-H, which is produced by the pozzolanic reaction, is described in section 3.7.

3.4 Effect of Pozzolanic Reaction on BET Specific Surface Area of Hardened Paste

The pozzolanic reaction rate of fly ash is much slower than the hydration rate of cement. Therefore the formation of microstructure in the paste appears to proceed in two separate reactions.

Variation of BET specific surface area of hardened paste, which is different fly ash replacement dosage, with age is shown on Figure 6.

The relation between the reaction ratio of fly ash and BET specific surface area of hardened paste is investigated. BET specific surface area due to fly ash is calculated with equation (6).

$$Sf_d = (Sr_d - S0_d * (1 - f_r)) / f_r \quad (6)$$

Sf_d : The difference of BET specific surface area result from 1g of fly ash at d days (%)

Figure 6. Variations of BET specific surface area of hardened paste with age.

Figure 7. The effect of pozzolanic reaction of unit fly ash on BET specific surface area of hardened paste.

Sr_d : The BET specific surface area of hardened paste with fly ash replacement dosage f_r at d days (%)

$S0_d$: The BET specific surface area of hardened paste of fly ash 0% at d days (%)

f_r : The replacement dosage of fly ash

Effect of pozzolanic reaction of fly ash on BET specific surface area of hardened paste is shown in Figure 7. BET specific surface area due to fly ash (Sf_d) decreases as the reaction ratio of fly ash increases. Fly ash reduces permeability to nitrogen gas. On the assumption that BET specific surface area is related to the microstructure of C-S-H, we predict that the BET value increases as pozzolanic reaction continues. However the BET value almost constantly decreases with reaction ratio of fly ash.

3.5 Affect of Pozzolanic Reaction on Pore Distribution of Hardened Paste

Pore distribution of hardened paste is shown in Figure 8.

Pore diameter in partition of 3nm-6nm is related to the gel of C-S-H. Pore diameters 6nm-50nm are the capillary pores. These three partitions of pore diameters mostly cover pore volume in hardened paste.

Pore diameters of 50nm-10 micrometer are seldom seen in the hardened paste. It is normally observed in concrete and distributed transition zone between aggregate surface and paste matrix. At 7 days, when cement was replaced with fly ash, pore diameters of 10nm-50nm initially increases but then decreases with age. Pores with diameters of 3nm-10nm increased with age. Total pore volume is constant with age at 60% of fly ash replacement dosage.

Figure 8. Pore distribution of hardened paste (W/P=50%, Curing Temperature 40°C).

The effect of pozzolanic reactions on pore distribution is investigated. Pore volumes due to fly ash were calculated with equation (7) as same as BET specific surface area.

$$Pf_d = (Pr_d - P0_d * (1 - f_r)) / f_r \quad (7)$$

Pf_d : The difference of pore volume result from 1g of fly ash at d days (%)

Pr_d : The pore volume of hardened paste with fly ash replacement dosage f_r at d days (%)

$P0_d$: The pore volume of hardened paste of fly ash 0% at d days (%)

f_r : The replacement dosage of fly ash

The relationship between the reaction ratio and variations of pore volume due to pozzolanic reaction of unit fly ash is shown in Figure 9. Pf of 3nm–10nm positively correlated with the reaction ratio of fly ash. This increase of Pf suggests C-S-H is constantly produced by the pozzolanic reaction. Pf of 10nm–50nm negatively correlated with the reaction ratio of fly ash. Pozzolanic reaction contributed to densify of paste by reducing capillary pore. When the reaction ratio of fly ash is 0%, Pf of 3nm–10nm is 0, therefore replacement of fly ash does not affect to C-S-H product of cement hydration. However Pf of 10nm–50nm increases when fly ash is replaced even though the reaction ratio is 0%. Therefore it suggests that fly ash affects capillary pores.

Figure 9. The effect of pozzolanic reaction of unit fly ash on microstructure of hardened paste.

3.6 Effect of Pozzolanic Reaction on Hardened Paste

Results of pozzolanic reaction on combined water, consumption of calcium hydroxide, BET specific surface area and pore distribution of hardened paste suggest that pozzolanic reaction of fly ash and cement hydration can be almost separate in these macro studies. Furthermore these phenomena quantitatively correlate with the reaction ratio of fly ash. This information on pozzolanic reaction of the fly ash contributes to elucidating the variation of properties and durability of concrete that includes all kinds of pozzolanic materials.

3.7 Ca/Si mole ratio of the hardened cement paste polished surface

EPMA is used to measure Ca/Si distribution on the polished surface of hardened cement paste. BEI of the measured areas and Ca/Si distributions are shown in Figure 10. Particles of C-S-H are smaller than the measurement beam diameter of 5 micrometer. Therefore the measured Ca/Si is the average of vicinity of the measuring point.

The appearance rate of Ca/Si for each measurement point is shown in Figure 11. By substituting the fly ash, the mode of Ca/Si lowers. In the case of the sample with 0% fly ash, frequency around - 20 micrometer.

Figure 10. Back scattered electron images and Ca/Si atom ratios images on polished surfaces of hardened paste (W/P = 50%, Curing temperature = 40°C).

Ca/Si = 1.8 increased with age. Frequencies between Ca/Si of 1.0 to 1.5 are low. However fly ash dosages are 40%, there are high frequencies between Ca/Si of 1.0 to 1.5 even at 7 days. The range of Ca/Si below 1.5 increases with age.

3.8 Ca/Si of C-S-H Produced by Pozzolanic Reaction

The Ca/Si mole ratios of C-S-H produced by pozzolanic reaction in cement paste and in CH paste were 0.28 and 1.47 respectively [7]. The values of Ca/Si were calculated as follow functions (8, 9) from the consumption of CH due to pozzolanic reaction which was determined in Figure 5.

$$\begin{aligned} \text{Si: } 0.907 &= P / X, \text{ Al: } 0.305 = q, \text{ Ca: } 0.079 + 1.086 = p + 3q, \text{ H}_2\text{O: } 1.086 + r = p + 6q \\ p &= 0.28\text{mol}, q = 0.305\text{mol}, r = 0.994\text{mol}, x = 0.276\text{mol}, 1/x = 3.62 \end{aligned}$$

When the sample has 40% fly ash, the mode of Ca/Si in Figure 11 becomes low with age. Because C-S-H with Ca/Si ratio of 0.28 is produced by pozzolanic reaction, it affects the mode of Ca/Si.

The relationship between Ca/Si of C-S-H and pH [8] is shown in Figure 12. The pH value of calcium hydroxide paste is about 12.6. Whereas in cement paste, it is higher than 12.6 due to alkali metal. At early ages, cement paste is porous. This allows Ca ions and water to easily react with fly ash. After a long period, cement paste becomes denser. Ca ions and water supply to fly ash are then controlled by diffusion speed. As a result that pH value in close area of fly ash becomes low.

Figure 11. Ca/Si atom ratio measured by point counting in the area of Figure 10.

Figure 12. Calculated change in CSH composition with pH [8].

Figure 13. Metastable equilibrium curve relating the Ca/Si ratios of C-S-H [9].

CH paste is also porous even after a long period so the pH value of close vicinity to fly ash is almost 12.6. Concerning pH, there was good agreement on Ca/Si of C-S-H.

The typical metastable equilibrium curve relating the Ca/Si ratio of C-S-H with Ca ion concentration [9] is shown on Figure 13.

It has been reported that Ca ion concentration in the pore solution of hardened cement paste is quite low, below 2 mmol/l [10], [11], [12]. In CH paste, Ca ion concentration is almost 20 mmol/l. These two figures support our results of Ca/Si of C-S-H. This result shows that the pH value surrounding the fly ash in the paste is a key factor of the pozzolanic reaction.

4. CONCLUSION

The pozzolanic reaction of fly ash in cement pastes was investigated. Using paste specimens, which were prepared with various water cement ratios, fly ash replacement dosages and curing temperatures. The effect of the pozzolanic reaction on hardened paste was elucidated. The effects of the pozzolanic reaction can be regarded as quantitative phenomena. Details of these are described below.

- (1) The pozzolanic reaction ratio of unit fly ash increases with decreasing replacement dosage of fly ash. Fly ash reaction ratio was calculated by determining the levels of insoluble residue of hardened paste.
- (2) The pozzolanic reaction ratio of unit fly ash was increased with increasing water/powder ratio and increasing curing temperature.
- (3) The pozzolanic reaction can be described as a constant chemical function in a macro model. Mixture proportion and curing conditions affect only the pozzolanic reaction speed of fly ash.
- (4) Variations of combined water, consumption of calcium hydroxide, variations of BET specific surface area and variations of pore distribution in hardened paste due to the pozzolanic reaction proceeding can be separated from the results of cement hydration.
- (5) The effect of pozzolanic reaction on cement paste, such as combined water, consumption of calcium hydroxide, BET specific surface area and pore distribution, could be described as a function of fly ash reaction ratio.
- (6) The expected Ca/Si mole ratios of C-S-H in cement paste, which were calculated from experimental results, agreed with its observation values of EPMA. Furthermore, the expected values in the cement paste and in the calcium hydroxide paste corresponded to the equilibrium curve between C-S-H and pH, and the relationship between Ca ion concentration and metastable Ca/Si ratio in the solution.
- (7) pH was a key factor of pozzolanic reaction, therefore these results seem to apply to different kinds of fly ash and pozzolans.

China Building Materials Academy, Beijing, P. R. China. E-mail: shguocbma@sohu.com

ABSTRACT

The paper studied the formation and burning process of high Belite cement (HBC) clinker when it had different interstitial phases' content. The results showed that the texture of Belite in HBC clinker would be remarkably different when the interstitial phases content in it was different. If the interstitial phases content in it was not higher than 10w%, the clinkering temperature required for HBC clinker would not be improved notably when interstitial phases content in it decreased. On the contrary, the clinkering temperature range of the clinker would be wider. The physical properties of the clinkers with different interstitial phases+ content would be notably different. The paste made of the cement prepared with the clinker with an interstitial phase content less than 15w% would have a fine workability and the 28-day strength of the mortar would also be high.

1. INTRODUCTION

High Belite cements (HBC) have been one of the highlights in the area of cement since the 1970's energy crisis. In the 1980's, it had become one of the high performance cements for preparing high performance concrete because the cement had such advantages as low heat of hydration, good resistance to chemical attack, and having a high strength and low shrinkage after a long hydration age [1].

For HBC clinker in which compositions lie in $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3$ system and Belite content in it is higher than 40%, the clinker would be easily dust during the quenching and the range of clinkering temperature of it would be generally sharp. Furthermore, the early strength of HBC is often very low and the quality of the cement would be not stable. One method to obtain high quality Portland cement (PC) and to simplify the burning process of the clinker is to control the mineral composition of it. However, there have been few studies published on HBC [2, 3]. It is well known that interstitial phases can influence the burning process of PC clinker notably and can also affect early hydration and performance of the cement. Because the guiding mineral of HBC is different from that of ordinary PC, the influences of interstitial phases on the burning process of HBC clinker or the performance of HBC would be also different. This paper studied the formation process and performance of Belite clinker when it had different interstitial phases' content.

2. EXPERIMENTAL

The raw materials used for the raw meals of HBC were limestone, clay and limonite, which were selected from some cement plants in China. Each raw material had first to be ground to a certain fineness and then mixed together to prepare the raw meal. The clinker samples were burned in an electric furnace and had been kept at the burning temperature for a certain time. To make samples for the burnability test, the time kept was 30min. To make samples for physical performance tests, they would be kept for 60 min. All clinker samples were quenched in air. Then chemical analysis,

XRD, optical examination and EDS would be carried out.

The cement samples were prepared with a SO_3 content of 3.5w% by mixing clinker with gypsum and then grinding them together to a specific surface area of about $325\text{m}^2.\text{kg}^{-1}$. Physical performances of cement such as setting time of cement, fluidity and strength of mortar were tested according to such national standards as GB1346-89, GB/T2419-94 and GB177-85 in China.

3. RESULTS AND DISCUSSION

3.1 The compositions and formation process of Belite clinkers

The chemical compositions of clinkers made as above, are shown in Table 1. Based on the Bogue method [3], the mineral compositions of clinker samples can be calculated and are listed in Table 1. The results indicated that the Belite in these samples were all higher than 65% and the difference of mineral compositions among them is the content of interstitial phases in the clinker.

The free calcium oxide contents of clinker samples are listed in Table 2, by which we can analyze the clinkering degree of the clinker when it is burned at different temperatures and can also analyze the clinkering temperature range of the clinker.

* The clinker sample shran notably. **The clinker began to melt.

When the content of interstitial phases is higher than 15w%, the clinker can be burned at a low temperature, but the clinkering temperature range of it will be very sharp and can only vary in a range not larger than 100°C. When the content of interstitial phases in clinker lies in the range of 10-15w%, the clinkering temperature required for the clinker will not be increased significantly and the clinker can be burned over a wide temperature range which can reach 150-200°C. When the interstitial phases content in it is lower than 9w%, the clinker should be burned at a high temperature.

According to XRD, the dusting amount of the clinker can be reduced when it is burned in a high temperature or the interstitial phases in it is high. When the burning temperature of the clinker is lower than 1300°C, the clinker will be dust easily, i.e. Belite of type β will be easy to transform to Belite of type γ during the quenching. When interstitial phases content in the clinker is lower than 10w% and the clinker is burned in a temperature not higher than 1300°C, there will be a lot of $\gamma\text{-C}_2\text{S}$ in the clinker as shown in Figure 1(b).

Figure 1. XRD patterns of HBC clinkers having different compositions which had been burned at different temperature conditions

Figure 2. Compositions' area of HBC (having a low aluminate content) in the phase diagram ^[2] of CaO-C₂S-C₁₂A₇ system

When the burning temperature of the clinker was higher than 1400°C, there would be some α' -C₂S formed in the clinker. This result was consistent with that of Fukuda ^[4, 5]. The result in the study had also indicated that the burning temperature required that α' -C₂S began to appear in the clinker would become lower when the interstitial phases content in the clinker was decreased. When the clinkers having different interstitial phases amount were burned in one given temperature, more α' -C₂S would form in the clinker having a low interstitial phases' content as shown in Figure 1.

When the interstitial phases content in the clinker is high, one of aluminates-C₁₂A₇ would be easily formed in the clinker. The main reason is that the composition of the clinker lies in the shadow area of Figure 2 and very close to the composition line of C₂S-C₃A. When the clinker compositions' point lies in the upper area of the line or the clinker is burned in a non-equilibrium state, the low-calcium aluminate mineral-C₁₂A₇ will be formed in the clinker.

3.2 Texture and compositions of Belite in the clinker

In HBC clinker of the same chemical compositions, the variation of burning temperature would not show a distinct influence on the texture of Belite. In contrast, the amount of interstitial phases in the clinker would have a great influence on the texture of Belite as shown in Figure 3.

When the interstitial phases content is higher than 10w%, Belite crystals formed in the clinker are rounded and normally striated. When the interstitial phases content decrease from 22.94w% to 11.31w%, the sizes of crystals will increase slightly but there will be more pores in the clinker. When the interstitial phases content in the clinker is lower than 10w%, Belite crystals will exhibit an irregular angular shape which may be even close to a hypidiomorphic texture.

p-1, 1350°C, $C_3A+C_4AF=22.94\%$

p-2, 1380°C, $C_3A+C_4AF=11.31\%$

p-4, 1450°C, $C_3A+C_4AF=8.89\%$

p-5, 1500°C, $C_3A+C_4AF=6.70\%$

Figure 3. Polished surface of Belite in clinkers having different interstitial phases' contents, etched with 1.0w% HNO_3 in alcohol

When the interstitial phases content in the clinker was different, the compositions of Belite (solid solution) would also be different. According to EDS analysis, we can see this variation of Belite's compositions as $(Ca+Mg+K+Na)/(Si+Al+Fe)$ mole ratio which is shown in Figure 4. Belite in the clinker having a higher interstitial phase content would have a relatively higher $n(Ca+Mg+K+Na)/n(Si+Al+Fe)$ ratio.

Figure 5. The relationship between interstitial phases amount and strength performance of HBC cement

3.3 Influence of interstitial phases on physical performance of HBC

All cement samples were prepared with the same gypsum content and the test results of their physical performance are listed in Table 3. It was found that the grindability of the clinker would be very bad when the content of interstitial phases in it was higher than 15%.

Table 3. Physical properties of HBC when the clinker had a different interstitial phases content

No.	Interstitial phases content /(w%)	Clinker		Fineness of cement /(w%)	Specific surface area of cement /(m ² .kg ⁻¹)	Setting time /(min)		Fluidity of mortar /(mm)	Bending strength /(MPa)			Compressive strength /(MPa)		
		Burning temperature	f-CaO /(w%)			Initial	Final		3d	7d	28d	3d	7d	28d
p-1	22.94	1350°C	0	13.6	329	6	9	102	1.48	1.85	2.19	5.21	5.74	8.53

p-3	11.31	1380°C	0.33	0.8	327	109	225	131	0.90	1.16	4.98	1.85	2.62	33.6
p-4	8.89	1450°C	0.33	0.5	326	200	328	130	0.80	1.70	6.65	4.17	5.55	36.2
p-5	6.70	1550°C	0.50	0.3	322	234	281	133	0.60	1.18	5.51	2.96	4.17	25.7

The influence of interstitial phases content on strength performance of HBC is shown in Figure 5. The early strength of the mortar would be improved by the increase of interstitial phases content when this content in the clinker was higher than 15%, but the strength of all samples were low. The 28day strength performance of the cement in which the clinker had an interstitial phases content not more than 15% would be far higher than that of other cement made of the clinker having a high interstitial phases content. The compressive strength of the former would be 30MPa higher than that of the later. To the clinkers having a high interstitial phases content, the strength increase of the mortar between 7-day and 28-day hydration age would be very small. The 28-day compressive strength of them would be not higher than 10MPa, which indicated that the Belite in the clinker had a very low hydration activity. This may be caused by the variation of Belite's composition. Figure 6 indicates that when the $n(\text{Ca}+\text{Mg}+\text{K}+\text{Na})/n(\text{Si}+\text{Al}+\text{Fe})$ ratio of Belite in the clinker was larger than 1.9, the 28-day compressive strength of the mortar would be far higher than that of the mortar in which the ratio of Belite in the clinker was lower than 1.9.

There may be another reason that the cement made of the clinker having a low content of interstitial phases had a higher strength performance. That is, there would be some α' -C₂S formed in the clinker as shown in Figure 7 or they had a higher C₃S content as in Table 1 than the clinkers having a higher interstitial phases content.

Figure 6. The relationship between $n(\text{Ca}+\text{Mg}+\text{K}+\text{Na})/n(\text{Si}+\text{Al}+\text{Fe})$ ratio and strength performance of the mortar

Figure 7. XRD pattern of HBC clinkers having different interstitial phases content

When the interstitial phases content in the clinker was higher than 15%, the cement will set rapidly and the mortar have a bad fluidity. This is because these samples have formed the low-calcium aluminate mineral C_{12}A_7 as in Figure 7.

4. CONCLUSIONS

- (1) When the content of interstitial phases in clinker lies in the 10-15% range, the clinkering temperature required for the HBC clinker will not be increased significantly by the decrease of interstitial phases content and the clinker can be clinkered in a wide temperature range. When the interstitial phases content in it is lower than 9%, the clinker should be burned at a high temperature.
- (2) The dusting amount of the clinker can be reduced by burning it at a high temperature or by improving the interstitial phases content in it.
- (3) When the interstitial phases content is higher than 10%, Belite crystals are rounded and normally striated. When the interstitial phases content in the clinker is lower than 10%, Belite crystals formed in the clinker will exhibit an irregular angular shape which may be even close to a hypidiomorphic texture.
- (4) The more interstitial phases in the clinker, the higher the $n(\text{Ca}+\text{Mg}+\text{K}+\text{Na})/n(\text{Si}+\text{Al}+\text{Fe})$ ratio of Belite would be. The 28-day compressive strength of the mortar prepared with the clinker in which Belite had a ratio higher than 1.9 would be far higher than that of others.
- (5) When the interstitial phases content in the clinker was very high, there would be some C_{12}A_7 formed in the clinker, the cement would set rapidly and the mortar would have a bad fluidity.

THE RELATIONSHIP AMONG THE AGGLOMERATION, MICROSTRUCTURE OF CLINKER AND THE PERFORMANCE OF HIGH BELITE CEMENT

Sui-hua Guo, Hong-tao Zhang, Zhen Lin, Wen-sheng Zhang and Yi-min Chen

China Building Materials Academy, Beijing, P. R. China. E-mail: shguocbma@sohu.com

ABSTRACT

The relationship between the agglomeration, microstructure of clinker and the performance of high Belite cement (HBC) is discussed in the paper. The results showed that, for similar dense particles larger than 3mm, the smaller the size, the faster the cooling of the clinker and the more α' -C₂S formed in it. The microstructure of the clinker and the performance of HBC will also be better. The strength performance of HBC will be best when the sizes of clinker particles lie between 5-15mm and Belite crystals formed are characterized by the intersecting lamella texture in which there are many foreign ions. The C₃S content in loose clinker will be relatively lower than that in the dense one of similar size and there will be no α' -C₂S in it. The strength performance of the cement made with it will also be lower than that of the cement made of dense clinker.

1. INTRODUCTION

During the production and application of high Belite cement (HBC) in which C₂S content is higher than 40w%, some puzzles probably exist. For example the clinkering temperature range of the clinker will be relatively sharp, the clinker will be dust easily during cooling and the early strength of the cement will probably be very low [1, 2]. The previous research has shown that the quality and hydration activity of HBC could be improved by optimizing the composition of the clinker, for example by adjusting the content of fluxing minerals in clinker [3]. It is believed that there is a close relationship between the microstructure and the burning process of the clinker according to the petrography theory of cement [4]. Therefore by optical examination, the quality of the clinker can be controlled conveniently. The paper studied the relationship between the agglomeration, microstructure of clinker and the performance of high Belite cement.

2. EXPERIMENTAL

2.1 Clinker of high Belite Portland cement

The clinkers studied were burned in a rotary kiln of $\phi 2.4/2.0/2.4 \times 45$ m with a shaft preheater. The clinker samples were then classified according to their densities and agglomeration sizes. Their compositions are listed in Table 1.

2.2 Phase and microstructure analysis

Phases of clinkers were analyzed by X-Ray diffractometer (D/MAX-III A, CuK α) in a condition of 37kV, 40mA with a scanning speed of 2°/min. Before scanning, the samples were ground to a fineness less than 40 μ . The microstructure of clinker was observed with a microscope of ORTHOLUX II POL-BK. The samples used in optical examination and EDS analysis were solidified with resin and etched first in a solution of 1% HNO₃ in alcohol.

2.3 Tests for physical performance of cement

The cement samples were prepared by grinding clinker and gypsum together with a SO_3 content of 3.2w%. The physical properties of cement such as setting time, fluidity and strength were tested according to GB1346-89, GB/T2419-94 and GB177-85 in China.

3. RESULTS AND DISCUSSION

3.1 Mineral compositions of clinker

The composition analysis showed that the larger the agglomeration sizes, the higher the C_3S content would be in the clinker. When particle sizes were similar, the C_3S content in loose clinker would be lower than that in the dense one as shown in Figure 1 and Table 1.

Figure 1. XRD patterns of clinker particles having different agglomeration sizes or different densification degrees

Table 1. Compositions of HBC clinker with different agglomerations

No.	Agglomeration sizes /mm	Chemical compositions /w%						Modulus			Mineral compositions /w%				
		SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Σ	KH	SM	IM	C_3S	C_2S	C_3A	C_4AF	f-CaO
B6	<3, dense	24.93	4.42	5.18	62.10	1.25	97.88	0.759	2.60	0.85	26.3	51.6	3.0	15.8	0.39
B5	5-15, dense	24.95	4.00	4.94	62.53	1.42	97.84	0.765	2.79	0.81	28.0	50.4	2.3	15.0	0.45
B7	25-40, dense	24.52	3.95	4.77	62.17	1.68	97.09	0.786	2.81	0.83	33.4	45.1	2.4	14.5	0.62
B3	>50, dense	24.64	3.84	4.73	62.80	0.99	97.43	0.794	2.88	0.81	35.8	43.7	2.2	14.4	0.61
B4	>50, loose	24.95	4.23	4.79	62.30	1.21	97.76	0.768	2.77	0.88	28.8	49.8	3.1	14.6	0.48

When agglomeration sizes or densities of clinkers were different, there were also some other differences in mineral composition. With clinkers of similar density, the α' - C_2S formed in small particles would be more and the f-CaO content in it would be relatively lower than that in the larger clinker particles as shown in Figure 1 and Table 1. For the clinkers of different densities, the α' - C_2S content formed in the denser one would be higher than that in the loose clinker. When the clinker was very loose and particle sizes were very big, some γ - C_2S could be found in it. The f-CaO contents in clinkers of different densities were close to each other.

DTA showed that, when the clinker was very loose, there would be an endothermic peak emerging in DTA pattern near the temperature of 810°C. This endothermic peak was caused by the phase transition from γ -C₂S to α' -C₂S, which was consistent with the result of XRD.

3.2 Microstructures of clinkers having different agglomerations

The color of HBC clinker is lighter than that of the ordinary Portland clinker and the litre weight of it (1.30-1.50kg.L⁻¹) is also remarkably lower than that of the latter. When the burning temperature in the kiln was too high, the clinker would be very dense and a brown core would appear in it. The agglomeration sizes of clinker particles out of the kiln would be in two opposing extremes, i.e. there was not only too many large particles but also too many small particles of less than 3mm in the clinker. When the burning temperature was relatively low, the particles of clinker would very loose and the litre weight of it would be even less than 1.10kg.L⁻¹.

3.2.1 Microstructure of clinker particles with a size of 5-15mm

The microstructure of the clinker that had an agglomeration size of 5-15mm is shown in Figure 2. The interstitial phases consist of dendritic ferrite (light) in a matrix of aluminite (dark). Alite and Belite had grown well and their boundaries were very clear. Belite crystals were rounded and normally striated. There were also many small crystals of Belite as inclusions in Alite. The sizes of Alite crystals lay in 10-30 μ range and the sizes of Belite in 10-25 μ . The interstitial phases in the clinker were about 15-20w% of the clinker and distributed uniformly in the clinker, which was suitable for the clinker to have a high performance. The microstructure of the clinker showed that the burning temperature of the clinker was high, the cooling of it was quick and the clinker had been burned in an oxidation condition [4].

Figure 2. Polished surface of clinker particles with a size of 5-15mm

Figure 3. Alite and fingered Belite in the fine clinker particles

3.2.2 Microstructure of small-and-dense clinker particles

The polished surface texture of small-and-dense clinker particles (<3mm) is shown in Figure 3 and Figure 4. The crystals of C₃A represented a state of rectangle or line shape. Much of the Alite in it had been grown together and there had been many melting phenomena in their boundaries. A kind of girdle banded texture was also found in their boundaries. The configuration of Belite had some different categories among which the fingered shape was typical and there were intersecting coarse striae in their surfaces. Part of the Belite was also like that in the clinker particles of 5-15mm and a part of the Belite showed a kind of encephalon texture as in Figure 4. The sizes of Alite and Belite crystals in the clinker were not uniform and in a range of 5-50 μ respectively. The distribution of various minerals in the clinker was also not uniform. In the field of crystal clusters of Belite, the amount of interstitial phases was few and in the field of Alite, there were more interstitial phases distributed.

Figure 4. Crystal cluster composed of different Belite textures in fine-and-dense clinker

Figure 5. Polished surface of clinker with a particle size of 25-40mm

This kind of clinker usually emerged together with the large particles of dense clinker. The microstructure of the clinker showed that the clinker had been over burned and had been burned unevenly. The cooling of the clinker particles was also relatively slow.

3.2.3 Microstructure of large clinker particles with a size larger than 25mm

For the clinker particles of 25-40mm, the interstitial phases consist of dendritic ferrite in a matrix of aluminate. Alite had grown very well and their boundaries were very clear. But a part of Alite crystals emerged as a kind of striated texture. Belite in the clinker had grown as fingered shape with a multi-pock surface or exhibited as a kind of encephalon shape with crossed striae in their section plane. The microstructure of it indicated that the clinker had been burned in a reductive atmosphere and had not been cooled quickly.

The structure of Belite in dense clinker particles larger than 50mm was similar to that in the dense clinker of 25-40mm. But the crystal sizes were approximately 30μ and remarkably larger than the latter. Furthermore there were also little of Belite emerged as dendritic shape (Figure 6). Compared with the clinker particles of 25-40mm, the sizes of Alite crystals in it were relatively high which were about 50μ . The boundaries of Alite also had much melting phenomena, moreover part of the Alite had decomposed completely into secondary free CaO and secondary Belite, and formed a misleading phenomenon as an Alite configuration (Figure 7). The C_3A in the clinker showed as a state of sheet texture. The optical examination of the clinker showed that the clinker had been burned at a very high temperature in a heavy reductive air and had been cooled slowly.

Figure 6. Microstructure of large particles of dense clinkers

Figure 7. Pseudo-Alite in the large particles of dense clinkers

3.2.4 Difference between the microstructures of loose HBC and dense HBC clinker

The microstructure of loose HBC clinker particles with a size larger than 50mm is shown in Figure 8 and Figure 9. Compared with the dense clinker having the same sizes range, the crystals of Alite were remarkably smaller and had a size of 10-20 μ . The texture of Belite was also different. Part of Belite emerged as a spindly shape and had a kind of parallel striae texture in their twins as in Figure 8. Other part of Belite showed as kidney shape with a multi-pock surface as in Figure 9. The C₃A in the clinker also showed as a kind of sheet texture, which showed that the clinker had been burned at a relatively low temperature and had been cooled very slowly.

Figure 9. Pockmarked Belite like kidney shape in the large particles of loose clinker

3.3 Relationship between physical properties of HBC and clinker agglomerations

3.3.1 Particle density of clinker agglomeration

The physical properties of HBC having different clinker agglomerations are shown in Table 2. The test showed that the strength performance of HBC made of dense clinker would be higher than that of HBC made of loose clinker which had similar agglomeration sizes to the dense one. One reason would be that the C₃S content of dense clinker was higher than that of loose clinker.

Table 2. Physical properties of high Belite cement prepared with different agglomeration clinkers

No.	Agglomeration sizes /mm	Specific surface area / (m ² .kg ⁻¹)	Fineness /% (in mass)	Water demand of paste at normal consistency /% (in mass)	Setting time		Bending strength /MPa							Compressive strength /MPa					
					Initial	Final	1d	3d	7d	28d	60d	91d	1d	3d	7d	28d	60d	91d	
B6	<3, dense	376	2.8	25.4	2:40	3:30	3.5	4.1	5.4	8.6	10.8	11.0	11.2	16.4	24.7	52.6	68.1	80.5	
B5	5~15, dense	379	2.2	25.2	2:35	3:25	4.0	5.2	6.5	9.1	10.3	10.3	15.4	21.8	33.4	54.0	69.6	78.5	
B7	25~40, dense	390	2.8	25.4	2:25	2:50	2.8	4.6	6.0	8.5	9.8	10.2	10.7	20.7	28.7	51.4	64.9	76.9	
B3	>50, dense	412	2.6	25.2	2:05	2:25	3.2	5.2	5.8	8.1	8.8	8.8	12.5	22.8	30.3	47.8	61.5	68.6	
B4	>50, loose	401	1.8	24.8	2:05	2:30	3.1	4.5	5.3	7.8	9.5	9.4	10.6	19.2	25.0	44.8	62.8	68.5	

According to the optical examination, the burning temperature of loose clinker was lower than that of dense clinker, which showed that increasing the burning temperature would also improve the strength properties of HBC. Fukuda believed that [5, 6] the original Belite at low temperature would be type α' and then could be as type α in high temperature conditions. When the two clinkers were cooled at the same speed, a transformation of $\alpha' \rightarrow \beta$ -C₂S+L for the Belite burned at low temperature and another transformation of $\alpha \rightarrow \alpha' \rightarrow \beta$ +L for the Belite burned at high temperature would take place respectively. Therefore, the α' -C₂S amount reserving in the twins of Belite burned in high temperature would be remarkably higher than that burned at low temperature as shown in Figure 2. The analysis of XRD showed that there would be some γ -C₂S in the loose clinker particles.

Figure 10. Strength properties of high Belite cement prepared with clinkers of different agglomeration sizes

3.3.2 Agglomeration sizes of clinker

The influence of clinker agglomeration on the strength properties of HBC was shown in Figure 10. The chemical analysis showed that the larger the agglomeration sizes of the clinker, the more C_3S would be in the clinker. But when the particle size of the clinker was larger than 3mm, the compressive strength of HBC, especially the strength performance after hydrating for 3 days would be decreased by the increase of the clinker particle sizes. This showed that the texture of Belite crystals had great influence on the performance of HBC. XRD analysis showed that the smaller the clinker particle was, the more α' - C_2S would be formed in the clinker. Moreover, the optical examination showed that the cooling speed of clinker would be decreased, the burning condition of clinker would become in a reductive air and the texture of Belite would not be very good when the particle size of clinker became larger in a similar particle density.

For the clinker having a particle size not larger than 3mm, the cooling of it was also not very good because it always come out of kiln along with the large and dense clinker particles. The texture of Belite in it would not be very good and the strength performance would also be relatively low.

The tests showed that the strength properties of HBC would be the best when particle sizes of the clinker were in the range of 5-15mm. This kind of clinker had been burned in a high temperature without reductive air and had been cooled rapidly. And there would be much more α' - C_2S formed in the clinker. According to the analysis of EDS, the foreign ions in the Belite would also be high.

Table 3. Ca/Si mole ratios and foreign ions content in Alite and Belite

No.	Agglomeration sizes	n(Ca)/ n(Si)		Foreign ion fraction /w%	
		Alite	Belite	Alite	Belite
B6	<3mm, dense	2.64	1.96	2.54	3.59
B5	5~15mm, dense	2.93	2.02	1.84	5.00
B7	25~40mm, dense	3.21	2.22	2.39	2.33
B3	>50mm, dense	2.73	2.05	3.04	3.90
B4	>50mm, loose	2.75	1.98	3.75	3.90

4. CONCLUSIONS

- (1) The analysis showed that the larger the size of clinker particles, the more C_3S in it. When particles sizes are similar, the C_3S content in loose clinker would be lower than that in the dense one.
- (2) For dense clinker, the smaller the size of the agglomeration, the more α' - C_2S would be formed. No α' - C_2S would form in loose clinker and there would be even some γ - C_2S formed in it when particle sizes of it were very large. The strength performance of HBC made of dense clinker would be better than that of HBC made of the loose one.
- (3) For similar dense clinker, the smaller the size of particles, the faster the cooling of the clinker and the higher the content of α' - C_2S formed when the particle sizes of clinker are larger than 3mm. The microstructure of the clinker and the performance of high Belite cement will be improved by the decreasing agglomeration size of the clinker.
- (4) The strength properties of HBC will be the best when the size of clinker agglomerations was in the range of 5-15mm. This clinker had been burned in a condition of high temperature without reductive air and had been cooled rapidly. There would be much more α' - C_2S formed in the clinker and the foreign ions in the Belite will be high.

ABSTRACT

The purpose of this study is to develop an effective way of utilization of the by-pass cement kiln dust (BP) in slag containing binders intended for general application in civil engineering. The study's results concluded that an alkaline activation of the slag by the salts contained in the BP is a problem because these are the salts of alkali of metals and strong acids, in particular, sulfates and chlorides. Moreover, the content of chlorides and sulfates is a main factor in determining the intensity of the development of corrosion of reinforcement in concrete, thus affecting its durability. The BP itself may be utilized as an alkaline component of the slag containing cements such as the slag alkaline binders (SAB), on condition that there is enough activity and degree of binding of the chlorides into new formations to use them in making durable reinforced concretes. A scheme of the process of how to lower concentration of free chlorine in the pore solution of the slag containing binders with the use of the BP has been proposed and is discussed in detail. A range of compositions of the modified binder in the system "slag- BP" to be used for making both non-reinforced and reinforced concretes has been developed.

1. INTRODUCTION

One of the key problems of the cement industry related to environmental protection is how to provide full recovery of cement kiln dust, including BP and its rational utilization. Utilization of the BP within the cement and concrete compositions, which would possess high strength, durability, and resistance to chemicals including those chemicals that are aggressive with regard to reinforcement, is of first priority.

The BP contains alkali metal salts of strong acids (such as R_2SO_4 , RCl), CaO , and clinker minerals. The BP aqueous leakage is characterised by high pH values varying between 13 and 14. Due to this, of interest is to use the BP for activation of blast furnace granulated slag in cement composition. The BP may be used not only as a complex activator of slag-containing cement, but as its structure-forming component. In this case, the slag containing cement may be classified as SAB that are known to contain ground granulated slag and alkaline component in a form of alkali metal compounds creating an alkaline medium. The composition of hydration products of the SABs is represented, predominantly, by low-basic calcium hydrosilicates and hydroaluminates as well as alkaline hydroaluminosilicates and these hydration products determine their high performance properties.

The purpose of this study is to develop an effective way of utilizing the BP in composite cement containing slag intended for general application in civil engineering.

2. OBJECTS AND METHODS

For the research presented the mineralogical and chemical composition BP and blast granulated slag used were representative of European materials. The mineralogical content of BP is represented by free calcium oxide (CaO), salts of alkali metals and strong acids such as potassium chloride (KCl), potassium sulphate (K_2SO_4) and complex salt of alkali metals ($K_3Na(SO_4)_2$). The chemical composition BP is represented in table 1.

The slag used belongs to a group of neutral slags with the value of a basicity $Mo < 1$ (table 1), that determines its low hydraulic activity. The specific surface of the slag is $S = 3860 \text{ cm}^2/\text{g}$. The slag is represented by a glass-like phase which contains calcium aluminosilicates.

Portland cement (PC) was used as calcium-containing admixture. The chemical composition CEM I 42.5R (complying with EN 197) is represented in table 1. A mineralogical composition of PC, mass. %: C_3S -42.3, C_2S - 28.6, C_3A - 8.8, C_4AF - 7.6.

Table 1. Chemical composition of BP, slag and PC

	Content of oxides, mass. %										
	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	CaO _{fr}	MgO	SO ₃	Na ₂ O	K ₂ O	Cl	TiO ₂
BP	9.1	2.8	1.7	27.1	10.1	0.9	12.0	1.3	24.9	14.3	-
Slag	36.4	12.0	1.1	39.9	-	7.3	0.4	0.3	0.6	0.0	0.47
PC	21.1	4.9	2.5	63.1	2.1	1.5	3.2	0.2	1.2	0.1	0.19

For involving of free chlorine in structure of hydrated products, hydrated calcium aluminate ($C_3A \cdot 6H_2O$) was utilized as an admixture. This is a by-pass product of ettringite production. The chemical composition the calcium aluminate admixture (CAA) is tabulated in table 2.

Table 2. Chemical composition of CAA*, mass. %

Al ₂ O ₃	CaO	SO ₃	Cl
23.2%	44.4%	0.1%	0.007%

note: CAA contains 86.07 % $C_3A \cdot 6H_2O$.

Preparation of the binders was undertaken in laboratory conditions by mechanical homogenization of dispersible dosed components. In the research presented the methods X-ray diffractometry (XRD), differential-calorimetric analysis (DCA), chemical analysis of pore solution of hydrated binders, and experimental-statistical simulation were applied.

3. RESULTS AND DISCUSSION

3.1 Activation of slag by BP

With the purpose to determine the influence of BP alkaline on structure formation processes during hydration of the binder and to define the rational composition limits of BP in this binder, the binders researched had a content of BP from 10 up to 100 % (remaining part of the binders was represented by the slag). The activity of the binders was taken as criterion to determine the rational content of BP in their composition.

The obtained results demonstrate (fig. 1), that with increase of hydration period leads to augmentation of BP amount that is involved in structure formation process. Thus the maximum activity of SAB can be achieved after 2 days of hydration at a content 10% of BP, and after 28 days of hydration at a content of near 30% of BP in SAB. These phenomena can be connected to the high density of silica-aluminium phase of slag, which causes a long period of interaction between

components of SAB and correspondingly – the involving of above quantity of BP. In this connection the role BP as an alkaline component SAB should be considered in view of a time factor.

Figure 1. Dependence of activity of SAB* upon composition and period of hydration

* - In further under SAB the composition “slag - BP” was meant.

Basing on the results, it was concluded that BP can be utilized as an alkaline component SAB. The components ratio in a system «slag - BP» should meet the following requirement: the ratio between the content of potassium and sodium oxides ($K_2O + Na_2O$) in BP and the content of alumina (Al_2O_3) in slag should be equal

$$\frac{K_2O + Na_2O}{Al_2O_3} \geq 1.$$

However, from the shown data follows, that despite a significant amount of dissoluble R_2O present in the system “slag - BP”, obtained SAB does not differ by high activity. This binder can not be attributed to any class on classification EN 197. The reasons of this fact can be connected as with weak hydration activity of slag with glass-like dense structure, so with the nature of anionic component of salts introduced in the binder with BP. The increase of SAB activity that is based on neutral slag can be achieved by utilization of portland cement clinker [1, 2, 3].

3.2 Activation of slag containing binder by PC

The three-component binding system “slag – BP - PC” was investigated. The carried out researches (figure 2) testify that in this binding system the optimal ratio between components is as follows: mass.%: slag -69.0, BP - 17.5, PC – 13.5.

Figure 2. The dependence of SAB activity after 28 d of hardening upon the content of PC

The binder of such composition essentially is the modified SAB. This binder is characterized by the class on strength 32.5 according to EN 197. The increase of compressive strength of this binder from 2 to 28 days of hardening is approximately in 4 times (9.6 and 38.6 MPa respectively). This fact can be connected with formation of low calcium hydrosilicates. The formation of these products can be confirmed by increase of intensity of a diffuse hum on the XRD of the binder radiogram astringent in characteristic for identification of such hydration products reflection angles $2\Theta = 28-34^\circ$ (figure 3, curves 2 and 3).

Figure 3. XRD of slag and modified SAB

It is known [4] that the main criterion for an estimation of aptitude of a binder for application in reinforced concretes alongside with activity, is the content of free chlorine in the pore solution. The high content of chlorine in a structure BP (as dissoluble salts) predetermines the necessity for the substantiation of BP usage in SAB, providing safety of steel reinforcement.

3.3 The regulation of conditions for passivation of steel reinforcement in medium of a binder

It's known that the most representative criterion for an estimation of probability of appearance of corrosion of the reinforcement in concrete is the ratio of ions Cl^-/OH^- [5]. It was shown that no conditions for depassivation of reinforcement can be observed at ratio Cl^-/OH^- in the pore solution not more than 0.6 [6].

The pore solution of SAB modified with PC is characterized by the molar relation Cl^-/OH^- equal to 9.83, i.e. by a value that exceeds the limit of 0.6. Therefore, it was necessary to solve the problem of this value reduction.

It is expedient to consider the process of free chlorine reduction in pore solution of SAB by its binding both chemically and adsorptive, including cases when the total content of chlorine exceeds the normative limits.

3.4 The hypothetical process of AFm-phases formation during hydration of SAB

In an initial stage of hydration up to crystallization of portlandite (Ca(OH)_2) the next reaction takes place:

The beginning of this process is determined by dissolution KCl of BP. The calcium chloride (CaCl_2) forms with portlandite the complex salt $\text{Ca}(\text{OH})_2 \cdot \text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, and the ions of alkali metal increase pH of pore solution. As hydration passes, the surface dissolution of $\text{Ca}(\text{OH})_2 \cdot \text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ take place. The reason of this process is determined by smaller dissolubility of portlandite in comparison with calcium chloride. The crystallization of portlandite and the migration of chlorine ions in the pore solution can be observed as a result.

It is known that chlorides of alkali metals can be bound in a slightly soluble AFm-phase known as Friedel's salt [7]. In view of the presence of potassium chloride in BP, the process of formation of Friedel's salt can take place according the following reaction [8]:

It suggests the possibility of modifying of the binder by one more additive – CAA. The role of CAA consists in accelerated formation of AFm-phases, which are presented by the system of complex salts $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4 \cdot n\text{H}_2\text{O}$ - $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$ - $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Ca}(\text{OH})_2 \cdot n\text{H}_2\text{O}$. These salts can be formed as thin pseudo-hexagonal slices only up to crystallization of portlandite. The crystals of these salts consist of brucite-like main layers $[\text{Ca}_2\text{Al}(\text{OH})_6]^+$ and interlayer material $[\frac{1}{2}\text{SO}_4 \cdot 3\text{H}_2\text{O}]^-$, $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ or $[\text{OH} \cdot 3\text{H}_2\text{O}]^-$ [9].

The nature of AFm-phases is that the anion can be freely changed. Thus the priority of involving of anions in a structure of AFm-phases varies in line: $\text{SO}_4^{2-} > \text{Cl}^- \gg \text{OH}^-$ [9].

The presence in the system of ions SO_4^{2-} determines composition of interlayer substance as $[\frac{1}{2}\text{SO}_4 \cdot 3\text{H}_2\text{O}]^-$, that under known conditions will determine the formation of ettringite covers around grains of aluminate and thus will slow down its reactivity. However, at high concentrations of ions OH^- and SO_4^{2-} the formation of ettringite in SAB is absent. This fact is caused by the following reaction:

Thus, the formation of a complex $\text{C}_3\text{A} \cdot \text{C} \cdot \text{S} \cdot \text{H}_{12}$ does not occur, as well as the formation of two-water calcium sulphate ($\text{C} \cdot \text{S} \cdot \text{H}_2$).

The sulphate-ions in solution do not directly cause depassivation of reinforcement, but determine the formation of sulphite hydrogen (H_2S), which is a catalyst of oxidation (carbonization) of hydrated products in SAB:

During carbonization the formation of solid solution of complex salts $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 0.5\text{Ca}(\text{OH})_2 \cdot 0.5\text{CaCO}_3 \cdot 10\text{H}_2\text{O}$ is possible. Besides the anions $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ can be replaced by $[\text{OH} \cdot 3\text{H}_2\text{O}]^-$ in already formed Friedel's salt [10].

As follows from above mentioned, prior to the beginning of portlandite crystallization the formation of Friedel's salt is marked predominantly among known AFm-phases. Thus the factors, which determine the composition of interlayer substance in the complex salt are: molar relation Cl/Al in the system, intensity of carbonization in the system.

The first factor determines the correlation between anions $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ and $[\text{OH} \cdot 3\text{H}_2\text{O}]^-$, the second – the correlation between anions $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ and $[0.5\text{CO}_3 \cdot \text{OH} \cdot 5.5\text{H}_2\text{O}]^{2-}$ in interlayer material of AFm-phases.

Utilization of BP as the alkaline component of SAB ensures values of pH not less than 11 and lack of corrosion of the reinforcement under intensive carbonization of the system at catalytic influencing of H_2S . At high pH values (more than 12.7) the period of formation and existence of Friedel's salt is determined only by intensity of portlandite crystallization and its further transformation in calcite (CaCO_3).

At modification of SAB by PC the replacement of anion $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ in Friedel's can be indemnified by formation of a sufficient amount of gel-like or submicrocrystalline calcium hydrosilicates (see fig. 3). It is known that such hydrated products are capable to adsorb chlorine in their structure [11]. However the process of formation of calcium hydrosilicates is stretched in time, caused by low hydration activity of the slag. This suggests that the role of CAA in SAB consists in intensification of directional formation of Friedel's salt at the initial stage of hydration.

3.5 SAB modified with CAA

CAA has the much greater surface of molecules in comparison with one- or two-calcium aluminate. This fact caused a larger adsorption and, accordingly, larger degree of binding of chlorine in Friedel's salt according to equation (2).

Based on suggested process of Friedel's salt formation among other hydrated products of SAB, the rational value of a molar ratio Cl/Al was under investigations. The researches were conducted on the model system «BP - CAA», because BP determines main content of chlorine and CAA - main content of reactive (in the initial stage of hydration) aluminium in modified SAB.

In fig. 4 the results obtained for model systems after 7 days of hydration are represented. The results testify to optimal molar relation $\text{Cl}/\text{Al} = 1$, that corresponds to stoichiometry of Friedel's salt. Such relation between ions Cl and Al corresponds to 53.06 % BP and 46.94 % CAA in model system, that is caused by chemical composition of BP and CAA.

The proportional decrease in the degree of chlorine binding at lowered Cl/Al less than 1 is caused by replacement of anions $[\text{Cl} \cdot 2\text{H}_2\text{O}]^-$ by $[\text{OH} \cdot 3\text{H}_2\text{O}]^-$ in the interlayer substance of complex salts $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Ca}(\text{OH})_2 \cdot n\text{H}_2\text{O}$. It confirms the AFm-phase formation described above and is compatible with results [10].

Figure 4. The dependence of degree of chlorine binding upon molar relation Cl/Al in model system «BP - CAA» during hydration

The low absolute degree of chlorine binding at sufficient C_3A content can be explained by different kinetics of portlandite and Friedel's salt crystallization. So, the curve of heat evolution of BP during hydration demonstrates completion of transformation of CaO in portlandite within the first 3 hours of hydration (fig. 5). The intensive formation of Friedel's salt passes during first 4-5 days of hydration [11]. It follows that in the system of complex salts $3CaO \cdot Al_2O_3 \cdot CaCl_2 \cdot 10H_2O$ and $3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot nH_2O$ an equilibrium displaces in towards the last complex salt. The high concentration SO_4^{2-} -ions determines formation of H_2S and, as a corollary, high intensity of carbonization of the system. Such evolution of hydration explains the slow formation of Friedel's salt at known priority of ions Cl^- before ions OH^- .

Figure 5. Integral heat-evolution during BP hydration

The results obtained are confirmed by XRD of the considered model system "BP - CAA". The analysis of kinetics of Friedel's salt formation in the system under the action carbonic acid and its lack is presented in fig. 6. So, let's accept the integral square of the defining reflex of Friedel's salt (area of the reflex angle 11°) after 28 d of hydrations as 100 %. In this case the intensity of Friedel's salt formation will be arranged in time as follows. The greatest intensity of Friedel's salt formation is fixed during first 48 h of a hydration as at absence of carbonic acid (fig. 6a) as well as under its influence (fig. 6b). However, despite an identical salt content that was formed in different conditions within the first 48 hours of hydration, its mass part in relation to the common content is various and depends on influence of carbonic acid on the system. So the mass part of Friedel's salt, which was formed during first 48 hours, makes 32 % in a system without the influence of carbonic acid and 67 % - in analog. This fact can be explained by considerable deceleration of formation of Friedel's salt under the influence of carbonic acid and is determined by intensive carbonization of the system in the presence of H_2S as catalyst. Thus the augmentation of Friedel's salt content in the system-analog (under influence of carbonic acid) up to 28 days of hydration is determined by presence of portlandite among hydrated products.

a) – without influence of carbonic acid

b) – under influence of carbonic acid

Figure 6. The Friedel's salt formation during 28 d of hydration in the model system «BP - CAA»

Thus, portlandite formation during the hydration of the model system «BP - CAA» and its transformation into calcite determines the intensity of Friedel's salt formation and the duration of the phase prior to the beginning its dissolution under the action of carbonic acid.

On the basis of the carried out research, the conclusion was made that the practical interest for usage as a binder for reinforced concretes has the system «BP - Slag - PC - CAA ». It was supposed that such a system could be characterized by a high degree of intense chemical binding of chlorine in Friedel's salt by pH-values (modifying function of CAA). And determine the absence of the corrosion process of reinforcement during carbonization – the function of alkalis that are formed from BP's salts according to equations (1) and (2) by high activity. (The combination of BP with modifier PC determines the mixed nature of activation of slag.)

3.6 Compounding decisions on BP's utilization in slag containing binders for reinforced concrete

By the method of experimental - statistical simulation of the dependence «composition - properties» the compositions of SABs (usable in reinforced concretes) was defined. This area is described by limits exhibited in tab. 3. The correspondence of SABs composition to indicated limits ensures its correspondence to the class on strength 42.5 (according to EN 197) and values Cl^-/OH^- in its pore solution in limits 0.6.

Table 3. The compounding of the binders for reinforced concretes

Components of the binder	Content, mass %
Slag	66 – 74
PC	26 – 34
BP	not more than 4.2
CAA	not more than 3.8

4. CONCLUSION

1. The investigation of slag-containing binders, which were projected as SABs, confirmed the complex activating influence of BP on hydration properties of blast granulated slag. It was established that slag-containing binders for both unreinforced and reinforced concretes can be obtained through BP usage as their component. The BP content in such binders is determined by degree of chlorine binding during hydration.
2. Slag containing-binders with high BP contents (17.5 %) and appropriate to the class on strength 32.5 (on EN 197) can be obtained if it is projected as SAB. The component ratio in this binder must meet the following requirement: the ratio between content of alkali metals oxides ($K_2O + Na_2O$) of BP and alumina content (Al_2O_3) of slag should correspond the inequality
$$\frac{K_2O + Na_2O}{Al_2O_3} \geq 1.$$
 Degree of chlorine binding (by criterion Cl^-/OH^-) in this binder predetermines its usage in unreinforced concretes.
3. The particular feature of BP utilization in slag-containing binders for reinforced concretes is the necessity of chlorine steady binding during hydration. For this purpose it was theoretically proved and experimentally confirmed the process of chlorine binding in slightly soluble Friedel's salt among other hydrate products of slag and containing BP. The stoichiometric calculation of the reaction of Friedel's salt formation confirms the necessity to preserve the equality $Cl/Al = 1$ in the binder. Based on data analysis about hydration activity of slag taking into account their chemical and phase structure, stoichiometry of Friedel's salt, the

compounding decisions on BP's utilization (up to 4.2 mass %) in slag-containing binders for reinforced concrete (by criterion Cl^-/OH^-) were proposed.

4. The supposition, that the process of chlorine binding during hydration of the binder system «BP - slag» is carried out both on chemical (primary), and on adsorptive (secondary) processes, was proved. The chemical binding of chlorine is caused by Friedel's salt formation, the adsorptive binding – by gel-like or submicrocrystalline calcium hydrosilicates. It was shown, that for such processes the investigated binder system should be modified by the following combination of additives:
- Calcium compounds (PC), which provide an increase in hydration activity of slag (as well as binding activity) due to calcium activation, as well as due to alkaline activation on the part of alkali which is formed by cation exchange between portlandite and alkali salts of BP;
 - Aluminate compounds (CAA), which provide intensive chlorine binding in Friedel's salt at the initial stage of hydration.

ABSTRACT

Calcium aluminate cements (CAC) are special cements that contain from about 40 to 80% alumina. Their wide range of composition and properties make them usable for a great number of applications. The most commonly used CAC's are those containing 40% Al_2O_3 . They are manufactured from natural raw materials by fusion and have complex phase compositions. This is due to the presence of elements other than Ca and Al in the clinker. The main impurities are Fe_2O_3 and SiO_2 . Smaller amounts of MgO and TiO_2 may also be found, depending on the raw materials used. Some of the iron is present as Fe^{2+} , as a result of a partially reducing atmosphere in the kiln. Recent applications of techniques such as X-ray quantification by the Rietveld method and TEM observations of the clinker have provided a better understanding of the mineralogy. This includes characterisation of a perovskite type phase, not previously identified because of its similarity (structure and composition) to brownmillerite. New SEM, TEM and Rietveld studies are presented in this paper. Comparisons of these analyses make it possible to obtain a new and coherent description of the mineralogical composition of this category calcium aluminate cements.

1. INTRODUCTION

Calcium aluminate cements (CAC) are a range of special cements. Their chemistry is quite different from Portland cements, in that the main reactive phases are calcium aluminates (CA , C_{12}A_7) rather than calcium silicates. For refractory concretes, they are produced with alumina contents ranging from 40 to 80%.

The principal applications of CACs are (a) in refractory concretes; (b) as a component, with Portland cement and other materials of mixed binder systems for special "building chemistry" mortars; and (c) to produce specialist CAC concretes with properties such as resistance to abrasion, chemical attack and rapid hardening.

The most commonly used CACs are those containing around 40% Al_2O_3 . These are manufactured from natural ores as raw materials – primarily bauxite and limestone. These raw materials are melted in a reverberatory kiln in a continuous process. The melt pours leaves the furnace by a tuyere and is cooled down in ingots. The use of natural ores means that elements other than Ca and Al are also present, which leads to a clinker with a complex mineralogical composition. The most important minor elements are Fe_2O_3 and SiO_2 . MgO and TiO_2 are also frequently found; their

amount depends upon the raw materials used. Some of the iron may be reduced to Fe^{2+} , according to the oxygen partial pressure in the kiln.

In all CACs, the principal phase is monocalcium aluminate CaAl_2O_4 (CA). The other calcium aluminate phase, present in much smaller amounts, is C_{12}A_7 . All the other phases present have very much lower reactivity. The silicates are mainly present in C_2S (belite) and /or C_2AS (gehlenite). The iron is mainly present as a ferrite solid solution, based on $\text{C}_2(\text{A},\text{F})$ and a perovskite solid solution. Small amounts of an iron rich spinel structure are usually present. Phases such as C_{12}A_7 , pleochroite and wüstite can also be found in small amounts.

All these phases show solid solution, which makes it difficult to develop any simple relation between chemistry and phase composition such as the Bogue equations for Portland cement. Attempts in this field are based on the subsolidus phase assemblage of simplified oxide system [1], which give only a partial description of the phase composition.

In order to control the phase composition of the product, it is then necessary to develop a method to measure the proportion of each phase. Quantitative X-ray diffraction analyses using the Rietveld method is the most accurate and efficient method, but an accurate crystallographic knowledge of the structure and composition of all the phases is needed to obtain reliable results.

In this paper, recent analyses carried out on the identification and quantification of phases of standard grade CACs are reported. Microstructural studies and chemical microanalyses by secondary (SEM) and transmission (TEM) electron microscope of clinker are shown and quantification by Rietveld analysis discussed. The use of this combination of techniques allows a coherent description of the mineralogy of these cements. In particular, it is shown that the regions previously identified just as “ferrite” contains one or both of a brownmillerite type phase and a perovskite type phase.

2. EXPERIMENTAL

The analyses reported in this study were carried out on a single calcium aluminate cement clinker. Its overall chemical composition is given in Table 1. For SEM characterisation, the samples were embedded in resin, polished, and coated with carbon. The polished sections were observed in the BSE mode on a JEOL 5800LV equipped with a PGT energy dispersive X-ray spectrometer (EDS) for chemical microanalyses. Microanalyses were done at 15 kV with a 1 nA current. For study by TEM, the samples were dry ground by the tripod polishing method. Ion milling was then used to reach electron transparency. The thin foil obtained was carbon coated on one side. Observations were done with a TOPCON OO2B TEM (200 KeV) equipped with a LaB_6 gun. Chemical analyses were performed with a TRACOR EDS equipment attached to the microscope. These two techniques for chemical microanalyses allow quantification of the oxide composition with oxygen calculated by assuming that the valence of each element is known. The oxidation state of iron was investigated by electron energy loss spectrometry (EELS), also available on the TEM. The methodology developed for the EELS study is described in detail in refs. 2 and 3.

Table 1. Chemical composition of the clinker investigated (wt%)

SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	TiO_2	Mn_2O_3	Cr_2O_3	K_2O	Na_2O	Others	l.o.i.	Total
4.6	38.5	16.2	36.8	0.7	1.8	0.8	0.1	<0.02	0.04	0.46	0.2	100.2

For the XRD analysis of calcium aluminate cements, described here, a Siemens diffractometer (Kristalloflex D5000) was used. This machine operates according to the Bragg-Brentano principle and uses $\text{CuK}\alpha$ -radiation. The $\text{K}\beta$ -radiation was eliminated by a Ni filter. The samples were X-

rayed in a range between 10° to 60° 2θ with a step width of 0.02° - 2θ . For quantification the Rietveld method was used [4,5,6]. The principal of the method is that the intensities calculated from the crystalline structures are fitted to the observed X-ray powder pattern by a least squares refinement. This is done by varying the parameters of the crystal structures and of the peak profiles to minimise the difference between observed and calculated powder patterns. Because the whole powder pattern is refined by the Rietveld method, problems of peak overlap are minimised and a very accurate quantitative analysis can be obtained. Quantitative Rietveld phase analysis of calcium aluminate cements is also described in ref. 7.

3. RESULTS

3.1 General description of the phase composition

A typical BSE SEM image of the CAC clinker is shown in Figure 1. The dark grey areas are CA (monocalcium aluminate). This is the first phase to crystallise from the melt and the areas are sections of dendritic crystals that are linked in three dimensions.

Between the CA regions, a number of other phases can be identified. In order of increasing brightness, these are: gehlenite, dicalcium silicate (belite), "ferrite" and spinel. The chemistry of these phases is discussed in the following sections. No distinct areas of $C_{12}A_7$ were observed in this sample by SEM. Although pleochroite was identified by X-ray diffraction, its low concentration and grey level close to CA made identification in the microstructure difficult, but it was observed in some areas. No other phases were identified, even at highest SEM magnification and the ferrite grains appear homogeneous.

Figure 1. BSE micrograph of a polished section of CAC clinker. A: CA; B: Ferrite; C: gehlenite; D: C_2S ; E: spinel. Pleochroite and $C_{12}A_7$ phases have too low concentration to be detected easily by SEM.

3.2 Calcium aluminates.

Fe^{3+} substitutes for Al^{3+} in monocalcium aluminate. The level of substitution measured by both TEM and SEM was 5 at%. This level of substitution does not change the crystal structure or lattice parameters, but does have an impact on the peak intensities in the diffraction pattern.

Detailed characterisation of $C_{12}A_7$ was not possible because of its small amount and crystal size. However, observations in the TEM indicated that both iron and to a lesser extent silicon, substitute for aluminium.

3.3 Ferrite phases

Until recently, the regions identified as ferrite were supposed to be monophasic, with the crystalline structure of brownmillerite Ca_2AlFeO_5 [7], which is a member of the solid solution $Ca_2(Fe_{1-x}Al_x)_2O_5$ where x ranges from 0 to about 0.7 [9,10]. This phase is known to contain impurities and some authors have suggested a correlated substitution of trivalent cations by $Mg^{2+}-(Si^{4+}+Ti^{4+})$ to ensure the charge balance of this phase in Portland cements [11,12]. In CACs fluctuation in the amount of these impurities had been observed but not explained. Jeanne [13] suggested the presence of two types of brownmillerite in CAC, with the composition of varying from grain to grain [14].

Studies using Rietveld analysis suggested the presence of a new phase not mentioned previously in CACs [15,16]. The structure of this phase was first proposed to be similar to that of merwinite C_3MS_2 , but with a different composition. It was not observed previously by XRD because of its similarity (structure and composition) to brownmillerite. However, even with the help of selective dissolution [17], it was not possible to characterise this phase in terms of its chemical composition, its precise structure or of its location in the microstructure.

TEM examination has allowed the resolution of this problem. It reveals that the “ferrite” regions can contain two phases: one phase has the structure of brownmillerite. TEM diffraction patterns suggest that the second is a perovskite-type phase. The ferrite regions can be monophasic regions of either the brownmillerite or the perovskite phase types or they can consist of fine lamellae of both phases as shown in Figure 2.

Figure 2. “Ferrite” observed by TEM. Area with lamellae, Brownmillerite layers of 40 nm separate Perovskite layers with 10-nm thickness.

The ferrite domains were analysed by both SEM and TEM, the (Fe+Al) versus (Ti+Si) content of these analyses are shown in Figure 3. This indicates that there is good agreement between the two

sets of analyses, although it is not possible to differentiate between the three types of assemblage in the SEM.

With TEM it is possible to verify the crystal structure associated with different compositions. At low titanium content, only brownmillerite is present. For intermediate Ti levels, perovskite appears in lamellae. For the highest Ti contents only perovskite is present. The levels of Si substitution tend to vary in the same way, but less consistently. This suggests that the presence of titanium, and maybe silicon, in solid solution stabilise the perovskite type phase.

Figure 3. Composition of “ferrite” regions, by SEM and TEM.

Similar layered microstructures have been already reported in previous studies on brownmillerite/perovskite or TiO_2 systems [18,19]. Although more investigations would be needed to confirm the mechanism, this structure probably results from the decomposition of a single high temperature phase into the two phases as described in ref. 19 for a series of perovskite related structures. The crystal structures of perovskite and brownmillerite are closely related. In perovskite, of ideal composition ABO_3 , layers of octahedra share corners. Brownmillerite, $\text{ABO}_{2.5}$ can be described on the basis of a perovskite structure where $1/6^{\text{th}}$ of the oxygen anion sites are vacant [19]. These vacancies are ordered in chains along the [101] direction of the perovskite lattice or [001] direction of the brownmillerite lattice. This leads to an arrangement made of successive layers of octahedra and tetrahedra (OTOT') along the [010] direction. Figure 4 shows this structural relationship in the plane of tetrahedra.

This transformation from the unique high temperature phase to the perovskite/brownmillerite lamellae mixture would in this hypothesis occur by an order/disorder transition of oxygen vacancies with an adjustment of their concentration. The latter would occur through solid state diffusion, which is possible only on a short scale, hence the fine lamellae. The presence of Ti^{4+} and Si^{4+} favour a lower content of oxygen vacancies and hence the perovskite type structure. It is also found that both phases are non-stoichiometric in oxygen; the perovskite having a deficit and the brownmillerite an excess.

Figure 4. Illustration of the structural relation between perovskite and brownmillerite (simplified)

3.4 Silicates

TEM analyses of dicalcium silicate indicate a low level of substitution of silicon by aluminium and iron. No other impurities were detected in this phase. Analyses in the SEM indicate higher levels of Al and Fe. This difference results from a matrix effect for the SEM analyses, where the interaction volume of the electron beam is broader and the analyses include contributions from the adjacent phases.

Gehlenite and pleochroite are the two other silicates present in CAC. TEM studies on synthetic samples [20,21] indicate that these two phases show intergrowth on the nanometric scale (similar to the biphasic areas of brownmillerite and perovskite). This explains why it was difficult to identify these two phases unambiguously in the SEM microstructure. SEM microanalyses of gehlenite regions gave more trivalent cations than expected from the ideal composition ($[A+F]/S \sim 1.5$ instead of 1). This is consistent with previous studies [22,23], which suggested that the phase in CAC is actually a solid solution between C_2AS - CA_2 - C_5A_3 , with complex crystallographic site exchange. In this study, no detailed observations of gehlenite and pleochroite were made in the TEM.

Pleochroite (sometimes referred to as Q phase or fibres) is generally accepted to form when there is some reduction of the iron in the melt, from Fe^{3+} to Fe^{2+} . Its crystallographic structure is similar to the quaternary phase $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$ [23]. The SEM measurements performed in this work give an average formula computed for 68 oxygen atoms of $\text{Ca}_{19.6}\text{Al}_{23.6}\text{Fe}_{4.0}\text{Mg}_{0.6}\text{Si}_{2.6}\text{O}_{68}$. This is close to the composition established by Sourie *et al.* [21], except for MgO that was absent in the composition studied by these authors. However, the MgO measured in the present investigation is lower than that reported in other studies [14]. This element does not appear as a major constituent of pleochroite. The substitution mechanism that leads to the chemical composition and structure of pleochroite in Fondu from the parent quaternary phase has not been completely solved.

3.5 Minor phases

The only other phase found in this clinker had a spinel structure, AB_2O_4 . This phase contains most of the MgO present in the clinker as there is very low substitution of this oxide in pleochroite or in any of the other phases. The chemical analyses indicate a solid solution between two spinel type compositions: MgAl_2O_4 and $(\text{Ca}, \text{Fe}^{2+})/\text{Fe}^{3+}_2\text{O}_4$. The $\text{Fe}^{2+}/\Sigma\text{Fe}$ ratio of 0.3 estimated by EELS in the TEM is consistent with this interpretation. The Mg/Al and $(\text{Fe}^{2+}+\text{Ca}^{2+})/\text{Fe}^{3+}$ ratios are close to the theoretical value 1/2. There is also a low level of manganese in the structure which could correspond to a third spinel: $\text{Mn}^{2+}\text{Mn}^{3+}_2\text{O}_4$. SEM Microanalyses (as well as TEM [2]) carried out on the spinel grains show a strong correlation between (Mg+Al) and (Ca+Fe+Mn) content, which further strengthens the idea of a ternary solid solution.

No other phases were found in the clinker studied here. It has been suggested that magnesio-wüstite ($\text{Mg}, \text{Fe}^{2+})\text{O}$) can occur in this type of cement. The iron-containing phases present will depend on the degree of reduction of Fe^{3+} to Fe^{2+} , which in turn depends on the clinkering atmosphere. In the pure iron - oxygen system, one moves from Fe_2O_3 , through Fe_3O_4 , FeO and finally Fe as the oxygen partial pressure is reduced. This is shown schematically in Figure 5. In the more complex system found in CAC clinker, this sequence is replaced by overlapping zones of brownmillerite, perovskite, pleochroite, spinel, Mg-wüstite. In extreme conditions even Fe-metal could be formed.

Figure 5. Sequences of Fe-compound as a function of the clinkering condition. Estimation of the stability domains of CAC iron containing phases with respect to the Fe-compounds.

3.6 Quantitative XRD-analysis

The clarification of the phases present in CAC and of their chemical composition makes it possible to further improve the phase quantification by Rietveld analysis. The suggested phase composition of the CAC clinker examined here is CA, C_{12}A_7 , gehlenite, pleochroite, dicalcium silicate, spinel, brownmillerite and the perovskite type phase. The quantification of a cement of similar composition is shown in Figure 6.

Figure 6. Quantitative Rietveld phase analysis of a standard grade CAC

To test the precision of the Rietveld method for such cement compositions, mixtures of defined amounts of synthetic produced phases $CA_{0.95}F_{0.05}$, $C_2A_{0.9}F_{0.1}S$, $C_4A_{0.5}F_{1.23}T_{0.54}$, CT, $MA_{0.15}F_{0.85}$, CaO, $C_{20}A_{13}M_3S_3O_{68}$, and $C_{12}A_7$ were made. This phase composition of the mixture was close to that of the cements. The samples were prepared and X-rayed ten times. The actual weight of the phases, calculated average amounts and the standard deviations are given in Table 2:

Table 2. Quantitative Rietveld phase analysis of a defined mixture of the synthetic phases $CA_{0.95}F_{0.05}$, $C_2A_{0.9}F_{0.1}S$, $C_4A_{0.5}F_{1.23}T_{0.54}$, CT, $MA_{0.15}F_{0.85}$, CaO, $C_{20}A_{13}M_3S_3O_{68}$, and $C_{12}A_7$. (wt.-%)

Phases	Weight in	Calculated composition (average)	Standard deviation
$CA_{0.95}F_{0.05}$	62.2	63.4	± 0.3
$C_2A_{0.9}F_{0.1}S$	3.2	3.0	± 0.2
$C_4A_{0.5}F_{1.23}T_{0.54}$	16.2	16.6	± 0.3
$MA_{0.15}F_{0.85}$	4.8	3.9	± 0.1
CaO	1.5	1.7	± 0.2
CT	7.0	6.7	± 0.2
$C_{20}A_{13}M_3S_3$	3.4	3.2	± 0.1
$C_{12}A_7$	1.7	1.5	± 0.1

A comparison of the oxide composition calculated from the Rietveld phase analysis with that measured directly by XRF for the same sample is shown in Figure 7. There is a generally good agreement between the results. XRD and Rietveld analysis can be done very quickly and is adaptable for routine use.

Figure 6. Comparison of the Rietveld analysis with chemical analysis

4. CONCLUSIONS

The low alumina CAC studied in this work contains eight phases. CA is the predominant compound. Its proportion, as measured by Rietveld, is around 55%. The other phases present in significant amounts (about 10%) are the two phases that are included in the domain previously assigned to ferrites. The first is the traditional brownmillerite, while the second could be called ferro-perovskite as it has a perovskite type crystalline structure and has a chemical composition close to the brownmillerite. Cross analyses by TEM and SEM observations, and X-ray diffraction have allowed identification of this latter phase. With the development of the Rietveld method for the analysis of clinkers, the detailed knowledge of this phase is of considerable importance.

This phase is unlikely to have an impact on the hydraulic activity of low alumina CAC clinkers. The iron-bearing phase shows negligible reactivity in these systems at early ages. Besides these main phases, $C_{12}A_7$, gehlenite, pleochroite, dicalcium silicate and spinel have been characterised. The improved knowledge of phase composition and element partition contributes to the understanding of the relationship between chemical composition and mineralogy and to the optimisation of CAC's of this type.

ABSTRACT

White cements with reduced contents of tricalcium aluminate were obtained. The raw mixtures for obtaining of such cement had a high saturation factor and silica modulus, as well as a small content of a clay constituent, that made them to be difficultly sintered. For intensification of processes of mineral formation high-activity silica constituent was added to a raw mixture, that allowed to reduce temperature of a burning of white clinker. The content of tricalcium aluminate (C_3A) in experimental clinker was reduced to 3 - 9 %, against 13-15 % in ordinary white clinker.

The cements with the reduced content of C_3A had high hydration activity, stability to effects of aggressive media and good frost resistance.

1. INTRODUCTION

White Portland cement (WPC) is a material with high operation properties, based on which it is possible to obtain coloured cements and concretes simulating a natural rock as well [1]. Despite its high aesthetic and construction-technical properties, a white Portland cement has a low resistance to corrosion, that does not allow it to be utilized widely in building and reduces its potential market ability.

One of the factors determining a low corrosion resistance of white cement, is the higher content in it of tricalcium aluminate. At the hydration of Portland cement, the interaction of C_3A with water results in cement paste containing large quantities of metastable calcium hydroaluminates along with ettringite. Further they chemically react with anions of SO_4^{2-} , existing in corrosive media, with the formation of additional amounts of ettringite late in the hydration, that results in destruction of cement paste and decrease of its strength [2]. Thus, one way to increase the corrosion resistance of white Portland cement is to decrease the content of tri-calcium aluminate in it.

2. EXPERIMENTAL

For analysis of impact of the content of C_3A on properties of white Portland cement, clinkers were produced, having the following parameters: the values of lime saturation factor (L.S.R.) was varied from 0.90 up to 0.94, and the content of tricalcium aluminate from 3 up to 9 % (Table 1).

To obtain white Portland cement clinker the most pure raw materials were utilized with minimum amounts of painting oxides: white limestone, clay, sand. The content of the clay component in the raw mixture was reduced.

As the raw mixture for production of WPC is difficultly sintered because of high indexes of L.S.R., silica modulus (SR), alumina modulus (AR) and a small content of Fe_2O_3 , the temperature of a burning of white Portland cement clinker is usually 1500-1550 °C. For mineralization of a raw mixture and the decrease of temperature of a burning a part of sand was substituted by a waste of chemical production – silica gel.

Table 1. Modulus and mineralogical composition of studied clinkers

No	Modulus at L.S.R. = 0.92		Calculated mineral content, mass., %				Factual* mineral content, mass., %			
	SM	AM	C ₃ S	C ₂ S	C ₃ A	C ₄ AF	C ₃ S	C ₂ S	C ₃ A	C ₄ AF
1	12.93	2.71	75.7	18.2	3.0	1.6	78.0	18.0	4.0	---

4	5.40	5.57	70.5	16.9	9.0	2.1	77.0	14.0	10	---

* Factual mineral content was determined by quantitative XRD

Silica gel represents an amorphous high dispersive silica, in which there are also impurities of alkaline and earth alkaline oxides and fluorides. The presence of impurities, amorphism of structure of silica gel make it a highly reactivity raw material having mineralization action. For intensification of a sintering process a highly reactivity additive of silica gel instead of a part of sand was injected into a raw mixture. The ratio of silica gel to sand (sg/s) was varied from 0 up to 1,0 in raw mixture. It was supposed, that the usage of silica gel would allow to decrease the viscosity of a clinker melt and intensify process of clinker formation.

Clinker were synthesized in a laboratory furnace at 1450 °C.

Temperature of decarbonization of CaCO_3 increased by 20-30 °C as the content of clay in a raw mixture decreased. On the other hand introducing of silica gel in a raw mixture resulted in a decrease of temperature of decarbonization of CaCO_3 and formation of C_2S and C_3S by 20-30 °C. The change of temperature of decarbonization was fixed by DTA of raw mixes.

The resultant fluid phase at sintering of white clinker is mainly represented by a highly aluminate melt. The increase of a clay component in a raw mixture leads to an increase of amount of a fluid phase when clinker burning and, as a consequence, an increase in its shrinkage. When silica gel is added, shrinkage of clinker increases by 2-4 % on the average (Table 2).

Table 2. Clinker shrinkage at sintering of raw mixture

Parameters of raw mixture C ₃ A-L.S.R. - sg/s	Shrinkage*, %			Parameters of raw mixture C ₃ A-L.S.R. - sg/s	Shrinkage*, %		
	Burning temperature, °C				Burning temperature, °C		
	1400	1450	1500		1400	1450	1500
3-0.9 0-0.0	6.3	7.1	7.9	9-0.90-0.00	11.5	13.0	13.6
3-0.90-0.25	6.5	8.2	8.3	9-0.90-0.25	12.6	14.6	14.9
3-0.90-0.50	8.7	9.0	9.3	9-0.90-0.50	13.6	15.5	15.7
3-0.92-0.00	6.6	9.3	9.9	9-0.92-0.00	14.5	17.0	17.8
3-0.92-0.25	7.1	10.8	11.3	9-0.92-0.25	17.1	18.8	19.3
3-0.92-0.50	9.3	11.8	12.3	9-0.92-0.50	18.8	21.0	23.1

* Shrinkage of samples was determined by the measuring of sample sizes before their sintering and after that. Then the results were calculated in %.

As amount of a clinker melt increases the processes of dissolution CaO and C_2S , defining a rate of alite formation, are speeded up. When a ratio of sg/s in a raw mixture was increased from 0 up to 0.5 content CaO_{free} was reduced from 7.2 up to 2.0 % in clinkers with 3 % C_3A and from 3.3 up to 1.2 % in clinkers consisted of 9 % C_3A . When L.S.R. of raw mixtures and amount of alitee in clinker was increased the role of the additive of silica gel raised (Figure 1).

Figure 1. Content of CaO_{free} in clinkers ($T_{\text{burning}} = 1450^\circ\text{C}$).

S.F. – sg/s: 1 - 0.90-0.5; 2 - 0.92-0.5; 3 - 0.90 - 0.25; 4 - 0.92-0.25; 5 - 0.90-0; 6 - 0.92-0.

Thus, in a raw mixture with the reduced content of a clay component, the addition of silica gel has led to more complete binding of lime. Such intensifying action of silica gel is associated with its high activity and presence in it of fluorine-containing compounds, which influence the properties of a clinker melt in turn, namely, reducing its viscosity, and decreasing temperature of decarbonization of limestone and alite formation.

The analysis of a microstructure of clinkers has shown that with increase of the ratio of silica gel to sand in a raw mixture structure sealing of clinker takes place. The porosity of clinker is reduced. The main clinker minerals have an indistinct crystallization, the amount of larger intergrown pieces of alite crystals (Figure 2) is raised.

Figure 2. The microstructure of white clinker obtained with the additive of silica gel . The content of C_3A is equal to 9 % (a) and 3 % (b). Magnification $1000\times$.

Grindability of experimental clinker consisted of C_3A equal to 9 % and ordinary clinker which had a C_3A content of 13 % were determined. Grindability was assessed by the residue on an $80\ \mu\text{m}$

sieve and by specific surface area (s.s.a.). The experimental clinker with the smaller content of C_3A is more easily ground than the ordinary one. It is explained by the fact that at a burning of a raw mixture with the small content of a clay component an amount of a forming clinker melt is less than for burning of ordinary raw mixture. The experimental clinker contains a smaller amount of glass phase, which is more difficult to grind. Its structure is more porous and friable. Besides, the minerals of clinker obtained in the presence of fluorine-containing additive, have defect structure and is more easy to grind (Figure 3).

Figure 3. Grinding of white clinkers: ordinary one (1) and clinker with reduced content of C_3A (2).

The study of impact of C_3A on construction-technical properties of white cement was carried out on cements obtained by joint grinding of laboratory synthesized clinkers with the addition of gypsum (2 % by SO_3) up to specific surface area equal to 340-380 m^2/kg .

The various content of C_3A did not render appreciable impact on normal consistency and setting time of investigated cements. The normal consistency was varied in the range from 28 to 29 %, and setting time in the order: a beginning - 45 - 60 min., end – 1 h 45 min. – 2 h 10 min (Table 3).

Table 3. Construction-technical properties of cements

The content of C_3A , %	S.s.a., m^2/kg	W/C, %	Setting time, min		Compressive strength*, MPa			
			beginning	end	3 days	7 days	14 days	28 days
3	380	28	60	130	51	57	59	60
5	355	28	55	120	57	62	66	69
7	350	29	50	112	61	64	73	75
9	342	29	45	105	69	72	77	79
14 (ordinary cement)	340	29	35	90	48	51	57	67

* strength of cement paste samples (without sand)

It is well known that the rate of hydration of cements depends both on alite and tri-calcium aluminate contents. The introduction of the additive of silica gel in a raw mixture while obtaining of white clinker influenced its hydration activity as well. The extent of a hydration of cements with C_3A equal to 9 % obtained without the addition of silica gel and with the substitution of a part of sand by silica gel, for 3 days of hardening was increased from 40 up to 53 %, and for 28 days - from 63 up to 69 %, accordingly. It is caused by greater imperfection of the crystalline structure of clinker and its minerals obtained with the additive of silica gel. Under a decrease of the content of C_3A up to 3 % the extent of a hydration of cement was increased and has comprised 64 and 78 % at 3 and 28 days of hardening, respectively.

As the content of C_3A in white cement increased from 3 up to 9 % its strength increased by 25 % on the average. When further increase of the content of C_3A took place the strength of cement has decreased.

It is well known that one of the reasons for a low stability to corrosion of cements is the higher content of calcium aluminates in them. Stability of cements to aggressive media and frost resistance were instituted on samples from paste previously hardening during 14 days in aerial - wet conditions.

As aggressive media 1 - 5 % solutions of $MgSO_4$, Na_2SO_4 and seawater were chosen, as they render most strong corrosive attack on cement paste.

Strength of cement, stored in aggressive media, was reduced as concentration of solution and content of C_3A in cement increase. So for cement with the content of C_3A equal to 3 % the decrease of strength concerning the standard samples has comprised - 6 % after 60 days of hardening in seawater, in solution of Na_2SO_4 - 11 % and in solution of $MgSO_4$ - 18 %. The cements with the contents of C_3A equal to 9 % at storage in aggressive media have lowered strength by 10, 15 and 21 %, accordingly. The extent of affecting of aggressive media was increased for white cement in an orderly sequence: seawater - Na_2SO_4 - $MgSO_4$.

The white cements are more subject to corrosion in environment of $MgSO_4$, because under its effect a breaking down occurs of hydroaluminates and calcium hydrosilicates as well.

The frost resistance of white cements with the various contents of C_3A was determined. The trials were conducted in rigorously controlled conditions on samples based on cement paste without sealing. After 35 cycles of freeze-thawing samples of ordinary white cement (14 % C_3A) were completely destroyed. Samples with the content of C_3A equal to 3 and 9 % after 60 cycles of freeze-thawing did not change their strength in comparison with standard samples. The reason of low frost resistance of cements with higher contents C_3A is the additional ettringite formation late in the hydration. Products of hydration of tricalcium aluminate are ettringite, monohydrosulphoaluminate and hydroaluminates of calcium. As composition of a fluid phase varies at hardening of cement ettringite partially transfers in calcium monohydrosulphoaluminate of calcium. The gypsum formed at transferring of the trisulphate calcium hydrosulphoaluminate in the monosulphate form, interacts with hydroaluminates of calcium, resulting in destruction of cement paste.

Based on laboratory studies the batch of white cement (L.S.R. 0.91; C_3A 5 %) was produced in an industrial kiln. Production of white cement with lower content of C_3A has allowed to diminish the consumption of a clay component in 1,8-2,0 times. Despite of high silica modulus of a raw mixture the formed clinker was well sintered and had not the high content CaO_{free} (0,5-1,5 %). Consumption of fuel rate has decreased. The clinker was more easily ground, raising the output of the grinding mills. The activity of experimental clinker was by 2-4 MPa above.

The experimental white cement with reduced content of C_3A was tested in concretes. Based on the given cement it is possible to obtain vibrocompressed and heavy-weight concretes of classes B 30 - B 45, having the type of frost resistance no less than F 200.

3. CONCLUSION

By the reduction of the clay content and the use of the high dispersed silica component instead of part of the sand in raw mix, it is possible to produce a white highly active cement. Because its corrosion and frost resistance also increases, the potential areas of application for this cement becomes far wider.

ABSTRACT

As already determined, manufacture of high sulfate resistant well cement with stable plugging qualities will need cement clinker based on raw material containing appropriate quantities of crystal silicon dioxide SiO_2 . Such raw mixtures have high reacting capacity in comparison with mixtures based on pure or high siliceous limestone and allow the production of high quality well cement.

1. INTRODUCTION

Manufacturing of high sulfate resistant well cement is complicated not only because of strict requirements regarding the chemical and mineralogical composition of the cement, but also because of the necessity to ensure that the compound exhibits of its physical and mechanical qualities – the so called plugging qualities.

According to API Spec 10A (ISO 10426-1) the content of C_3A in high sulfate resistant well cement should not exceed 3 mass. %, C_3S content should not be less than 48 and not more than 65 mass. % and the sum of minerals $2\text{C}_3\text{A} + \text{C}_4\text{AF}$ not more than 24 mass. %. Such cement can be produced only when limestone (used as raw material), has the desirable SiO_2 content or a special correcting component with a high level of silicon dioxide added. The difference in reacting capacity of raw materials composed of components of a different nature, influence the qualities of clinker greatly and thus the qualities of the oil well cement produced.

2. EXPERIMENTAL

To manufacture well cement clinker, three raw mixes were taken with close modulus characteristics: saturation coefficient 1.01, alumina ratio p 0.70 and silica ratio n 2.02-2.05.

The raw mix 1 has been prepared on the basis of pure limestone (SiO_2 content in the limestone 0.89 mass. %) and of large quantity (~ 9 %) of correcting component - siliceous schist with SiO_2 content of 86.54 mass. %. Raw mix 2 has been prepared on the basis of limestone with moderate SiO_2 content (4.28 mass. %) and small quantity (~ 2.6 %) of correcting component. Raw mix 3 has been fully composed on the basis of limestone with high SiO_2 content (12.47 mass. %).

All the raw mixes were ground under the same conditions, then burned at the temperature of 1420°C for 5, 10, 15, 20 and 30 minutes. In the burned mixes measures were taken of the general level of calcium oxide assimilation α_1 , as well as the level of CaO assimilation during the formation of calcium silicates $\text{C}_2\text{S} + \text{C}_3\text{S}$ α_2 and separately the same of the mineral C_3S α_3 . The computation was done using the formulas:

$$\alpha_1 = 1 - \frac{C_{free\tau}}{C_{total}} \quad (1)$$

$$\alpha_2 = 1 - \frac{C_{free\tau}}{C_{total} - (1,65A + 0,35F)} \quad (2)$$

$$\alpha_3 = 1 - \frac{C_{free\tau}}{C_{total} - (1,87S + 1,65A + 0,35F)} \quad (3)$$

where C_{total} , S , A and F - content of corresponding oxides in the composition of the raw mix (calculated as ignited matter), and $C_{free\tau}$ - content of free calcium oxide in the mix at the moment τ .

The computation of the clinker formation process was made following the Erofeev-Kolmogorov equation:

$$\alpha_i = 1 - \exp(-k \cdot \tau^n) \quad (4)$$

where k - constant of chemical reaction rate, min^{-1} , τ - isothermal burning time, min, and n - the constant showing the stage limiting the process rate: when $n > 1$ the limiting stage is chemical reaction rate, when $n < 0,5$ - diffusion rate, and when $0,5 < n < 1$ the clinker formation process is going in the transition tract.

3. RESULTS AND DISCUSSION

The results of computation of k and n parameters of reaction kinetics equations are presented in Table 1.

Table 1. Kinetics process equation parameters

Process	Raw mix	k, min^{-1}	n
General reaction	1	0,407	0,530
	2	0,525	0,536
	3	0,472	0,530
$\text{C}_2\text{S} + \text{C}_3\text{S}$ Formation	1	0,3165	0,562
	2	0,4382	0,577
	3	0,4012	0,550
C_3S Formation	1	0,00015	2,534
	2	0,00329	1,909
	3	0,00018	2,692

In accordance with the results obtained, the raw mixes can be ranged in the following order according to their reacting capacity:

$$\text{Raw mix 2} > \text{Raw mix 3} > \text{Raw mix 1}$$

The meaning of the n parameter shows that the general clinker formation process and the process of calcium silicate synthesis $\text{C}_2\text{S} + \text{C}_3\text{S}$ are taking place in the transition area and the rate of the process of mineral C_3S synthesis is limited by the rate of the chemical reaction. At the same time the higher n_1 and n_3 meanings in comparison with the parameter n_2 point to the lower reacting capacity of the chemical reaction components, depending on the presence in the mixes 1 and 3 of considerable

amount of a crystalline silicon dioxide. This conclusion is confirmed by the results of X-ray and differential-thermal analysis, as well as by the results of particle size distribution of the initial raw mixes studies: the presence in the mixes 1 and 3 of high quantity particles measuring 180-240 micrometers, points to the presence of difficult to crush crystalline quartz particles.

The clinker produced by burning of raw mix 2 is characterized by more profoundly completed clinkergenerating process. Its content of C_3S mineral determined by X-ray quantity method corresponds to estimated values, though in the mixes 1 and 3 it is 2 - 3% lower than estimated.

There were marked visible differences in the microstructure of the clinkers. Crystallization of the principal clinker minerals in the clinker based on mix 2 is more distinct, though in the clinkers based on mixes 1 and 3 there are wide agglomerations of badly formed belite crystals and alite crystals often having defective forms.

To determine the influence of reacting capacity of the raw mix on the quality of clinker and well cements of G and H classes it was necessary to previously determine the meanings of the cement parameters - specific surface and SO_3 content, under which the requirements of technical specifications of API Spec 10A for these cements are met.

With this in mind, 25 cements manufactured with the above clinkers were ground in a laboratory mill to the specific surface of 270 - 410 m^2/kg and SO_3 quantity of 1.6-3,2 mass. %. For all cements thus manufactured, the set of plugging qualities has been determined with water contents of 44 % (class G cement) and 38 % (class H cement).

Using the results received from the binary diagram - specific surface / SO_3 content - there have been traced the lines of qualities corresponding to requirements specified by API Spec 10A - Figure 1(a) and 1(b):

- free fluid content - maximum 5.5 ml;
- consistency 15 - 30 minutes after stirring period - maximum 30 B_c (Bearden units consistency);
- thickening time to 100 B_c - minimum 90 and maximum 120 min.;
- compressive strength after 8 hours of hardening at 38 $^{\circ}C$ (R_{38}) - minimum 2.1 MPa and 60 $^{\circ}C$ (R_{60}) - minimum 10.3 MPa.

The areas where at least one of the specification requirements were not met have been colored gray. It is seen that for class G cement - Figure 1(a), to ensure free fluid capacity of less than 5.5 ml, the cement specific surface must be more than 330 - 360 m^2/kg depending on SO_3 content. The upper acceptable value of the cement specific surface is limited by starting thickening time, and the maximum acceptable SO_3 content - by starting consistency of the cement paste.

For class H cement, as shown in Figure 1(b), the area of acceptable values is limited by free fluid lines (shown in the lower left and the upper right parts of the diagram), the critical thickening time (shown in the lower left part), as well as the starting consistency (shown in the upper left part). With low cement specific surface, which limits the content of SO_3 for this cement, is the standard specification.

The clear part of the diagram shows the sphere of specific surface values and SO_3 content under which this clinker can be used to manufacture the cement corresponding to all the requirements specified by the standard. In the central part of the diagram the spheres of acceptable parameters are marked where the risk to break at least one of the specified requirements has been reduced to a minimum.

(a)

(b)

Figure 1. Areas of acceptable parameters corresponding to requirements specified by API Spec 10A for high sulfate-resistant well cements: (a) Class G; (b) Class H

For class G cements the center of the areas of acceptable parameters will have a specific surface value of 370 m²/kg and SO₃ content 2.36 mass %. The same acceptable parameters for class H cements will have corresponding specific surface values of 310 m²/kg and SO₃ 2.55 mass %.

The limits obtained for cement dispersion and gypsum content have been used in further research on raw materials' reaction capacities to influence cement qualities.

The qualities of high sulfate resistant oil well cements of G and H classes according to API Spec 10A manufactured from clinkers based on raw mixtures 1, 2 and 3 are presented on Table 2.

Table 2. Cements plugging qualities

Clinker based on raw mix No	Specific surface, m ² /kg	SO ₃ , mass. %	Free fluid, ml.	Consistency after 15-30 min. stirring period, Bc	Time before consistency 100 Bc, min.	Compressive strength, MPa, 8 hours curing time	
						At 38 °C	At 60 °C
Well cement, Class G							
1	373	2,38	3,2	17	105	2,4	11,8
2	375	2,36	2,9	21	100	3,4	14,2
3	371	2,39	2,9	18	100	2,9	13,6
Well cement, Class H							
1	312	2,54	3,3	24	95	3,1	13,7
2	311	2,51	2,8	26	105	3,8	15,4
3	308	2,56	2,9	26	115	3,3	12,6

It is evident that, other things being equal, the cements manufactured from clinker based on raw mix 2 have the highest compressive strength after 8 hours of hardening under the fixed curing temperature. Further research showed that cements based on this raw mixture exhibit more stable plugging qualities that change little during 3 months of cement storage in appropriate packaging.

4. CONCLUSIONS

Raw mix components' reaction capacity influences not only the kinetics of the clinker generating process, but also the quality of manufactured cements. For the production of high sulfate resistant well cements showing stable plugging qualities, it is necessary to use the raw mixtures composed of the components which allow (within the fixed chemical composition), the content of crystalline silica in the raw mix to be minimized.

ABSTRACT

In this paper the results of the formation and stability of hydrated phases in the hardened sulphoaluminate cement (SAC) are presented.

The study of the influence of carbonation on the calcium hydrosulphoaluminates shows that AFt is stable in some aggressive mediums. AFm under carbonation is decomposed and ettringite is formed instead of calcium monosulphate.

Influence of carbonate and hydro carbonate ions on crystallization of AFt and AFm is investigated. It is established that at the first stage carbonate phases are crystallized. When all carbonate ions are bonded into hydro carbonate phases and carbonate ions are absent in the liquid phase, ettringite is formed. Similar processes take place in the case of prepared liquid phase to obtain AFm. Instead, ettringite is crystallized.

1. INTRODUCTION

The formation and stability of hydrated phases under the effect of CO₂ and hydro carbonate or carbonate ions in the pores is the actual problem. It is known that carbon dioxide in air or dissolved in water reacts with hydrated phases of cement [1,2]. Ca(OH)₂ is more exposed to carbonation than the other phases. According to thermodynamic calculation [3] the reaction of calcium hydroxide and carbon dioxide leads to the formation of CaCO₃ and the equilibrium pressure of CO₂ is lower than the partial pressure of CO₂ in air. To indicate a stability of AFt and AFm hydration of calcium sulphoaluminate in the presence of carbon dioxide and carbon ions was studied. Their influence on the formed crystals of AFt and AFm was also investigated.

2. MATERIALS

According to methods [4] C₄A₃ \bar{S} , hydrated AFt and AFm were prepared for the study. Chemical compositions of the samples are presented in Table 1.

Table 1. Chemical composition of initial materials (%)

Sample	CaO	Al ₂ O ₃	SO ₃	Ig.loss
C ₄ A ₃ S	36.55	50.32	13.08	0.20
C ₃ A3CSH31 (AFt)	27.2	8.2	19.4	45.2
C ₃ ACSH ₁₂ (AFm)	36.1	16.1	12.9	34.9

To study hydration and carbonation, the following methods were used: XRD, IRS, SEM and chemical analysis.

3. EXPERIMENTS AND DISCUSSION

3.1 Thermodynamic analyses of reaction under carbonation

At the first stage of the investigation, the thermodynamic calculation of the probability of interaction of ettringite and calcium monosulphate with carbonate ions was undertaken. Calculations were carried out by the methods described by Babuschkin V.I., Matveev G.M., and Mtchedlov-Petrosian O.P. [3]. According to thermodynamic analysis, calcium monosulphate in the presence of HCO_3^- and CO_2 can be decomposed. In this case the hydrated products are formed as follow as: CAH_{10} , CaSO_4 , CaCO_3 , calcium hydrocarboaluminate (CHCA) and gibbsite $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$ (Table 2).

Table 2. Results of thermodynamic calculation of the reaction of carbonation

№	Scheme of reaction	ΔG_{298}^0 , kJ/mol
1	$\text{C}_3\text{ACS}_3\text{H}_{31} + \text{CO}_2 \rightarrow \text{C}_3\text{ACaCO}_3\text{H}_{11} + \text{C}_2\text{AH}_8 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$	-23,3
2	$\text{C}_3\text{ACS}_3\text{H}_{31} + \text{CO}_2 \rightarrow \text{CAH}_{10} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{CaCO}_3 + \text{Al}(\text{OH})_3$	+14,5
3	$\text{C}_3\text{ACS}_3\text{H}_{31} + \text{HCO}_3^- \rightarrow \text{C}_3\text{ACaCO}_3\text{H}_{11} + \text{C}_2\text{AH}_8 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$	-15,8
4	$\text{C}_3\text{ACS}_3\text{H}_{31} + \text{HCO}_3^- \rightarrow \text{CAH}_{10} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{CaCO}_3 + \text{Al}(\text{OH})_3$	-3,9
5	$\text{C}_3\text{ACSH}_{12} + \text{CO}_2 \rightarrow \text{C}_3\text{ACaCO}_3\text{H}_{11} + \text{C}_2\text{AH}_8 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$	-140,47
6	$\text{C}_3\text{ACSH}_{12} + \text{CO}_2 \rightarrow \text{CAH}_{10} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{CaCO}_3 + \text{Al}(\text{OH})_3$	-339,3
7	$\text{C}_3\text{ACSH}_{12} + \text{HCO}_3^- \rightarrow \text{C}_3\text{ACaCO}_3\text{H}_{11} + \text{C}_2\text{AH}_8 + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{Ca}(\text{OH})_2 + \text{H}_2\text{O}$	-412,17
8	$\text{C}_3\text{ACSH}_{12} + \text{HCO}_3^- \rightarrow \text{CAH}_{10} + \text{CaSO}_4 \cdot 2\text{H}_2\text{O} + \text{CaCO}_3 + \text{Al}(\text{OH})_3$	-11,2

Table 2 data shows that AFt under carbonation is stable (reaction No.2 has $\Delta G = +14,5$ kJ/mol) and there is thermodynamic probability of the decomposition of AFm (reaction No.6 has $\Delta G = -339,3$ kJ/mol). Reaction takes place at the pressure of CO_2 lower the partial atmospheric pressure that it is need to the beginning of reaction. As thermodynamic calculation shows the probability of reaction only, therefore the experiments of carbonation influence on AFt and AFm were carried out.

3.2 Experimental data on the influence of carbonation on Aft and Afm phases

AFt and AFm were stored in the air for one year. The changes of hydrates were studied by IR-spectroscopy (IRS). Infrared absorption spectra of AFm show strong bands at 1420 and 1480 cm^{-1} due to CO_2 after 9 month of the storage of samples. But, AFt spectra are characterized by weak peaks in abovementioned regions only after one year storage (Figure1).

AFt under water consisting of hydrocarbonate and carbonate ions is stable for 6 months. At the further period crystal edges begin to alter due to the extraction of calcium and aluminium ions

into liquid phase. Up to 9 month the partial crystal destruction is observed. Colourless hexagonal plates with the refractive indices $n_o = 1.554$ and $n_e = 1.538$ are appeared. After one year storage of AFt crystals in water saturated by carbon dioxide calcium carboaluminate $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCO}_3 \cdot 12\text{H}_2\text{O}$ and a small amount of gibbsite are fixed by XRD (Figure 2).

AFm – phase is less stable to the exposure of hydrocarbonate and carbonate ions. Even in one month of exposure the sample begins to disintegrate. This process is accompanied by the formation of calcium hydro carbonate, gibbsite, calcium aluminates and calcium sulphate. After 3 months of exposure, AFm is destroyed completely and ettringite is crystallized (Figure 3).

Figure 1. Infrared spectra of the prepared AFt (a), AFm(c) and after their storage during: AFt – 1 year (b), AFm – 9 month (d)

Figure 2. XRD powder diffraction (Cu Kα) of AFt before (1) and after carbonation (2)

• - $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$

Figure 3. XRD powder diffraction (Cu K α) of AFm before (1) and after carbonation (2)

Symbol: \square – $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot 3\text{CaSO}_4 \cdot 31\text{H}_2\text{O}$

Δ - $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCO}_3 \cdot 12\text{H}_2\text{O}$

\bullet - $\text{Al}_2\text{O}_3 \cdot \text{H}_2\text{O}$

Recrystallization of AFm into AFt leads to the destruction of the samples due to their difference in sizes and the morphology of crystals.

It was noticed that crystallization of AFt and AFm from a solution saturated by HCO_3^- -ions is difficult because Al-ions form gel of $\text{Al}(\text{OH})_3$ and Ca-ions form CaCO_3 . In the presence of hydrocarbonate the pH of liquid phase reduces from 12 to 10.9. As a result, there are calcium hydroaluminates and gypsum in the solid phase. When CaCO_3 precipitates from the solution completely, calcium hydroaluminates react with gypsum, producing ettringite. The same process takes place at the study of AFm – phase.

For the investigation of hydration of calcium sulphotoaluminate (CSA) suspensions were prepared. Mineral \ water ratio was equal 1:50. Suspensions were mixed during 24 h. After that CO_2 was passed through part of suspensions, and the other part of suspensions was used as the control.

At the first stage calcium sulphotoaluminate reacts with water and is dissolved. The concentration of SO_4^{2-} reduces rapidly in the liquid phase and after 24 h it equals 38 mg/l. The $\text{CaO}/\text{Al}_2\text{O}_3$ ratio is equal to 1 and concentrations of Ca-ions and Al-ions reduce quickly (Figure 4). In the samples of suspensions consisting of CO_2 concentration of Ca-ions and Al-ions reduces rapidly and $\text{C}/\text{A}=2$.

Concentration of SO_4^{2-} is changed very little during 6 h (Figure 5). Gibbsite, calcium carbonate and calcium hydrocarboaluminate are fixed in solid phase.

In the presence of CO_2 hydration of calcium sulphotoaluminate is reacting intensively. Ettringite is fixed by XR-analyses on peaks with $d=0.971, 0.557, 0.494, 0.254$ nm (Figure). It is noted that ettringite peaks are more intensive in the control samples (Figure 7).

The reduction of amounts of Ca-ions in the liquid phase consisting of CO_2 during 6-18 h is the result of its ability to transform into CaCO_3 and $\text{Ca}(\text{HCO}_3)_2$ which are fixed by XRD on peaks with $d=0.303, 0.206, 0.187$ nm (CaCO_3) and $d=0.433, 0.284, 0.248$ nm ($\text{Ca}(\text{HCO}_3)_2$).

Figure 4. Chemical composition of liquid phase at hydration of calcium sulphoaluminate

Figure 5. Chemical composition of liquid phase at hydration of calcium sulphoaluminate in the presence of CO₂

Figure 6. XRD powder diffraction (Cu K α) $C_4A_3\bar{S}$ hydrated in CO₂ medium (1) and in water (2)

Figure 7. Change of intensity of peaks of calcium sulfoaluminate hydrated in CO_2 medium and in water

Infrared spectra show the bands in regions 1420 and 1480 cm^{-1} due to CO_2 (Figure 8). Liquid phase at hydration of calcium sulfoaluminate in the presence of CO_2 has a small amount of Al-ions because calcium carboaluminates are formed. The final products are: carboaluminate, gibbsite and calcium carbonate. Calcium carbonate can react with sulphate-ions and form ettringite in the late period.

Figure 8. IR-spectra C_4A_3S hydrated in CO_2 medium

4. CONCLUSION

Exclusion of the influence of CO_2 at hydration of calcium sulfoaluminate leads to ettringite formation. In the presence of CO_2 the formation of calcium carboaluminate inhibits the growth of ettringite. After AFt phase formation hydrocarbonate and CO_2 do not influence the stability of ettringite.

ABSTRACT

The use of plasticisers and accelerators with Portland Cement is now well established enabling the production of extremely workable mixes with significantly reduced water contents.

With reference to alumina cements, the use of such admixtures is seldom described. Previous studies on alumina cement with plasticisers have shown the tendency for unacceptable set retardation. It was noted that the use of accelerators increases the water/ cement ratio that was responsible for the loss of strength of alumina cement mixes.

This paper describes the influence of superplasticisers and accelerators and their mixes on the hydration of alumina cements, their properties at usual temperatures, hardening and also as refractory cements.

1. INTRODUCTION

Calcium alumina cement was found to have excellent resistance to many forms of chemical attack and to set normally but to harden rapidly. Its strength at 24 h equals to that of Portland cement in 28 days. This cement is used in a wide range of general and specialized applications [1,2,3]. It is suitable for use at low temperatures for winter construction in cold climates or for repairs in cold stores. Calcium alumina cement is especially useful to make castables having applications in the steel and heat-using industries. However, the strength of this cement can be reduced due to conversion of $C_2AH_8 \rightarrow C_3AH_6$. Conversion and its practical implications have been widely studied but not always well-understood [4,5]. In our research we studied the influence of some admixtures on conversion and the properties of calcium alumina cement.

2. EXPERIMENTAL AND DISCUSSION

For the study the materials used were follows as:

- alumina cement with the bulk composition (weight %): $Al_2O_3=52.4$, $SiO_2=7.5$, $CaO=38.0$, $Fe_2O_3=0.4$, $R_2O=0.2$, $TiO_2=1.0$. The mineralogical composition of alumina cement was calcium monoaluminate (CA), gellenite (C_2AS) and small quantity of aluminoferrite phase.
- accelerator - LiOH
- plasticiser - sulphonated naphtalene formaldehyde condensate

The first step of the study was the influence of LiOH on the properties of the cement. It was shown that it accelerated the setting and thus decreased the rate of hydration. When 0.2% LiOH was added to alumina cement, an exothermal effect was detected immediately and cement paste became so thick, that it was not possible to mix cement with water. The optimal addition of LiOH to cement is 0.05 - 0.1 %. (This is shown in Table 1).

Table 1. Influence of LiOH on the properties of alumina cement

Quantity of LiOH, %	W/C	Setting time (minutes)		Compressive strength, MPa, after hardening during hours		
		initial	final	2	6	24
0	0.35	55	120	—*	—*	25
0.05	0.35	23	50	3.2	25	38
0.1	0.35	12	20	4.5	30	40
0.5	0.35	8	10	5.5	23	30
1.0	0.35	2	5	5.0	12	20

* — means the samples had no strength.

In spite of high heat evolution of hydrated cement paste, the cubic form C_3AH_6 was not formed. Among the hydrated products CAH_{10} , C_2AH_8 and $Al(OH)_3$ were detected. X-ray pattern showed the peaks of 0.524, 0.349, 0.287 nm (C_2AH_8), and 0.141, 0.356, 0.255 nm (CAH_{10}). Besides them the diffraction peaks $LiH(AlO_2)_2 \cdot 5H_2O$ (0.534nm) were registered. In the authors' opinion this compound increases the hydration rate and hardening of alumina cement. In the presence of LiOH the strength of cement is high, even after 6 hours hardened cement paste reached 25-30 MPa. Alumina cement without the addition of LiOH has such strength only after 24 hours of hardening. But when LiOH was added to alumina cement in quantities of 0.5% and more, the strength of the cement paste became less than with the addition of 0.1% LiOH in the cement. It was explained by very high thickening process of cement paste with high qualities of LiOH. It was not possible to mix cement with water and the prepared samples had high porosity. That is why the rate of hydration of cement, samples showed low strength due to their porosity.

It is known that the addition of superplasticizers to Portland cement produces extremely workable mixes of cement with water. In our paper we tried to investigate the influence of superplasticizer (sulphonated naphthalene formaldehyde condensate).

It is fact, the addition of superplasticiser to alumina cement made setting time lower but improved flowability of cement paste but the setting time of cement paste became longer in comparison the setting time of cement without superplasticizer. The duration of improved workability is dependent on temperature (Table 2).

Table 2. The influence of superplasticizer on setting time and compressive strength of alumina cement paste

Quantity of superplasticizer, %	Final setting time (minutes) and hardened temperature, °C			Compressive strength, MPa, after 24 h hardening at 20°C
	20	30	40	
0	120	65	30	25
0.3	140	85	50	24
0.6	220	135	100	15
1.0	300	175	135	8

The addition of LiOH and Plasticiser simultaneously allowed us to increase the water/cement ratio up to 0.3, to reach the high strength of cement paste at early ages as well as at 28 days of hardening without its decrease (Table 3).

Table 3. The properties of alumina cement as a function of quantity of complex additives

Additives,% LiOH Superplasticizer		W/C	Porosity, cm ³ /g	Setting time (min) initial final		Compressive strength, MPa, after hardening for 2 h 6h 28 days		
–	–	0.35	0.0510	50	120	–	–	42.5
–	0.3	0.32	0.0480	70	140	–	–	46.0
–	0.5	0.30	0.0460	102	220	–	3.6	48.5
0.5	0.3	0.30	0.0024	20	45	10	20.5	52.8

The reason for this phenomenon is the formation of hexagonal hydrates of calcium aluminate that did not recrystallize into cubic C₃AH₆.

A very important property of alumina cement is its suitability for refractory applications. The study of cement paste after thermal heating at 200, 400, 600, 800, 1000, 1200°C showed that the addition of the above mentioned admixtures have improved all refractory properties of the cement paste: strength after heating, pore structure, microstructure of cement stone, heat resistance, contact zone formation.

3. CONCLUSION

It was established that the use of accelerators and plasticizers as the admixtures with alumina cements is useful in both the ordinary applications and to make refractory castables.

ABSTRACT

Usually expansive cements are manufactured from sulphoaluminate clinker or mix aluminate clinker with calcium sulphates (gypsum, hemihydrate, anhydrate). For these cements ettringite is an important hydration product and reaction kinetics of this phase plays an important role in determining performance. The alternative aluminate phases may be ferrite-containing ones.

This paper deals with the composition and properties of solid solution calcium sulphoaluminate, sulphoferrite and sulphoaluminoferrite cements. The influence of calcium sulphate on structure and properties of calcium aluminate and ferrite phases, and their stability under high temperatures was studied. In addition, the properties of cements containing these phases were studied.

The investigation of hydration and properties of sulphomineral cements shows that ettringite and its analogies are formed thus providing expansion and compression of cement stone. The degree of expansion and self-stressing of cement stone depends not only on the composition of sulphated minerals but also on the ratio and types of clinkers. Higher expansion is achieved by the use of high alite containing Portland cement clinker together with sulphoaluminate or sulphoaluminoferrite and lower expansion is found by addition of sulphoaluminoferrite and sulphoferrite clinkers. These cements are classified as selfstressing, expansive or shrinkage-compensating cements depending on the degree of expansion after 28 days of curing.

1. INTRODUCTION

The chemistry of expansive cements was comprehensively discussed at the previous congresses and in many research publications [1,2,3,4,5]. The majority of practical expansive cements have depended on the modification of a Portland cement in such a way as to increase the formation of ettringite. Single expansive cement clinkers are made and they are blended or interground with a normal Portland cement or clinker. In widely used terminology, expansive cements based on Portland cement and calcium sulphate are categorized as types K, M or S, according to the source of additional Al_2O_3 that is required. Usually cement K is produced by intergrinding Portland cement clinker, gypsum and clinker consisting of $\text{C}_4\text{A}_3\bar{\text{S}}$. Type M cements contain Portland cement, a high alumina (CA) cement and additional calcium sulphate. Type S cements are Portland cements high in C_3A and with suitable contents of calcium sulphate.

The proportions of expansive clinker and of gypsum added to the Portland cement depend on composition of the expansive clinker and the degree of expansion required. Depending on the degree of expansion all these cements can be made as shrinkage-compensated, expansive [6] or self-stressing cements. It should be noted that there are some problems in production and

application of the above mentioned cements. For example, Type S cements have found little favour as they too difficult to control. To produce cement of Type M calcium aluminate cements are heeded, but it is too costly for wide application. The composition of expansive clinker can be varied considerably by the use of raw materials most economically available.

2. MATERIALS AND METHODS

Calcium sulphoaluminate (CSA) and calcium sulffoferrite (CSF) were synthesized previously. To examine the solubility of ferric oxides in CSA ferric oxides an amount of 1 to 15 % by mass was added. The mix of CSA and ferrite oxide had been held for 20 minutes at 1350⁰C and then the samples were analyzed by XRA and optical microscopy.

Minerals were blended to investigate the solid solutions of CSA and CSF. The ratio in all the experiments ranges from 25 to 75 %. The prepared mixes were pressured in the form of briquettes and fired at temperatures of 1050 - 1300⁰C for 20 minutes each. The obtained cakes were subjected to XRA and optical microscopical analyses.

Calcium sulphoferrites were obtained by the burning of raw mixes intended for the production of calcium aluminoferrates with composition of C₆AF₂, C₄AF, C₆A₂F with the addition of calcium sulphate and a blend of calcium aluminoferrites having been synthesized beforehand with anhydrite, as well as by the crystallization of sulphated aluminoferrite melts.

The expansive clinkers obtained were used to produce expansive cements by intergrinding with Portland cement and gypsum. Cements were tested according to Standard methods.

3. RESULTS OF EXPERIMENTS

To study the solubility of ferrite oxides in CSA the samples were analyzed after sintering at 1350⁰C. XR-analysis has revealed that the addition of Fe₂O₃ caused a shift in the major diffraction peaks of C₄A₃ \bar{S} , this being more evident as Fe₂O₃ levels increase (Table 1). The IRE-spectra data show a shift and spreading of the band referring to the various oscillations of the SO₄²⁻ group in the original C₄A₃ \bar{S} (absorption bands 1093 and 1180 cm⁻¹) which is due to a change in the coordination environment of that group as a result of the incorporation of ferrite oxides whose presence is evidenced by the emergence of absorption bands in the region of 400 to 500 cm⁻¹.

Table 1. XRD of calcium sulphoaluminate with addition of Fe₂O₃

Sample	Position of the major diffraction peaks (hkl)		
	422	444	822
Without addition	3.750	2.650	2.166
1% Fe ₂ O ₃	3.748	2.644	2.163
3% Fe ₂ O ₃	3.745	2.641	2.161
5% Fe ₂ O ₃	3.740	2.636	2.158
7% Fe ₂ O ₃	3.733	2.630	2.156
9% Fe ₂ O ₃	3.729	2.575	2.138

Such changes in spectra of calcium sulphoaluminate occur when up to 9% ferrite oxides are added, but when the iron content is greater than 9% the formation of aluminoferrite phase was observed. The structure of calcium sulphoaluminate can comprise up to 9% Fe₂O₃, the principal pattern of its crystall lattice remaining unchanged.

The study of the hydration of modified $C_4A_3\bar{S}$ in micropreparations has demonstrated that the oxides available in the calcium sulphoaluminate structure retards the hydration reaction. $C_4A_3\bar{S}$ reacts with water during the first minutes of being mixed with water, whereas the start of the hydration of modified $C_4A_3\bar{S}$ is shifted by one hour in proportion to the amount of Fe_2O_3 addition. By the end of the first day, however, the quantity of ettringite is equal to its amount at hydration of the initial calcium sulphoaluminate. The study of powders, consisting of preliminary synthesized minerals (C_4A_3S , C_2F and $CaSO_4$) shows that there is an exchange of aluminate and ferrite oxides between minerals and they are stable under heating up to $1350^{\circ}C$. The following increase of temperature causes the decomposition of calcium sulphoaluminate find melt appearance which solves the formed earlier phases. During melt cooling calcium aluminoferrites with varying composition are formed. They consist of sulphates. It has been found that minerals burned together changed their colour, while XR-spectra feature a shift of major diffraction peaks of the minerals compared with their initial matrixes, i.e. an exchange of aluminium and iron ions takes place between the minerals.

XR-spectra microanalysis of the samples shows that calcium sulphoaluminate has Fe_2O_3 in its structure and calcium ferrite has aluminium oxide (Table 2).

Table 2. Composition of calcium sulphoaluminate and sulphoferrite

Compound	Content of oxides, % y mass			
	CaO	Al_2O_3	Fe_2O_3	SO_3
$C_4A_3\bar{S}$	35.69	47.69	3.12	13.76
$C_4A_3\bar{S}$	34.26	46.28	5.24	12.20
$C_4A_3\bar{S}$	36.39	43.15	7.28	13.45
$C_2FC\bar{S}$	44.82	3.76	46.09	4.98
$C_2FC\bar{S}$	43.58	1.89	48.67	6.01
$C_2FC\bar{S}$	42.42	4.41	47.42	5.94

The results of burning calcium aluminoferrites C_6A_2F , C_4AF , C_6AF_2 together with calcium sulphate testify to the fact that there occurs a location of the latter with aluminoferrite, for the XRD analysis does not indicate the formation of the other compounds.

The general aspect of the radiographs of calcium aluminoferrites and sulphoferrites remains almost unchanged. It indicates the fact that the major pattern of the crystalline structure is preserved. In all cases, however, calcium sulphoaluminoferrites differ from calcium aluminoferrites in the intensity of the characteristic diffraction peaks and the shift of interplanar spacings is caused by a distortion of the crystal lattice of calcium aluminoferrites by calcium sulphates (Table 3).

The investigation of calcium sulphoalumoferrite crystallization from the melt shows that the composition of crystals emerging depends on the cooling rate. It has been established that in the case of a rapid cooling of the melt the crystals are enriched in aluminium to a greater extent than is the case for solidified melt. In the case of slow cooling the composition of the crystallising phase is identical with that of the melt.

Calcium aluminoferrites modified by calcium sulphate differ both in the composition and hydraulic activity. It is to be noted that the degree of hydration increased with the increase of the A\F ratio in calcium sulphoaluminoferrite.

Using these data, three clinkers were produced at an experimental plant. Chemical composition of these clinkers is given in Table 4.

Backscattered electron (BE) imaging and X-ray microanalysis are very useful in examining the microstructure of polished clinker sections. Clinker phase identification from SEM images is made on the basis of phase brightness, grain morphology, and grain association via the BE image, and chemical composition by qualitative and quantitative EDS analysis.

Table 3.XRD characteristics of aluminoferrites and sulphoaluminoferrites

Compounds	Position of peaks (hkl)		
	200	141	202

Table 4.Chemical composition of clinkers, in weight percent

Clinker Index	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	R ₂ O
CSF	11.14	3.93	32.64	41.70	2.08	7.53	0.13
CSAF	16.60	9.88	13.02	53.15	1.61	4.27	0.16
CSA	10.36	28.6	3.46	43.75	2.03	6.94	0.30

CSF is sulphoferrite clinker, CSAF - sulphoaluminoferrite clinker, CSA - sulphoaluminate clinker.

Clinker CSF exhibits a fine - grained microstructure composed of dicalcium silicate and a matrix of calcium ferrites. Two calcium ferrite phases appear in the BE images, the first is bright and massive and the second ferrite is calcium, iron and SO₃-rich and Al-poor (Fig.1a).

Clinker CSAF is a medium -grained clinker with subhedral alite, well-rounded belite, blocky ferrite matrix. Brightness of the ferrite phase varies within this clinker and the bright ferrite will be referred to as ferrite-1, and the darker designated sulphoaluminoferrite (ferrite-2). Ferrite-1 is higher in iron, and ferrite-2 higher in aluminum and SO₃ (Fig.1b).

Clinker CSA consists of belite and aluminate matrix. Spot EDS analyses indicate that parts of grain have aluminate, and others are aluminium and SO₃ in a similar manner to the clinker (Fig.1b).

Figure 1. Microstructure of clinker CSF (a), CSAF (b), CSA (c)

All clinkers were used as an addition to Portland cement clinker. All components were ground to a fineness of 4000 cm² /g.

The investigation of hydration and properties of sulphomineral cements shows that ettringite and its analogies are formed thus providing expansion and compression of cement stone. The degree of expansion and self-stressing of cement stone depends not only on the composition of sulphated minerals but on the ratio and types of clinkers. Higher expansion is achieved by using high-alite Portland cement clinker together with sulphoaluminate clinker (Table 5). Lower expansion is found with addition of sulphoaluminoferrite and sulphoferrite clinkers. Thus cements are classified as expansive with expansion of 0.1 to 0.4% and strength of 57 to 62 MPa after 28 days of curing.

Table 5. Results of tests of expansive cements

Type of clinker as additive to OPC	Strength, MPa		Expansion, %		Self-stressing, Mpa	
	1 day	28 days	2 days	28 days	1 day	28 days
CSF	15	57	0.04	0.1	0.5	1.5
CASF	16.2	58	0.1	0.2	0.6	2.1
CSA	18	62	0.1	0.4	1.0	3.2

Corrosion resistance is of inverse relationship: sulphoferrite cements are more resistant to attack of aggressive media. These cements are suitable for obtaining waterproof, crack-resistant and corrosion-resistant concretes.

4. CONCLUSION

A new type of clinker was obtained consisting of sulphoferrite, sulphoaluminoferrite phases and dicalcium silicate. These clinkers are used for the production of expansive cements.

ABSTRACT

The formation of alite phase, micro- and macrostructure of clinker pellets runs at occurrence of a steady melt in system, the nature of these processes is instituted by quantity, composition and constitution of clinker fluid. The catalytic influence on the process of alite formation is affected by melts with lower viscosity and high surface energy. The formation of melts with high fluidity in clinker grain can be carried out at the expense of variation of the acid-base equal balance between the various coordination molding boxes of aluminum and iron in the direction of increasing of a part of a fraction of octahedral cations and by making halogen-containing regions of liquation, which activate dissolution of CaO. The all-up influence of elements, achieved by applying of various wastes, is more effective than operating of individual compounds. Optimization of structure of compositions allows to reach considerable catalyzed effect and to obtain alite clinkers at 1350°C. The inhibition sulphate-alkaline or activating of a halogen-containing liquation in clinker melt is one of the effective paths of optimization of clinker structure and improvement in quality of Portland cement.

1. INTRODUCTION

The formation of clinker pellets, their phase composition, micro- and macrostructure is a multiphase process including both aggregation at a stage of liquid-phase sintering and staircase reactions of clinker formation causing variation of morphology, modification, type and quantity of defects in the mineral structure. The mechanism and kinetics of these processes in many respects depend on composition and properties of a clinker melt.

In plant clinkers regions of nonuniform distribution of minerals and distinctions in their microstructure are practically always observed [1]. It is explained by chemical heterogeneity of an initial raw mixture. Regions of a crystallization of a C₂S solid phase, being in equilibrium with a fluid phase, are separated from fields of a CaO crystallization by regions containing alite in a melt. Immediately during a burning such factors, influencing on heterogeneity of composition and structure of clinker, as occurrence in an oxide melt of microbulks of sulphate-alkaline or halogen-containing composition can appear [2]. It is owing to recycling of material streams in a kiln, especially of dry method one, or due to fuel ash additive, agglomeration of particles of burnt material present in a melt [3], fluctuation of heat rate of a material and burning temperature [4,5].

Liquation phenomena are well enough studied in acidic silicate melts and glasses [6-14]. They are explained by the ability for cations to associate with the complex groups. Weakly polarizing cations (K⁺, Na⁺, etc.) are concentrated in the tetrahedrons [AlO₄] and they form [AlO₄]R⁺ or [AlO₄]R²⁺. The stronger cations (Mg²⁺) are close to oxygen ions of tetrahedrons [SiO₄]⁴⁻. Moreover Al₂O₃ can form with SiO₂ heteropolyacids (AlSiO₄⁻, AlSi₂O₆⁻, AlSi₃O₈⁻) which associate with cations of the

strong bases thus promoting the association of less basicity cations with silica-oxygen anions [10,11].

At the liquation, the melt consists of two liquid phase: high silicate and high calcium melts which have different structure and properties. Aluminate complexes are dissolved in the high-calcium and strongly depolymerized phase thus increasing its polymerization and making its properties close to the high silicate one. As a result the mutual solubility of two phases increases but liquation temperature decreases. The solubility rises with the decrease of the bond force Al-O what is observed when field force of compensated cation in aluminate complexes $[\text{AlO}_4]\text{R}^+$ and $[\text{AlO}_4]\text{R}^{2+}$ increased [10].

The liquation region of the binary and the ternary silicate systems increases with the growth of the cation force field but the complex ability for the homogenization decreases as follows: $[\text{AlO}_4]\text{K} \rightarrow [\text{AlO}_4]\text{Na} \rightarrow [\text{AlO}_4]\text{Ca} \rightarrow [\text{AlO}_4]\text{Mg}$ [10]. Similarly the mean size of a disperse phase decreases at the expense of dominance of the entropic factor and the width of the region of a metastable liquation is narrowed. The addition of the third component (oxide) to binary liquation melts results in its distribution between coexisted phases. In the presence of oxide, containing a weaker cation, liquation phenomena are loosened in melts, having a stronger cation.

Anion solubility in silicate melts depends on the structure and basicity of the system. It decreases in number as follows [12]: $\text{BO}_4^{5-} \rightarrow \text{PO}_4^{3-} \rightarrow \text{SO}_4^{2-} \rightarrow \text{F}^- \rightarrow \text{Cl}^- \rightarrow \text{OH}^- \rightarrow \text{CO}_3^{2-}$. Tetrahedron groupings (BO_4 , PO_4 , SO_4) are characterized by higher solubility than trigonal ones. When the basicity of liquid phase increases the anion solubility rises.

The considered rules of liquation phenomena take place in clinker melts as well though their high basicity promotes the different anomalies. These data were obtained by our research.

2. EXPERIMENTAL

2.1 Materials and methods

To study the influence of microelements (alkaline- and halogen contained additives) on the properties of eutectic oxide melt forming in the burning row mixes at 1338°C we prepared a raw mix, with composition as follows: $\text{CaO} = 54,8\%$; $\text{SiO}_2 = 6,0\%$; $\text{Al}_2\text{O}_3 = 22,7\%$; $\text{Fe}_2\text{O}_3 = 16,5\%$. By heating the above mentioned mix to 1500°C , we obtained “oxide melt”.

“Oxide melt” is high basicity melt in system C-A-F-S. At 1338°C it consists of (weight %): $\text{CaO} = 54,8$; $\text{SiO}_2 = 6,0$; $\text{Al}_2\text{O}_3 = 22,7$; $\text{Fe}_2\text{O}_3 = 16,5$. With further increase of temperature melt the saturated by calcium, silicon, aluminum, iron oxides and at 1450°C , the melt consists of $\text{CaO} = 57\%$; $\text{SiO}_2 = 7,5\%$; $\text{Al}_2\text{O}_3 = 22,6\%$; $\text{Fe}_2\text{O}_3 = 12,9\%$. When salt agents are added into the melt, they dissolve in melt matrix. When concentrations of salt agents are more than their solubility in the melt matrix, salt melt is displaced from oxide melt matrix and oxide-salt melt is formed.

In our research “salt melts” were obtained by agitation of the above mentioned raw mix with eutectic salt mixes (CaF_2 , CaSO_4 , Na_2SO_4 , K_2SO_4 , CaCl_2 , BaCl_2 , MgCl_2 , $\text{Ca}_3(\text{PO}_4)_2$, etc.) or oxides (MgO , Mn_2O_3 , R_2O , etc.). All mixes were heated to 1500°C and after homogenization they were quenched.

The Immiscibility of oxide and salt melts, and the formation of calcium silicates in oxide melt were studied by SEM, IRS, XRD, DTA and chemical analysis. Solubility of CaO , SiO_2 , Al_2O_3 and Fe_2O_3 in salt melts was determined by the method of isothermic saturation of liquid phase with corresponding oxides.

Viscosity was determined by rotary electroviscosimeter EVI-70PM. The surface tension of the melt was determined by the gas-bubble technique, density was determined by hydrostatic weighing.

For the preparation of the model system CaO and β -C₂S were used. Their synthesis was made by two-multiple sintering at 1450°C and 1800°C over two hours.

3. DISCUSSION

In our study it was determined that depending on the nature and concentration of impurities in a clinker grain the oxide or oxide-salt melts are formed, the properties which one are instituted by a proportion of elements in local volume of a reshaped clinker pellet. The occurrence of a salt component conditions liquation phenomena, and the propensity to segregation of melts increases with growth of acidity of p-elements and with growth of basicity of s-elements. It correlates well with the value of their interphase surface energy.

The appearance of the salt liquation region melt was detected in the high basicity oxide under the combined influence of SO_4^{2-} , Na^+ , K^+ . When sulphate content is equal to 0.5-0.8%, mass., sulphates dissolve completely in oxide melt. When this melt quenched the fairly homogeneous glass phase is formed. Micro liquation is observed when the R_2SO_4 content is equal to 1% and more (Figure 1). It was determined that there is a correlation between width of a liquation region and the parameters of cations, from which it is possible to determine ionic potential, force of the field of the cation or its electronegativity. Potassium sulphate melt has a lower surface energy than a melt with Na^+ . Thus at the expense of dominance of entropy from $\text{Na} \rightarrow \text{K}$ the mean size of particles will be decreased and the width of the field of a metastable liquation will be narrowed. If for a melt containing 1%, mass, of K_2SO_4 , the size of liquation drops is equal $(0.6-1.3) \cdot 10^3 \text{ \AA}$, to a melt containing 1%, mass., of Na_2SO_4 , the mean size of drops comprises $(1-3) \cdot 10^3 \text{ \AA}$. When the K_2SO_4 content increases up to 2% by weight it is observed that individual drops are merged and they form a net structure. When concentration of the salt phase exceeds 3% the matrix of the oxide salt melt is not able to hold large regions of salt melt together. They start to move towards the surface layer (micro liquation transfers to macro liquation) (Figure 1 a,b). Taking into account, that in a sintering grain 25-30 %, mass. of a melt is formed, the micro liquation arises at the content of alkaline sulphates in clinker equal to 0.5-0.6 %, mass., and with growth of their quantity, macro liquation regions arise.

In terms of obtaining quality clinker (a good aggregation of a material in a sintering zone and a stable operation of a rotary kiln) macro liquation phenomena are undesirable for forming during phase separation melt drops, having sulphate-alkaline composition which are characterized by low values of a surface tension. It assists in the formation of dust-like clinker grains during aggregation of a sintering powder that leads to impairment of kiln operation and decrease of clinker activity.

Liquation phenomena may be considerably depressed by the introduction of a third component (MgO, for example) into liquating sulphate-alkaline melts. In this case it is distributed throughout coexisting phases. As a result of increasing surface energy of an oxide melt, solubility of alkaline sulphates rises. The structure and properties of clinker melt in the presence of both individual (MgO, Mn_2O_3) and complex ($\text{R}_2\text{O-MgO-SO}_3$, $\text{Mn}_2\text{O}_3\text{-TiO}_2\text{-SO}_3$, $\text{R}_2\text{SO}_4\text{-MgO-Mn}_2\text{O}_3$, $\text{TiO}_2\text{-Fe}_2\text{SO}_4\text{-MgO}$) compounds were studied.

Liquation phenomena in halogen-containing melts are observed at a lower concentration of anions than in sulphate melts. It is attributable to the theory of screening, according to which degree of screening of cations increases with an increase of anion polarization. Since F^- ions have a lower value of polarization (0.96 \AA^3) than oxygen ions (2.74 \AA^3), it is completely displaced from a coordination sphere of complex formation (Si, Al, Fe) into a coordination sphere required to screen cations Ca^{2+} and especially Na^+ and K^+ that defines differentiation of a composition of a liquid

phase. At concentration of F^- up to 0.7%, mass., it is dissolved completely in an oxide melt. Subsequent increasing of its content, liquation regions occur with dimension $(2-3) \cdot 10^3$ Å in size (Figure 1 c). Cl^- ions are characterized by higher polarization than F^- ions. That is the reason that a degree of screening increases in their presence and a micro liquation occurs at higher concentration of Cl^- (2-3%, mass.). It is accompanied by formation of liquation regions of smaller dimension. In the presence of alkaline cations liquation is observed at a lower concentration (0.3-0.5%, mass.) of halogen ions in a melt.

At halogen inducing along with sulphates microliquation occurs at lower absolute concentration of p-elements with formation of regions with larger sizes (Figure 1 d). With substitution of $CaCl_2$ by $CaSO_4$ in fluorine-containing melt the size of liquation regions increases from $(0.5-1.0) \cdot 10^3$ Å up to $(6-12) \cdot 10^3$ Å. For halogen-containing melts, immiscibility phenomena are shown even in the absence of alkaline cations, and at a complex salt inducing their concentration reduces by about a factor of two. It results in the occurrence of salt melts. That is the reason that at the total content in a sintering clinker equal to 0.3-0.5%, mass., of compounds of fluorine, sulfur and chlorine in combination with R^+ microliquation regions should be expected in an oxide melt, which influences the mechanism and kinetics of alite formation.

Figure 1. Microstructure of clinker glasses, modified by (% mass):
a – 1.0 Na_2SO_4 ; b – 4.2 Na_2SO_4 ; c – 1.0 F^- ; d – 1.0 $CaF_2 + CaSO_4$
magnification of $6000 \times$

In systems of $R_2O-CaSO_4-MgO$, $CaCl_2-CaSO_4$, CaF_2-CaSO_4 the formed composite oxide-salt melts are characterized by 2-4 times (Table 1) the lower viscosity (η) and lower surface tension (σ) in than oxide melts formed in the C-A-F-S system. That is the reason that their function in a mineral formation cannot be ignored. So, for the combination of $CaCl_2-CaO$ the salt melt viscosity decreases in the range $(2.5-5) \cdot 10^{-3}$ Pa·s with the temperature rise in the range from 900 to 1100 °C, and the surface tension is not practically changed and it is equal to 0.14-0.15 N/m. The melt structure consists of Ca^{2+} and $CaCl^+$ cations, and $[Ca_{(4-x)}O_x]^{2-}$ anions. The volume of microspaces increases in 5-10 times in the salt melts in comparison with the oxide melts and therefore the viscosity mechanism changes. The fluidity of the salt melt and the fluidity of the structure formed ions increase.

The solubility of salt melts in the oxide one does not exceed 3-5% at 1450 °C, but at the bigger concentration micro-and macroliquation appears. When temperature falls down the solubility is reduced that promotes the separation of eutectic melt, containing below 1% of the salts, at slow cooling. The liquated salt melts dissolve 8-16 % of calcium oxide, below 3% of Al_2O_3 , SiO_2 and Fe_2O_3 . The solubility of oxides (especially CaO) is changed considerably depending on temperature as is the composition of the liquated phase. In the salt melts based on R_2SO_4 , 5.9-

5.95% of CaO, 1.3-1.4% of SiO₂, but Al₂O₃ and Fe₂O₃ are insoluble practically. In the melts based on Na₂SO₄ - K₂SO₄ - MgSO₄, Na₂SO₄·3 MgSO₄, K₂SO₄·2MgSO₄, the concentration of CaO comprises 13.49 - 13.78%, the content of SiO₂ increases from 1.93 to 2.31 %, the solubility Al₂O₃ and Fe₂O₃ is in the range 0.19 - 1.09%. So, if in salt melt of potassium sulphate there are 5.9% of CaO; 1.30% of SiO₂; 0.08% of Al₂O₃; 1.09% of Fe₂O₃, then in the eutectic melt of K₂SO₄·2MgSO₄ there are 13.98% of CaO; 2.28% of SiO₂; 0.98% of Al₂O₃; 1.09% of Fe₂O₃%. High solubility of CaO in sulphate - magnesium melts is caused by the formation of intermediate complexes of K₂SO₄·CaSO₄ - MgSO₄, K₂SO₄·2CaSO₄.

Table 1. Properties of salt and oxide-salt melts

Addition	Salt melt				% of addition **	Oxide-salt melt

* - the properties of a melt are gauged at T=950°C;

** - quantity of the addition in an oxide melt resulting in a liquation;

*** - maximal size of drops of a salt melt at the given concentration of the additive.

In the range 950-1220 °C solubility of CaO in the composite salt melts based on CaF₂-CaCl₂, CaSO₄ -CaF₂, CaCl₂ - CaSO₄ increases. The temperature coefficient is equal to 2·10⁻² % by mass/degree. Maximum solubility of CaO (12-15%, mass.) at 950-1300 °C is observed for the salt melt based on CaCl₂ - CaSO₄. Its value reduces when anions change in the following number Cl⁻ → F⁻ → SO₄²⁻. However all studied melts were characterized by the rather high solubility of CaO at relatively low temperatures. If the dependencies are extrapolated up to 1450 °C then the top solubility of CaO will essentially exceed the value defined for alkaline-sulphate compositions. In the saturated composite salt melts SiO₂ dissolves up to 1.15 % (at 900 °C in the system CaF₂ - CaCl₂) and up to 0,58% of aluminum and iron oxides (Table 2).

The study of the salt melt properties showed that their viscosity is 1-2 times less (1·10⁻³ - 5·10⁻³ Pa·s) and the surface tension is 2-3 times less (0.09-0.15 N/m) than the viscosity and the surface tension of the oxide melts (Table 1). When calcium silicon, aluminum and iron oxides are added to

the salt melts η of the liquid phase rises to $(5-9) \cdot 10^{-3}$ Pa·s (at 900°C) (Figure 2). In the presence of CaO viscosity of chlorine-contained melts increases due to the amalgamation of the viscous units and the strengthening of the interaction between the separate structure units of the melt. The increase of CaO in chlorine melts leads to the formation the larger complex groups $(\text{CaCl}_{4-x}\text{O}_x)^{(2-x)}$, which have the greater size and electric charge than these parameters of the structure unit of calcium chlorine melt (CaCl_4). This promotes the interaction between the melt groups and the increase of the system viscosity. In the fluorite- and sulphate-containing melts the formation of the complex double compounds of $\text{CaO} \cdot x\text{CaF}_2$ -type (where $x = 1$ or 2) is possible, which structuralize the system, decreasing the fluidity of the main structure formation ions.

Table 2. Equilibrium concentrations of silicon, aluminium and iron oxides in salt melts, saturated by calcium oxide

Melt	Oxide	Concentration of oxides, % by weight, at the temperature, $^\circ\text{C}$				
		800	850	900	950	1000
$\text{CaCl}_2 +$ 10.7% CaO	SiO_2	0.15	0.19	0.22	0.26	0.32
	Al_2O_3	0.02	0.03	0.05	0.06	0.08
	Fe_2O_3	0.02	0.03	0.05	0.06	0.08
	CaO_{Free}	0.05	0.07	0.11	0.09	0.11
$\text{CaF}_2 +$ $\text{CaCl}_2 +$ 11.33% CaO	SiO_2	0.50	0.81	1.15	1.56	1.83
	Al_2O_3	0.04	0.05	0.08	0.11	0.15
	Fe_2O_3	0.41	0.45	0.50	0.51	0.55

$\text{CaCl}_2 +$ $\text{CaSO}_4 +$ 15.38% CaO	SiO_2	0.15	0.54	0.90	1.22	1.65
	Al_2O_3	0.02	0.03	0.05	0.08	0.10
	Fe_2O_3	0.44	0.55	0.63	0.75	0.85
	CaO_{Free}	0.08	0.10	0.15	0.28	0.35

The salt melt viscosity is changed exponentially as a function of temperature. Activation energy of the melt viscosity has low values (25-48 kJ/mol.) and increases as the quantity of the dissolved oxides increases. In the presence of calcium, silicon, aluminum, iron the salt melt surface tension increases slightly: from 0.005 to 0.002 N/m.

The density (ρ) of the salt eutectic melts is $2000 - 2500 \text{ kg/m}^3$ (at 1500°C). When CaO, SiO_2 , Al_2O_3 , Fe_2O_3 are dissolved in them it is observed the common trend is for the density to increase, although for the same compositions the relationship passes through the inflection point and the extremums, which characterize the definite interaction in the system. The density is a readily decreasing function of temperature. The low density and the surface tension of the salt melts confirms the low ability to aggregate of the liquating systems and the negative impact of macroliquation in the clinker oxide melt on the agglomeration and sintering processes.

In the salt melts with high fluidity CaO dissolves more readily and these melts carry out the function of the transport surroundings for calcium cations which diffuse into the local regions. These regions are enriched in silica-containing components. The alite formation and crystallization take place there. The low density and surface tension of the salt melts confirms the bad aggregate ability of the liquating systems and the negative influence macro liquation in the clinker oxide melt on the agglomeration and sintering processes. It has been found that liquating salt melts when saturated with calcium, aluminum, silicon and iron oxides, crystallize, the individual or complex melts and silicate phase, especially C_3S , are formed. In alkaline-sulphate melts 4-5% by weight of calcium silicates are formed. In eutectic halogen-containing salt melts, saturated with the oxides, C_3S and C_2S are crystallized up to 9% by weight.

Figure 2. Change of viscosity of salt eutectic melts versus content of calcium oxide:
 1 - CaCl_2 ; 2 - CaCl_2 - BaCl_2 ; 3 - CaCl_2 - $\text{Ca}_3(\text{PO}_4)_2$; 4 - CaCl_2 - CaSO_4 ; 5 - CaCl_2 - BaCl_2 - CaSO_4 ; 6 - CaF_2 - CaCl_2 ; 7 - CaF_2 - CaSO_4 . (1-6 $T=900^\circ\text{C}$; 7 - $T=950^\circ\text{C}$)

The process of the formation of alite phase in actual sintering clinkers proceeds at the start of equilibrium melt and at sufficient temperature in volume of pellets. By the time of the advent of melt topochemical reactions of mineral formation and in the system the grains of CaO and C_2S are present, relatively uniformly distributed in clinker melt, which quantity varies in the range from 25-35%, mass.

For modeling of alite formation, taking place in microvolumes of clinker grain, the system of CaO - C_2S -melt was used. Particles of CaO and C_2S were obtained by burning of briquettes at 1800°C during 2 h in vacuum oven and subsequent grinding of cakes and extraction of fraction equal to 40-60 μm . The density of particles comprises 3280 (C_2S) and 3370 (CaO) kg/m^3 ; the size of crystals varied in the range from 25 to 60 μm . The structure of thus obtained grains consisted of one or two crystals that excluded dispergation in melt and allowed to study diffusion nature of the process. The ratio of CaO (14.83%), C_2S (55.17%) and a mix for obtaining a melt ($M=30\%$) corresponded to clinker with $L.S.F.=0.92$.

In clinker melt involving Na_2SO_4 and K_2SO_4 liquating regions with sulphate-alkaline composition are formed. In these regions belite is corroded actively under the effect of surface-active cations of Na^+ and K^+ . In this case the rate of dissolution (J) of C_2S exceeds J_{CaO} two or three times and alite formation is limited by the kinetics of interaction between calcium oxide and a melt.

As a result of fast dissolution of belite in a clinker liquid and slow diffusion of the silica-oxygen anions formed they enrich the melt in the immediate regions of dissolving grains of C_2S . The resulting concentration gradient is a motive force, which seeks equilibrium, that is uniform distribution of ions in a melt. However, a lower fluidity of silica-oxygen radicles as against such ions as Al^{3+} , Fe^{3+} , Ca^{2+} , Na^+ , K^+ , etc. and steadily going on process of dissolution of C_2S supports the higher concentration of complexes in these regions and provides formation of micro-ununiformities. Cations of Ca^{2+} , Mg^{2+} , Na^+ , K^+ , etc., surrounding these microvolumes, interact with complexes $[\text{Si}_n\text{O}_{3n+1}]^{(2n+2)-}$ -type, that leads to their depolymerization and the formation of isolated tetrahedrons of $[\text{SiO}_4^{4-}]$. These tetrahedrons are bonded with Ca^{2+} ions thus forming the lattice of C_3S .

Liquating sulphate-alkaline melts marked by a low surface tension hamper the dispergation of CaO grains and diffusion dissolution of individual crystals. As a result alite formation is retarded, liquid phase is slowly saturated with Ca^{2+} , and due to diffusion, the progressive growth of formed alite

crystals takes place that defines a coarse-crystal structure of clinker. With slow dissolution of CaO crystals their capture by growing alite crystals is observed. In this case interlocked grains of calcium oxide do not enter into a reaction of alite formation. Their occurrence provides an increase of CaO_{free} content and decrease of alite content in clinker in comparison with calculated value (Figure 3).

Figure 3. Crystallization of minerals in model systems at addition in a melt (% mass.):

the photo was made by the optical microscopy, magnification of 400^x

With the suppression of liquation in the presence of Mg, (or at a low content of sulphate-alkaline melts) a fine-crystal clinker structure is formed with a clear mineral crystallization.

With the dissolution of CaO and C_2S in halogen-containing melts, alite forms immediately. Fine-crystal C_3S is indicative of fast supersaturation of liquid phase and a formation of a greater content of crystallization centers. It is significant that changes of crystal nature do not occur as F^- and Cl^- content in a melt increases. Needle-like crystals of C_3S bear witness to its crystallization from a melt. In the presence of F^- and Cl^- J_{CaO} is greater than $J_{\text{C}_2\text{S}}$.

In the presence of all halogen-containing modified additions the following function is observed as a whole: with increase of liquation regions alite crystal sizes decrease. Their faces develop broad and indefinite appearance due to recrystallization taking place in salt melts. The rate of CaO dissolution exceeds $J_{\text{C}_2\text{S}}$ and this distinction increases with increase of the acidity of the interface layer with adsorption of ions of F^- , Cl^- and SO_4^{2-} . In the liquating salt melts $J_{\text{CaO}} \geq J_{\text{C}_2\text{S}}$ and crystallization frequently occurs at the surface of C_2S . The most intensive alite formation occurs in the presence of combined salt melts and the rate of reaction increases as follows: CaCl_2 - $\text{CaSO}_4 \rightarrow \text{CaF}_2$ - $\text{CaSO}_4 \rightarrow \text{CaF}_2$ - CaCl_2 . Accordingly the size of C_3S crystals decreases.

The resulting liquid phase in burned material fills separate pores and capillaries thus forming films on particles. In [13, 14] it is shown that a melt is represented by continuous phase with grains of CaO, C_2S and C_3S . Interaction between these minerals and melt takes place restrained conditions when diffusion of required ions for growth of C_3S crystals limits the progress of a reaction of synthesis. Between grains of CaO - C_2S , CaO - C_3S melt regions, enriched in Ca^{2+} , occurs. In these regions, crystals of C_3S are in prospect. Locally positioned melts, characterized by concentration gradients and different acid-basicity properties, exchange ions on interface on contact, tending to equilibrium. At large melt volumes convection is favorable to the averaging of melt composition. However, in thin capillaries and films material transfer executes due to diffusion only. The conservation of non-uniform melt volumes in clinker grains (metastable micro liquation), the availability of liquation regions leads to extraction of solid phases, which are in equilibrium with these fluids.

In the system $\text{CaO-C}_2\text{S-M}$ liquid phase is formed at 1338°C , because of this at burning of mix without addition at 1300°C CaO and C_2S does not bind together. Initial content of calcium oxide (14.83%, mass.) is contained in cakes (Figure 4), that is confirmed by the absence of solid-phase interaction between CaO and C_2S under these conditions. In the presence of modifiers, temperature of the occurrence of melt decreases (up to $1240\text{-}1300^\circ\text{C}$) and at the occurrence of liquid phase absorption of CaO starts. The degree of completion increases with growth of content in melt (in the range from 1 to 5%, mass.) of all studied modifiers. The nature of influence of individual and complex modifiers is defined by both change of viscosity of oxide component and the occurrence of liquation regions of salt composition.

Figure 4. Impact of content of addition on binding of free calcium oxide in the presence:
 1 - Na_2SO_4 ; 2 - $\text{K}_2\text{SO}_4\cdot 2\text{MgSO}_4$; 3 - MgO ; 4 - $\text{R}_2\text{O-MgO-SO}_3$; 5 - Cl^- ; 6 - F^- ;
 7 - $\text{CaCl}_2 + \text{CaSO}_4$; 8 - $\text{CaF}_2 + \text{CaSO}_4$; $\text{CaF}_2 + \text{CaCl}_2$ ($T=1300^\circ\text{C}$, $\tau=20\text{ min}$)

With incorporation of alkaline sulphates, alite formation intensified mainly due to essential acceleration of C_2S solubility in the presence of R^+ . The degree of transformation of CaO increases with decrease in melt viscosity, but this rule is violated by the occurrence of salt melt. At increase of the trend of melt to separation in the following order: $\text{R}_2\text{O-MgO-SO}_3 \rightarrow \text{Na}_2\text{SO}_4\cdot 3\text{MgSO}_4 \rightarrow \text{Na}_2\text{SO}_4 - \text{K}_2\text{SO}_4 - \text{MgSO}_4 \rightarrow \text{K}_2\text{SO}_4\cdot 2\text{MgSO}_4 \rightarrow \text{Na}_2\text{SO}_4$ slowing down of binding of calcium oxide is observed that corresponds with impact of cations $\text{Mg} \rightarrow \text{Na} \rightarrow \text{K}$ on liquation. This rule is conditioned by the lower solubility and the rate of CaO dissolution in sulphate-alkaline melts. Suppression of liquation assists in activation of the process. So, for the system $\text{R}_2\text{O-MgO-SO}_3$, liquation is observed at the higher oxide content (over 3%, mass.) in comparison with other sulphate-alkaline compositions, as manifests by its catalyzing ability. As this takes place, before the start of liquation process occurs intensively while at the advent of salt melts it slows down at the concentration of complex more than 3%, mass.

For halogen-containing melts, liquation phenomena catalyze alite formation in the order $\text{SO}_4^{2-} \rightarrow \text{Cl}^- \rightarrow \text{F}^-$ that agrees with the sequence, typical for strengthening of liquation ability of clinker melt. F^- ion has the highest effectiveness, absolute concentration being the same. However, the injection of eutectic salt melts anion concentration changes to a lesser extent than with halogen injection. As this takes place, Cl^- (1.6-2.65%, mass.) combined with a small quantity of F^- (0.07-0.35%, mass.) considerably overcomes impact of single F^- in intensity. Substitution of F^- by SO_4^{2-} leads to

considerable slowing down of the reaction, concentrations being the same that agrees with comparison of their impact on viscosity of an oxide melt and an liquation ability of the system. That is, liquation phenomena in halogen-containing clinker melts catalyzes alite formation. The opposite type of impact of halogen-containing and sulphate-alkaline melts is explained in terms of the higher solubility of CaO in salt melts based on F^- and Cl^- and their lower values of viscosity as well.

4. CONCLUSIONS

In the presence of salts or their compositions and depending on ion concentration in clinker melt a separation of clinker melt is observed. A separation takes place into two coexisting fluids: an oxide one with dissolved ion salt and a salt fluid with oxide ions. The trend of the system to liquation increases with growth of acidity of induced anions in the order $SO_4^{2-} \rightarrow Cl^- \rightarrow F^-$ and with increase of basicity of s-elements $Mg^{2+} \rightarrow Na^+ \rightarrow K^+$ that agrees with change of surface tension of a melt and correlates with the rules determined for more acidic systems. Calcium oxide is dissolved in salt melts, having high fluidity, to the greatest extent. In so doing higher concentrations of CaO were observed in melts, containing Mg^{2+} and Ca^{2+} , and the lowest ones in fluids of sulphate-alkaline composition. It can be explained by the fact that dissolution of calcium oxide occurs by ion exchange $Mg^{2+} \rightarrow Ca^{2+}$ at the phase interface of CaO – salt melt. The proximity of energetic and geometric parameters of these cations just defines process of dissolution. For alkaline cations an exchange between Na^+ , K^+ and Ca^{2+} is hampered due to distinction in their charges that reduces CaO concentration in melts of R_2SO_4 and RCl . Ions of silica, aluminium and iron have not isomorphous anions in salt melts, that is why their concentrations are small. At crystallization of salt melts, saturated with oxides of calcium, silica, aluminium and iron, 4-9%, mass., of calcium silicates are formed. It testifies that alite formation is possible in liquating liquid phases of salt composition. The decrease of viscosity of oxide melt due to transfer $[MeO_4] \rightarrow [MeO_6]$ and occurrence of liquation regions with high fluidity is called upon to support acceleration of mineral formation at synthesis of clinkers with different compositions. The change of kinetics and mechanism of clinker formation in accordance with composition of liquating melts was found. The control over composition and properties of melts allows intensifying clinker formation with optimization of a phase composition and clinker microstructure. Joint impact of elements, achieved by usage of various wastes, is more effective than action of individual compounds. The optimization of composition allows considerable catalyzed effect and to obtain alite clinkers at 1350 °C. The suppression of sulphate-alkaline or halogen-containing liquation in a clinker melt is one of the helpful means of optimization of clinker structure and improving Portland cement quality.

ABSTRACT

The hydration mechanisms of granulated blast furnace (GBFS) slag sand can be described as a corrosion process. It was investigated by several sophisticated methods, i.e. SEM (Scanning Electron Microscopy), AFM (Atomic Force Microscopy) and SNMS (Secondary Neutral Mass Spectrometry) after being treated with water and $\text{Ca}(\text{OH})_2$ -, KOH - and CaSO_4 -containing solutions. The layers of hydration products on the surface of the glassy slag particles could be analysed accurately against hydration time, accompanied by the parallel running analysis of the eluate composition. It was observed that at first the dissolution of mainly Ca and other ions occurs, leaving the solid surface enriched in the residual composition. The composition of those surface layers, however, undergoes significant alterations upon the kind of solution and during the time of hydration. The formation of initial and subsequently formed layers and their composition is illustrated and discussed.

1. INTRODUCTION

Slag cements have gained increasing market share during recent years due to their advantages in low heat development, high durability and resistance against sulphate and other chemical attack, their light colour, low production cost and high CO_2 -savings potential. The major drawback, however, is the slow early strength development in relation to portland cement.

Figure 1. Systematics of influences on slag reactivity (red = considered in this contribution)

Slag cements have been produced for more than 100 years and repeatedly it has been reported that the strength performance is varying within a broad range and being subject to many influences as shown in Figure 1. Most recently a very comprehensive study on the optimization of slag cements has been published, which also contains a very detailed literature list on the subject. [1].

Since the influences on slag reactivity are rather complex, a detailed study was carried out to obtain more information about the relationship between the properties of the slag and the kind of aqueous solutions which attack the glass structure. Very advanced investigation methods like Electron Paramagnetic Resonance Spectrometry (EPR), Scanning Electron Microscopy with micro analyses (SEM-EDX), Atomic Force Microscopy (AFM) and the Secondary Neutral Mass Spectrometry (SNMS) were applied. All details of the materials, apparatus and procedures applied are given in [2] and [3].

2. MATERIALS

15 industrial and artificial slags and slag glasses were investigated which covered the common range of chemical compositions, but also the extremes like a very high alumina content, a highly increased titanium content or an increased C/S ratio. Some attention was given to the magnesium oxide content, as well. Out of that large quantity of data, only experiments with one material, "HSM/0", can be reported within this contribution in detail. The chemical composition of HSM/0 is given in table 1.

Table 1. Chemical composition of slags in mass-%

	CaO	SiO ₂	MgO	Al ₂ O ₃	TiO ₂	MnO	Fe	S	Alk.	C/S
HSM-0	39	36	11,5	10,1	0,5	0,3	0,1	1,2	(0,5)	1,07

The corrosive solutions used were
pure water,
lime saturated water,
lime and sulphate saturated water,
aqueous potassium hydroxide solution and
pore solutions gained from industrial mortars after some hours of hydration by high pressure.

For all corrosion experiments the glass fraction 25-63µm was used at a water/solid ratio of 200. Such a high excess water amount was necessary for ensuring that slag grains hydrate independently and do not form a solidified microstructure. Otherwise the layer investigations by SNMS etc. could not be carried out in the way they are done here. The suspension was treated within air-sealed polyethylene bottles at 20 – 25 °C, which were agitated constantly. After the desired period, a part of the suspension was extracted and the hydration process was stopped by acetone.

3. REACTIVITY AND STRUCTURE

Slag sand <63µm was cooked for one hour in pure water. The total amount of diluted ions was determined with HCl by titration. This is called the hydrolytic reactivity which is in good relation to the value of non-bridging oxygens in (SiO₄)-tetraedra (NBO/T), see Figure 2. The NBO/T value was calculated according to [4]. Except for very high alumina slags the HCl-reactivity-value also corresponds quite well with the strength development in early and late ages (Figure 3). Therefore, we can suppose that the structural influences on the slag reactivity are mainly governed by those glass components, which are modifying the network towards higher NBO/T's, i.e. CaO, MgO, alkalis etc.

Figure 2. Correlation of hydrolytic reactivity and NBO/T values of GBFS

Figure 3. Correlation between hydrolytic GBFS reactivity and its compressive strength

Figure 4. Fitting of reactivity vs. strength coefficient by coordination number variation of Mg

Magnesium oxide normally is considered as a 1/1 substitute of calcium oxide. However, magnesium can occur within tetrahedral oxygen co-ordination, which calcium in glass never enters [5]. By fitting the correlation between reactivity and NBO/T values of all the slags, the best values were gained if between 25 and 35% of the magnesium was considered to be tetrahedrally coordinated (see Figure 4). Since manganese as Mn^{2+} follows exactly the positions of magnesium, it could be checked very accurately by EPR that around 30% of the Mn^{2+} - and Mg resp. - is network stabilizing and only 70% of it may be calculated as being equivalent to calcium in terms of slag reactivity. Furthermore titanium was investigated towards Ti^{4+}/Ti^{3+} distribution. It was found that both oxidation states occur simultaneously in GBFS, Ti^{4+} on Si^{4+} sites, whereas Ti^{3+} replaces Ca^{2+} preferably. The latter has a tightening effect on the network, thus explaining its liquifying effect on molten slag as well as its well known retarding influence on hydration.

4. CORROSION EXPERIMENTS

Figure 5. Images of the untreated GBFS

Figure 5a shows a SEM image of a sharply edged morphology of normal slag sand HSM-0. Quite high resolution of the surface microstructure could be achieved with the AFM (Figure 5b). The surface of such "fresh" slag can be considered as gel-coated already. As far as the gel contains

calcium hydroxide, carbonation can proceed as shown in Figure 5c. This means that the corrosion process starts already during the wet or humid storage period before the slag is further processed.

The corrosion experiments also started with water treatment. Figure 6 shows in the upper part the development of the ionic concentration in the eluate. At the beginning, magnesium is leached out, but with increasing calcium and silicon content in the solution the magnesium precipitates almost completely. The alumina content in the solution is also very low.

Figure 6. Eluate concentration and SNMS of corrosion layer composition: water treatment

From the fresh material and after seven days of water treatment a SMNS profile was taken (Figure 6, lower part). To obtain such composition profiles of fine grained materials, it had to be softly pressed into an indium foil before being sputtered. Comparing the fresh slag and the one after seven days of water treatment, it can be seen that the corrosion has already reached a depth of some hundred nm. It divides into at least two zones - an outer one being enriched in magnesium and silicon at a very low calcium content and an inner corrosion zone, where the calcium content slowly

comes up to its normal concentration. This corresponds very well to the eluate compositions, which show calcium dissolution quite dominantly.

If the corrosive solution is made more basic by calcium hydroxide, the alumina content in the solution is almost only half of that in water. In the beginning of the corrosion process silicon is leached out of the GBFS, which results in a reduced silicon level in zone I. Due to the low solubility of silicon in the $\text{Ca}(\text{OH})_2$ saturated solution, CSH and calcium hydroxide precipitate (see also Figure 8) which leads to a second zone II which is characterized by high concentrations of silicon and calcium and low concentrations of magnesium (Figure 7, lower part). Right at the top surface silicon seems to be even more enriched, where calcium and magnesium are very low. Below that top layer magnesium goes up, but only at the beginning of the corrosion process inside to grains that seem to be somewhat increased. This finding is almost in accordance with [6], which investigated slag hydration in alkaline environments.

Figure 7. Eluate concentration and SNMS of corrosion layer composition: CH treatment

Figure 8. AFM images of CH and CSH on hydrated GBFS surface: 7 d CH treatment

Closest to the practical pore solution composition at the beginning of hydration should be one saturated by calcium hydroxide and calcium sulphate. Figure 10 shows a very slight but not significant increase in the magnesium content of the solution. The SNMS profiles however (Figure 10, lower part) show the CSH-layer formation at the surface accompanied by a decreased magnesium content. Also the sulphate seems to penetrate that corrosion layer to some extent. The calcium sulphate visible at the top surface in early ages, seems to be replaced later by a silicon rich cover layer.

The SEM and AFM images (Figure 9) show a mixture of CSH-phases and well crystallised AFt. If the tri-phases would consist only of ettringite, the alumina content in the surface layer should be significantly increased. This is definitely not the case. The explanation could be that already from the beginning silica is entering the AFt-phases to some extent. Regarding magnesium it can be stated that it does not easily enter the hydration products because in layer II its content is very low. However, the corrosion layer I of GBFS shows significantly less MgO related to water or CH treatment. This behaviour could be explained by the higher solubility of MgSO_4 in water compared to $\text{Mg}(\text{OH})_2$, promoting thereby its leaching out of the GBFS.

Figure 9. SEM and AFM images of GBFS surface corroded 7d by CH- and CaSO_4 -solution

Finally, a 0,1-n-KOH solution was used as the corrosive medium. This is justified by the observation of [7,8] that, already after one day of hydration, the pore solution of mortar can contain almost only alkali hydroxides and almost no calcium and sulphate ions any longer. Figure 11 shows in the upper part an increased solubility of alumina whereas decreased silica and calcium, correspondingly.

Figure 10. Eluate concentration and SNMS of corrosion layer composition: CH and CaSO₄

Figure 11. Eluate concentration and SNMS of corrosion layer composition: 7d KOH treatment

The outer hydration layer now contains even more silicon and some potassium is penetrating. Magnesium is sharply enriched at the outer surface at the beginning of hydration, but this effect should not be relevant in practice, because the presence of sulphate makes the magnesium more soluble. After seven days, it again seems that magnesium is reduced in the outer hydration layer but increased in the inner one.

Other experiments carried out with varying chemistry of the slag glass showed that in principle layer formation is always similar. A higher C/S-ratio significantly increases the depth of the hydration layer, whereas increased amounts of titanium act as a retarder.

The role of alumina during hydration has to be re-evaluated upon the above reported findings, because it seems that an increased alumina content only boosts the early hydration due to accelerated ettringite or Aft formation. At the later stage, if no sulphate is available any longer for reacting with the alumina, the latter seems to retard hydration and strength development.

Figure 12. Layer formation model of GBFS corrosion under CH/CaSO₄ (upper series) and KOH treatment (lower series); the dotted red arrow indicates the transformation of the reactions following the pore solution alteration during hardening from CaSO₄- to KOH-dominated

5. CONCLUSIONS

The reactivity of glassy blast furnace slag is controlled by the corrosion process of the glass framework. The more the glass structure incorporates ions which produce non-bridging oxygens (NBO's) at the SiO₄ tetrahedra, the faster the corrosion starts.

Primary acting according to this mechanism is calcium. Magnesium cannot simply be considered as a substitute for calcium, because around 20-35% of the magnesium is substituting silicon in tetrahedral oxygen co-ordination. Therefore magnesium is also partially stabilizing the glass framework.

Titanium stabilizes the glass framework, both as Ti^{4+} instead of Si^{4+} and as Ti^{3+} instead of Ca^{2+} in octahedral co-ordination. But, in contrast to calcium, titanium is tightening the framework in this position.

Also alumina is stabilising the glass framework because it is always tetrahedrally co-ordinated. This seems to be senseless because the alumina-rich slags are well known to be the most reactivities. An explanation could be that only at the early hydration stages sulphate is present in the solution which makes the alumina react faster than silicon. Later on, however, if sulphate is missing the alumina is not released faster than the silicon out of the framework and the stabilizing effect of alumina limits the GBFS reactivity.

At later hydration stages when alkali hydroxide is the main constituent of the pore solution and calcium sulphate is no longer available, CSH-phases are formed predominantly at the outer part of the hydration layer. Magnesium is only a little increased deeper inside, where the corrosion starts. Taking into account the transient area of the layers, only minor differences in the corrosion depths after corrosion in the various basic solutions for seven days can be observed. Because of the continuous agitating of the suspensions in the laboratory and the high excess of water available, that might be different in practice.

The composition of the outer layer changes significantly if KOH is present because the OH^- is quasi catalytic promoting the corrosion process. It can be assumed that the concentrated KOH in pore solutions of aged mortars would act much faster than the 0,1-n-KOH applied here. Additional experiments were carried out with pore solutions pressed out of ordinary mortars after 6 and 16 hours - not discussed here - which in principle show a similar reaction scheme but deeper corrosion, faster precipitation and much higher Si concentration at the surface (at reduced solution/solid ratio of only 5).

The hydration mechanism observed here is principally divided into two steps (Figure 12)

1. a leaching of the glass structure and
2. the formation of surface layers by secondary phases occur.

Moreover, the significant difference between pore solution compositions of early stage ("CHCS") and later stages ("CH" ... "KOH") must always be considered.

The reactivity of slags can never only be calculated from their chemical composition. The pore solution as well as many other factors have to be considered when modelling it.

ACKNOWLEDGMENTS

The investigations reported in this paper have been part of a research project of Readymix Cement, Germany, under the project management of Dr. Joachim Bruckmann and the supervisory of Dr.-Ing. Hans A. Brodersen. The project was supported by the German Ministry of Science, Research and Technology within its PIUS-Program, Project.-Nr. 01 RK 9651.

PERFORMANCE OF BLENDS OF POLYCARBOXYLATE POLYMERS IN DIFFERENT CEMENTS

U. Maeder and I. Schober

Research and Development, Sika Schweiz AG, Zürich, Switzerland.

E-mail: maeder.urs@ch.sika.com and schober.irene@ch.sika.com

ABSTRACT

The number of different cement types, aggregates and consequently concrete mixes is increasing. Incompatibilities of the different constituents with admixtures can therefore not be excluded, especially when low water/cement ratios are used.

Effects of polymers having a different number of polyoxyethylene (PEO) graft chains relative to the length of the backbone or having modified backbones were evaluated in cement paste by measuring adsorption and in mortar and concrete compositions. The effects of the polymers on the fluidity of the cementitious systems are significantly different. Whilst one polymer gives a very strong initial water reduction another one shows increasing flow with time. Different blends of the two polymers have been successfully used in RMC and self-compacting concrete mixes in different climate zones.

U. Maeder is Product Technology Director, Construction Chemicals and Mortars at Central R+D, Sika Schweiz AG, Zürich, Switzerland.

I. Schober is Head of the Polymer Development Lab at Central R+D, Sika Schweiz AG, Zürich, Switzerland.

Keywords: adsorption, polymer blends, cement, polycarboxylates, superplasticizers, workability, retention.

1. INTRODUCTION

In the last few years special concretes have become increasingly important in many parts of the world, but especially in Japan. There is a trend within the ready mixed concrete industry towards trademark concretes with specific performance characteristics.

These concretes can be used to improve appearance, construction efficiency and technical performance of concrete structures.

Apart from high strength, high durability or low density concrete the SCC (Self compacting concrete) is taking increasing market share. SCC is able to flow under its own weight through and around densely packed reinforcement without bleeding or segregation, forming a compact void free mass without the need for any vibration.

The benefits of this technique include reduced construction time, reduced noise, less manpower for placing and potential for increased automation (1).

To achieve this goal a new approach to concrete mix design is required. The volumes of paste and fines are increased while the coarse aggregate volume is reduced to minimize the risk of aggregate bridging. The low water content combined with the high paste volume leads to a cohesive mix with low tendency to segregate. The required flow and the flow retention is achieved by using special types of superplasticizers.

While concrete with normal requirements can be produced using traditional superplasticizers like Naphthalenesulfonate, Vinylcopolymers or Melamine sulfonate, the high requirements of special concretes and in particular SCC requires the use of special polymers (2, 3, 4). Among these special polymers the polycarboxylate-type superplasticizers have become the most widely used within the last few years.

The molecular structure of the new polymers differs completely from conventional ones (8, 9-11). The traditional polymers consist of long main chains carrying negatively charged side groups. These polymer adsorb strongly onto the surface of the cement grains and the ionic groups exert an electrostatic repulsion that prevents particles coming too close together.

The new polymers on the other hand typically feature short principal chains (backbone) containing ionic functions and very long polyether type side chains, that can separate particles by strong steric repulsion.

Considering the manifold properties of a polymer, like molecular weight of the whole polymer, backbone or side chains, ionic strength, chemical composition or production conditions, an extraordinary variety of special performing polymers is feasible.

Worldwide an increasing number of different cements, binders and aggregates are used for concrete production and different climates have to be considered. With a set of different polycarboxylatetype superplasticizers that can be blended, nearly all requirements to fit the various applications are covered. The blending of water reducing and slump-retaining polymers will be presented in this paper as well as case studies, which benefited from the principle.

2. EXPERIMENTAL

2.1 Polymers:

Five polymers of the polycarboxylate-polyglycolether type were tested in this study. Polymers P1 and P2 are based on polymethacrylic acid and polymer P3 is based on polyacrylic acid. Polymers P1 and P5 are specifically designed as water reducing polymers while polymers P2, P3 and P4 are designed as slump-retaining polymers. Molecular weight and sodium content of the polymers are listed in Table 1.

Table 1. Physical data

Polymer	M _w	Na ⁺ (%)
P1	24 000	5.8
P2	24 000	2.6
P3	20 000	1.1
P4	31 000	4.7
P5	22 000	3.8

2.2 Composition of the Mortar Mixtures

The two most widely used Swiss cements (C1, C2) and one Japanese cement (C3) were used for testing the polymers. The composition of the cements can be found in Table 2.

A rotary type laboratory mixer (Hobart X1 N) was used to manufacture all mortars employing the same standard procedure: The superplasticizer was dissolved in the water and the solution added to the previously dry mixed (1 minute) sand and cement. The mortar was then mixed for three minutes and The consistency was determined using the "flow table spread" according to DIN 18555, part 2.

The diameters of the spread mortar were measured in two directions and the average value was regarded as initial flow value. The measurement was repeated after 30 and 60 minutes with 30 seconds mixing of the mortar. The change of the flow value with time is a measure of the loss of fluidity of the mortar. The water cement ratio was fixed at 0,42. The cement used in the single tests is always indicated. A defoamer was added to all polymers prior to the tests.

In a second series of tests, the polymers P4 and P5 were tested in cement pastes with cements C1 and C3. This test was described by Nawa et. al. [6] and consists of placing a cement slurry with constant W/C ratio into a cylindrical cone of 50 mm diameter and 51 mm height. The cone is lifted and the width of flow of the slurry measured.

Table 2. Cement types

Cement	C1	C2	C3
C3S (%)	66.3	67.5	64.7
C2S (%)	10.8	5.7	13.9
C3A (%)	6.4	1.2	7.6
C4AF (%)	8.2	21.3	8.9

2.3 Adsorption measurements

Cement and water including the superplasticizer were mixed with a mechanical stirrer at a constant speed. The water cement ratio was fixed at 0,5. The dosage of the polymer was chosen as 1% of a 40% solution (400mg solids per 100 g PC). After a determined period of time the slurry was centrifuged and the supernatant separated and filtered. The remaining amount of polymer in solution was then determined by high performance liquid chromatography (HPLC). The difference of polymer concentration in solution before and after contact with cement was calculated as adsorbed polymer.

This procedure was feasible and accurate for P1, P2, P4 and P5 but not for P3. P3 contains side chains that are cleaved off in alkaline media resulting in a change of the polymer peak in HPLC detection. In this case the adsorption could not be measured.

The cements used in the adsorption measurements are listed in Table 2. The cement phases were determined according to Bogue's equation. The specific surface was of the same order for all three types (Blaine value 3500 cm²/g +/- 100)

3. DISCUSSION

3.1 Mode of action of Superplasticizers

Due to an optimised ratio of methacrylic acid to polyoxyethylene side chains, polymer P1 was designed as a water reducer for type I cements. The dispersing effect is due to ionic repulsion combined with sterical hindrance. The relatively high ionic strength leads to a fast adsorption on the cement grains during the mixing process and, thus, a strong initial plasticizing effect.

P2 is designed as a slump-retaining polymer due to a different ratio of methacrylic acid and polyoxyethylene side chains. The ionic content is much lower compared to P1 and thus adsorption

is slower and less giving a lower initial flow. The polymer remaining in the water phase of the cement paste can adsorb later on the growing surface of the hydrated cement particles.

Polymer 3 was also designed as a slump-retaining polymer. It is based on polyacrylic acid. The side chains are attached via ester bonds that are cleavable under the highly basic conditions we have in hydrating cement paste (pH 13.5). The very low ionic content of the polymer causes a very low initial flow, leading to the interpretation that only a small portion of the polymer adsorbs on the cement grain. However, as the cleaving of the side chains starts immediately after addition to the cement, the molecule gets a more ionic character and its adsorption potential increases with time. The result in mortar or concrete is an increased workability over the time (6, 8-9).

Polymer P4 is another slump-retaining polymer, which shows its best performance at moderate to low w/c ratios. It is based on polymethacrylic acid and has a similarly low ionic content to P3.

Polymer P5 is similar to P1 with about the same number of ionic groups but with a smaller molecular weight distribution.

3.2 Influence of cement quality

Superplasticizers (SP) are increasingly used for the production of quality concrete. The problem is that a SP might work well with one cement but not with another, or in one place but not the other. Some of the results from experimental work with Portland cement are presented in earlier papers (2, 3, 4).

Even in a small market like Switzerland (4 Million tons/year), cements of the same class (CEM I 42.5) from different suppliers sometimes produce concrete with a completely different performance with the same admixture and aggregates. With the help of adsorption measurements, we are able to reveal but not necessarily explain such differences in all cases.

3.3 Adsorption Tests

Adsorption of water reducing polymers on the cement is one key factor to obtaining a plasticizing effect. The influence of the C3A content on adsorption is understood today (4-7, 9-10). In Figure 1 the adsorption of Polymer P1 and P2 is shown on three different cements that are listed in Table 2.

Figure 1. Adsorption of P1 and P2

Polymer P1 adsorbs on all cements in a higher amount compared to P2 due the higher ionic strength of P1. The amount of adsorbed polymer of P1 on C3 is much higher compared to C1 while the adsorption of P2 is of a similar order. Although C1 and C3 have nearly the same composition the adsorption of P1 on these cements is significantly different.

As the adsorption is closely related to water reduction (12) a different performance can be expected in mortar.

We found that P1 is more sensitive towards different cements in adsorption, and hence should also be more sensitive in water reduction.

Comparing adsorption of P4 and P5 on Swiss (C1) and Japanese cements (C3), we find a clearly higher amount of slump-retaining polymer P4 adsorbed on C3 whereas the adsorption of P5 is in the same range with both cements. The water-reducing polymer P5 is clearly more adsorbed than P4 in both cements.

Figure 2. Adsorption of P4 and P5 on C1 (400 resp. 200/200 mg in blend per 100 g PC)

Figure 3. Adsorption of P4 and P5 on C3 (400 resp. 200/200 mg in blend per 100 g PC)

However, both polymers adsorb faster on C1 than on C3. In both cements the 1:1 blend of the polymers adsorbs less than the individual components and polymer P5 is preferentially adsorbed.

3.4 Results in Mortar

Mortar tests of a polymer 1 based SP with three different commercial cements (CEM I 42.4) and with one blend (C1-3) of the three are shown in Figure 4. The admixture shows the best performance in the cement blend. Significant differences were obtained with the single cements. A much higher flow and the best flow retaining effect was observed with C1 compared to mortars with C2 and C3. Hence, P1 is less useful as SP for C2 and C3 compared to C1. The synergistic effect of P1 in a blend of the three cements has often been observed and could be explained by the resulting broader grain size distribution of the blend.

Figure 4. Mortar tests of P1 on different cement types

Both adsorption and mortar tests revealed that an admixture often has to cope with a large number of cements having different chemical and physical characteristics. Considering furthermore all different types of aggregates (spherical, crushed, volcanic) used to prepare concrete, or the different climates concrete is used in, the adaptation of polymers or admixtures to face this problem is essential. Blending of P1 with P2 or P3 is one possibility.

3.5 Performance of P5 and P4 in cement pastes

Comparing the flow results of polymers P4 and P5 in Swiss (C1) or Japanese (C3) cement pastes we see a higher water demand for C1 compared with C3. The flow with P5 alone is high and steady in both cements, but much lower with slump-retaining polymer P4 which showed increase of slump with time in C3. The 1:1 blend of the two polymers shows good effect in C3 with constant flow with time, whereas the effect of blending P5 with P4 in C1 is poor. We see a generally more sensitive behaviour towards different polymers of the Swiss cement compared to the Japanese one.

Figure 5. Cement paste flow with C1 (W/C = 0.30)

Figure 6. Cement paste flow with C3 (W/C = 0.23)

3.6 Performance of polymer blends in mortar

Blending polymer P1 with P2 or P3 has the main target to produce a SP with high initial flow and good flow retaining capabilities with time. Figure 7 shows mortar tests of admixtures based on P1 and P 2. For this tests cement C1 was used.

Figure 7. Mortar tests of Blend 1

P1 shows a high initial plasticizing effect followed by a loss of workability whereas P2 shows a constant but lower flow over time. Blend 1 is obtained by mixing P1 and P2 in a ratio of P1/P2 = 2/1. As a result the flow retaining capabilities are enhanced at lower flow level than with P1 alone.

However, the reduction of the initial flow is due to a reduced amount of P1. P1 adsorbs fast because of its higher ionic strength. P2 remains in the liquid phase of the cement paste and will adsorb when

the specific surface of the hydrated cement increases and the hydration products would lead to stiffening of the paste.

Figure 8 shows mortar tests of admixtures based on P1 and P3. For this tests cement C1 was used. The main characteristic of P3 is its increasing plasticizing effect over the time. Blend 2 is obtained by mixing P1 and P3 in a ratio 3.5/1. Compared to P1 a more constant flow retaining effect can be observed, however, some loss of initial flow has to be accepted. P1 adsorbs preferably and more rapidly, while most of P3 remains in the liquid of the cement paste. As soon as a certain number of side chains of P3 are cleaved, P3 will be able to absorb more readily as well and compensate for the fluidity loss of P1.

Figure 8. Mortar tests of Blend 2

Although the flow retaining capabilities of P2 and P3 are based on different modes of action, both can be used to compensate for loss of flow of a water reducing polymer like P1. The ratio of P2 and P3 to be used depends on cement type and water cement ratio. Hence, a tool to compensate for fluctuations in concrete mixes due to different cements, climates or aggregates is at hand.

In order to improve the flow retaining capabilities of a P1 based admixture, blend 3 (P1/P2 = 1.5/1) and Blend 4 (P1/P3 = 2.5/1) were tested. In both cases the desired property was improved and especially the performance of blend 4 was now comparable to the mortar made with cement C1 with polymer P1. (Figure 9) Hence, the blending of the polymers P1, P2 and P3 is a smart solution to overcome problems due to variations in cement.

Figure 9. Mortar tests of Blends 3 and 4

4. CASE STUDIES

Two case studies demonstrate the successful application of this concept on construction sites with SCC applications. Having different cements, aggregates, and requirements for both job sites, the

same basic polymers were used by simply varying the polymer ratio. The concept has been successfully used in numerous applications in all parts of the world and in SCC, precast or ready mix concrete applications.

4.1 Protection shield of a railway tunnel

4.1.1 Problem

For protection of a railway tunnel a shield of several horizontal jacked concrete pipes was designed. The pipes had to be filled with concrete to increase their stability. Each pipe was 150 meters long with a diameter of 1.5 m. For this purpose 2000 m³ concrete had to be placed (Figure 10).

Figure 10. Railway tunnel

4.1.2 Solution

The pipes had to be filled completely in two stages of 75 meters each. A posterior injection was not necessary. SCC was proposed to be the concrete of choice for this difficult task. Blend 3 was chosen because of the best compatibility with the cement used for this job, regarding both slump retention and strength requirements. The mix design used is listed in Table 3.

Table 3. Mix Design

Aggregate	0 / 16 mm
Cement	380 kg/m ³ , CEM II / A – L 32.5
Additive	50 kg/m ³ Flyash
Admixture	1.7 % admixture for SCC based on P1 and P3
Water	200 l/m ³
Slump flow	71 cm

4.1.3 Application

The concrete was pumped over a distance of 120 m and had to flow for an additional distance of 25 m. The quality of concrete did not suffer at all even after this long transportation distance. Quality checks before and after pumping gave comparable results regarding flowability. Furthermore, the early strength (7 days) before (35.2 N/mm²) and after pumping (37.9 N/mm²) as well as the final strength (28 days) before (47.2 N/mm²) and after pumping (44.6 N/mm²) gave

nearly the same values. This indicates the homogeneity achieved with the selected SCC mix after placing.

Compared to conventional concreting (207 working days), a time saving of 2500 working hours was achieved by the use of SCC. By using SCC the job was completed in 28 stages of 50m lengths, instead of 90 stages of 15m lengths using traditional concreting.

Additionally, the use of vibrators would make the operation difficult and time consuming, something which is unnecessary when SCC is used.

4.2 Reconstruction of a Hydro Power Station

4.2.1 Problem

For the reconstruction of a hydro power station, columns had to be filled with concrete. The height of each column was 9 meters. A special feature of these columns was their particularly dense reinforcement and their varying cross-sections. Hence, in this case the use of normal concrete with vibrating equipment was hardly possible. Figure 11 shows a picture of the columns.

Figure 11. Hydro Power Station

4.2.2 Solution

As a solution SCC concrete was proposed. The columns could be perfectly filled with a crane bucket only using a Tremie near to the bottom of the formwork. The mix design listed in Table 4 was used:

Table 4. Mix Design

Aggregate	0 / 16 mm
Cement	350 kg/m ³ , CEM I 42.5
Additive	80 kg/m ³ Flyash
Admixture	1.4 % admixture for SCC based on P1 and P3
W/B	0.44
Water	190 l/m ³

4.2.3 Application

The filling could be done in one pour. The columns were completely filled without any bugholes. The hardened concrete achieved a compressive strength of 59 N/mm² after 28 days as planned. The constructor was able to reduce his costs due to time and labour saving during the placing of the concrete.

5. CONCLUSIONS

It is well known and it was shown in this paper that different cements often interact in a different way with a particular superplasticizer.

There are many ways to overcome cement/superplasticizer incompatibilities, which can be expressed as a rapid loss of fluidity with time. One way is to formulate the superplasticizer with flow enhancing admixtures or, what was shown in this paper, to combine water reducing and flow retaining polymers.

The new developments in concrete technology like HPC or SCC require a new generation of polymers with their extremely high water reduction and /or flow retaining properties. Polycarboxylate polymers can be designed to show different adsorption properties on specific cements. The different adsorption properties can be correlated with high initial flow in cement paste or mortar and with retarded action of the molecules, giving flow-retaining properties.

The numerous successful applications of this blending concept, which have been completed worldwide, confirm the findings made in this lab study.

THE EFFICIENCY IMPROVEMENT IN CEMENT PRODUCTION BY KILN PRODUCTION UPGRADES, MODERNIZATION AND THUS OPTIMIZING PRODUCTIVITY - A STEP BY STEP APPROACH

Tapash Mukherjee

Works General Manager, Fujairah Cement Industries, U.A.E.

ABSTRACT

Often the plant manager of cement plant with comparatively old and obsolete technology faces the problem of maintaining stable operation of the plant and thus optimizing the cost of production. Such plants are often prone to breakdowns, and have higher cost of production due to old technologies with high cost of maintenance and manpower requirements. Here in most of the cases, the plant manager would like to modernize his facilities and at the same time upgrade the production to the maximum extent possible and completely modernize the plant. Such decisions can be considered only when the market is moving upward and permits some investment. However, the huge investment that might be required for complete upgrading and modernization may not be available and it always become difficult to get approval from higher authorities/Board of Directors. The best course in this case, as per the experience of the author, is to take a step by step approach so that each time the investment cost is maintained within tolerable limits and achieving at the same time considerable improvement. Thus the additional money made by such steps can be further utilized for taking further steps for achieving the final goal of optimum production and upgrading. This was tried in Fujairah Cement Industries (FCI Plant) located at a small town called Dibba in Emirates of Fujairah in United Arab Emirates. This was one of the smallest plants in the whole of the Emirates. Voest Alpine of Austria originally supplied the plant. The kiln was manufactured by Sket of then East Germany, having diameter of 4.6 M and 69 M long with Sket design 5-Stage shaft type preheater having one of the lowest thermal efficiencies. The plant capacity was under utilized with annual production remaining between 450-465,000 tons of clinker per annum.

It was decided to upgrade and modernize the plant facilities and this was done step by step keeping always the investment as small as possible with maximum benefit. The projects were formulated so that they could be executed in the shortest possible time to take advantage of upbeat market. Thus, with the benefit achieved in each step, the next step was taken easily with the additional revenue generated. The present paper describes these step by step approaches taken by Fujairah Cement Industries starting with stabilizing the existing plant and then upgrading and modernizing the plant facility. Thus, making today a plant having largest clinker production facility from a single kiln and one of the most modern plants in the whole of the Emirates.

1. DETAILS OF STEP BY STEP APPROACH ADAPTED FOR STABILIZATION, UPGRADING AND MODERNIZATION OF FUJAIRAH CEMENT PLANT.

As noted in the abstract, Fujairah Cement Industries commissioned in 1992, the following stepwise approach to reach the ultimate goal of increased production with optimum productivity by optimizing the cost of production.

The first step taken was to stabilize and optimize the operation of the existing plant with minor investment solving the existing bottlenecks. The emphasis was given on stable and continuous operation lowering breakdowns or plant stoppages as far as possible. This in itself increased the production by around 10-15% excess of the rated capacity and thus reducing the cost of production as well. From this point onwards, the plant started turning around.

Seeing the boom in the cement market starting around 1993, Fujairah Cement Industries embarked on an ambitious project of expansion and modernization of their kiln line. However, this upgrading was only partial, keeping the capital cost as low as possible. The production was targeted to be increased by 50% at the same time lowering the heat consumption by more than 25-30%. This was done by replacing the shaft preheater with a six-stage cyclone type preheater and incorporating an air through in-line precalciner system. Also, the existing control system through PLC was replaced by Distributed Control System (DCS).

After commissioning the new facilities, production reached around 10% beyond rated capacity. The maximum production reached was around 860,000 tons clinker per year in place of guaranteed 750,000 tons clinker per year. The specific heat consumption came down from average 900-950 k.cal/kg. to around 700-725 k.cal/kg.

The market for cement at this point still continued to be good and Fujairah Cement Industries decided on second step of plant upgrading to take the capacity to One Million tonnes per year. This was done by replacing the air through precalciner system by air separate precalcining system with tertiary air ducts. The first grate of the cooler was modified with a stationery step grate and a third cooling grate was added.

Again this project was completed in record time of just over one year, and after initial teething troubles, the production was stabilized at around 3500 tons per day against a guaranteed production of 3300 tons per day.

At this stage, complete process measurements were made and it was found that pressure drop from the preheater last stage to ID fan was too high. Also ID fan was under utilized. At this time, the oil price also started going up from end of 2000/beginning 2001 and cement price also started dropping due to excess supply in the market and the Far East crisis. At this stage, FCI decided and implemented a dual firing system with provision for firing coal/petrocoke or other solid fuel as a substitute for oil, keeping the oil firing intact. Together with this, the ducting, from stage 6 to ID fan, diameter was increased to reduce the pressure drop. After completing this project in May-June 2001, today FCI is kiln is the only one in Gulf, even probably in the Middle East, being operated with 100% coal firing. Together with this, the daily average daily output has been taken to 4100-4150 tpd.

FCI has not stopped here and is already planning to take further cost saving measures in the future and if possible further increase in the production at a future opportune moment when again the market starts going up.

2. STABILIZATION OF THE EXISTING PLANT

The initial plant commissioned in 1982 was found to have mostly 3 main problems, namely, increasing vibration of ID fan due to build-up, build-up in the inlet of the shaft preheater due to high alkali and continuous snow man formation in the cooler. These problems were solved by strengthening the ID fan foundation, putting selective air blasters in the preheater to avoid build-up and also by putting air blasters in cooler to break/avoid snow man formation. By this, production could be optimized and 1990 onwards production reached around 540-560,000 tons of clinker per

year. With a single cement-grinding mill, it was difficult to cope with the market requirement and thus the cement-grinding mill was modified by replacing the old Sturtevant separator with a high efficiency separator.

3. FIRST UPGRADING PROJECT

Seeing the boom in the market the first project of upgrading was commenced at end 1993/beginning 1994 and executed over one year to complete the project in middle of 1995 in record time. Only five weeks shutdown was taken to connect the new facilities to the existing plant. The emphasis on this project was to increase production and at the same time reduce the cost of production by lowering heat consumption with the introduction of more modern technology. With this project, the kiln capacity was designed to be increased by 50% from the existing 1600 tpd to 2500 tpd at the same time to reduce the heat consumption by more than 25-30% from level of 900-950 kcal/kg of clinker in the past to around 700 kcal/kg of clinker guaranteed. Krupp Polysius was selected for detail engineering as well as supplying the main machinery. UB Engineers of India was selected for fabricating steel structures and normal steel items and for erection of the plant.

Krupp Polysius supplied the following:

- Kiln feed system with new AEROPOL for feeding kiln at the higher output.
- 6 stage DOPOL-90 Preheater with PREPOL AT in place of the existing Sket shaft preheater.
- New I.D. fan with new exhaust gas duct. ID fan was driven by a VFD in place of old D.C. motor.
- Oil fired Precaliner burners.
- Enlarged kiln inlet section to reduce the velocity at inlet.
- Increase Kiln speed increase 2 to 2.7 rpm by putting a new gear box and girth gear and pinion.
- Modification of the existing clinker cooler with larger throat, jet ring plates and different cooling air fans.

A vertical roller mill with 80 tph capacity was added to meet the additional demand of raw meal keeping the existing ball mill operating as it is.

The kiln was back on stream after a short shutdown of five weeks in May 1999. This was a unique achievement with 6 stage preheater of 135 m height, which is one of the tallest industrial structures in the whole of United Arab Emirates and was built in record time of just one year. Within a short period, the kiln reached its rated capacity and in fact it exceeded its design output by more than 10% using the built-in provision kept in the design.

Stage I Operating Results:

	Guaranteed	Achieved
Throughput:	2500 tpd of clinker	2925 tpd of clinker
Heat consumption:	721 kcal/kg clinker	723 kcal/kg clinker
Power consumption:	16 kWh/t	14.28 kWh/t
Clinker temperature:	90 Deg. C above ambient	132 Deg. C above ambient.

The increased clinker outlet temperature has to be seen in connection with the very high clinker throughput. The electrical system was supplied by ABB of Dubai and old PLC with Procontic computer was replaced by a Distributed Control System with kiln and mill operation controlled through colour monitors and an operating station recording and logging all the parameters and giving commands for plant operation through a keyboard and mouse.

A baghouse was introduced in the kiln and raw mill exhaust system parallel to the existing electrostatic precipitator to take care of increased exhaust gas and the conditioning tower was modified for improved ESP efficiency.

4. UPGRADING AND MODERNIZATION

Seeing the continued upbeat market, it was decided to further upgrade production to one million tonne clinker per annum at the same time emphasizing further cost reduction and introducing greater environment or pollution control. The latest electrostatic precipitator was provided for dedusting of the cooler exhaust air and a further baghouse unit was added for dedusting of the kiln and mill system.

The project design for the kiln line was to incorporate the following:

- New larger kiln feed system with AEROPOL.
- New larger dedusting cyclones on top of preheater.
- New larger I.D. fan.
- Tertiary air duct.
- New Precalciner burners to increase the proportion of oil firing in the calciner from 40-60%.
- Increased Kiln speed increase to 2.7 to 4 rpm.
- New static grate at existing clinker cooler.
- Additional 3rd clinker cooler grate.

To meet the additional demand of raw meal, a new ball mill of 2500 KW was added with combiflex drive having 4.2m in dia. x 9 m long working in tandem with the first ball mill to increase the ball mill output from 110-130 tph to around 210 tph. The actual achieved output was 240-250 tph by changing the grinding media pattern and replacing the old mill liner to have only crushing at this stage and grinding being taken care of in second mill. This tandem operation was done in conjunction with a sepol separator with provision for reject going to both the ball mills.

After a stoppage of around seven weeks, for the tie-in works, as well as changing the kiln roller bearing system, the kiln line went back on stream on March the 15th, 1999. Initial teething trouble was faced by way of a blockage in the riser duct after the calciner and in the first stage preheater cyclone as well as buildup in the tertiary duct at the inlet to the venturi. These were solved by selectively putting blasters in the venturi as well as tertiary air duct and 6 stage cyclone inlet. As the pressure drop across the cyclone was found to be comparatively higher a guide vane was put to reduce the pressure drop. After this, the production became stable and kiln output reached around 3500 tons per day.

Stage II Operating Results:

	<u>Guaranteed</u>	<u>Achieved</u>
Throughput:	3300 tpd of clinker	3500 tpd of clinker
Heat consumption:	700 kcal/kg clinker	742 kcal/kg clinker
Power consumption:	18 kWh/t	16 kWh/t
Clinker temperature:	135 Deg. C above ambient.	145 Deg. C above ambient.

Together with the above project, the second phase of the project also included increasing the clinker grinding capacity by 110 t/h with a Polysius ball mill with Combiflex drive 4.2m dia. x 15.2m length.

5. ADDITIONAL CEMENT-GRINDING UNIT

To take care of additional grinding requirements with the increased clinker output, together with the above second stage kiln upgrading project, another project was undertaken to add a second grinding unit again supplied by Krupp Polysius. The ball mill was of 4.2m dia. and 15.2 m long driven through a combiflex drive. The mill was also equipped with a sepol separator. The output reached was 110-120 tph against guaranteed output of 110 tph. This plant was also commissioned immediately after restarting of the kiln. A Polcid NT DCS system was used this time for controlling the old as well as the new cement-grinding mills.

As mentioned above, Krupp Polysius was the supplier and engineering contractor for both the plants whereas Petron Emirates LLC., based at Dubai was used in second phase expansion for local fabrication of structure and equipment as well as erection. During both the phases, East Coast Contracting based at Fujairah was used for civil construction.

6. CONVERSION TO SOLID FUEL FIRING AND FURTHER OPTIMIZING THE PLANT OUTPUT

After completing the stage II upgrading project in 1999, in the next year, i.e. year 2000, all-time record production figures were achieved which were as follows:

FCI'S RECORD PRODUCTION/SALES YEAR 2000

<u>CLINKER</u> <u>PROD.</u> <u>(TONNES)</u>	<u>CEMENT</u> <u>GRINDING</u> <u>(TONNES)</u>	<u>CEMENT</u> <u>SALES</u> <u>(TONNES)</u>
<u>1,103,705.00</u>	<u>1,112,740.00</u>	<u>1,093,456.50</u>

After enjoying a good market for a period of 7-8 years starting 1991-92, the UAE cement industry, as a whole started sliding down mainly due to over supply of cement in the market and a steep hike in the oil price. At this stage FCI, which was totally dependent on oil firing contributing higher percentage in operating costs decided to make provision for coal/petrocok firing thus reducing the cost. For this, a coal/petrocok crushing and grinding mill was added with two Poldos for firing coal or petrocok to the front burner and calciner. Two solid fuel burners were added in the calciner and the main burner was replaced by a dual fuel burner capable of using, both oil as well as coal or mixture thereof. The calciner loop was extended to ensure complete combustion in case of petrocok firing. Taking advantage of this project, the ducting from stage 6 preheater to ID fan diameter was increased to reduce the pressure drop and the impellor of dopol fan was changed to take care of the additional gas flow from the preheater. This project was again executed in less then one year and complete coal firing was started from 27.06.2001. Polcid NT was included for coal grinding and coal firing system. During this phase of the project, ETA Electric Co. based in Dubai was used for local fabrication of structures and equipment as well as erection including installation of electrical and instrumentation equipment. Once again for civil construction, East Coast Contracting based at Fujairah were awarded the job.

7. CONCLUSION

Thus FCI went on taking step by step movements forward and has not stopped yet. It has always believed in taking the right decision at the right moment to take the best of the market condition at the same time lowering the cost of production so that it can survive even in bad market conditions.

Further studies are in the pipeline for future projects including upgrading the pollution control system, further production upgrade, improving cooler efficiency to reduce heat consumption and considering other alternative fuels, including waste, in the future.

ABSTRACT

The purpose of this paper – to investigate the composite cement, which provides high early strength (40 MPa after 24 hours) with a small amount of high alumina cement (HAC) in comparison with well known binder compositions. The cement with such properties is required for use in thin layer applications for finishing and special building work. The composition meeting such high requirements was made using blast-furnace slag (20-25 %) and Al_2O_3 as an additive. It was shown the effectiveness of using such materials in dry building admixtures for self-leveling floor.

1. INTRODUCTION

It is known that the thin layer technology of using Portland cement includes such special building works, as surfacing interiors and exteriors, tiling, joint filling, and smoothing horizontal and vertical surfaces [1]. This technology makes demands of Portland cement, which are different from ordinary uses of Portland cement in concrete. The common requirement is high water retention in the hardening thin layer due to intensive water adsorption by the sub-floor and evaporation in to the air [2].

Modern technology of using Portland cement solves this problem by using additives of cellulose ether and plasticizers, but the problems of a high early strength, control of deformation and an economic effectiveness are unsolved [3]. It should be noted, that cement compositions for thin layer applications have a high price due to the inclusion of special cements. The combination of those components in one binder system permits it to be classified as “Composite cement” due to its content of one or two inorganic materials, which take part in hydration with the formation of new phases besides Portland cement [4]. Definitely, this classification generally implies the use of mineral active additives, but doesn't exclude using such mineral binders, as Portland cement. HAC and gypsum. Such compositions are very complicated for their high hydration activity and the recipe is very sensitive to deviation from the optimal proportions. Such compositions allow obtaining properties which are needed for the self-leveling compounds in floor preparations. A good example of using composite cements is in dry building admixtures, which are produced by «Henkel Bautechnik (Ukraine)» which distinguishes itself by its high quality from those of other producers [5].

This work researched the effective additives for substitution of HAC in composite cements with the same performances for thin layer applications.

2. OBJECTS AND METHODS

The chemical composition of the binders tested are shown in Table 1. Their properties are shown in Table 2. The composite cements were made by grinding the ingredients to a fineness of 350-420 m²/kg. The cement activity was determined by testing 4x4x16 cm specimens made according to EN 196 with water/cement ratio 0,5. The tests were carried out after 1 and 28 days of curing at laboratory conditions at temperature 20⁰C and relative humidity of 60 %. The deformation was measured to within 0,001 mm/m from the moment of stripping up to 28 days. When analyzing the structure formation processes X-ray phase and differential thermal methods were applied. Mathematic methods were applied to analyzed with obtained data.

Table 1. Chemical composition of binders

Binder		Al ₂ O ₃	CaO	SiO ₂	Fe ₂ O ₃	MgO	TiO ₂
Portland cement 500		8,5	63,4	24,0	4,6	0,9	0,5
HAC	Gorkal 40	39,4	40,5	4,5	15,4	-	-
	Lafarge 40	37,5	39,0	5,0	18,0	-	-
	Istra 40	41,0	39,0	25,0	16,0	1,1	-
Mariupol blast-furnace slag		9,4	45,2	38,8	2,3	3,6	-

Table 2. Properties of ingredients

Binder		Water demand, %	Setting time, h		Strength, MPa Rf/Rc at			
			initial	final	1 day	2 days	7 days	28 days
Portland cement 500		24,2	1-50	3-00	-	3,5 / 18,0	5,5 / 30,0	6,9 / 53,5
High alumina Cement	Gorkal 40	25,0	4-20	4-48	4,5 / 50,7	-	5,6 / 53,9	7,5 / 69,3
	Lafarge 40	26,0	6-10	6-35	4,9 / 59,4	-	6,3 / 64,2	6,5 / 66,0
	Istra 40	27,0	7-00	7-25	7,0 / 68,1	-	6,4 / 70,0	6,3 / 68,5
Gypsum G5		63,0	0-15	0-21	2,8 / 6,5	-	-	-

3. RESULTS AND DISCUSSIONS

The compositions investigated consisted of the following components: Portland cement M 500 (30 to 60 %), High alumina cement M 400 (30 to 50 %) and Gypsum M 5 (10 to 25%). The results of strength tests shows existing large strength variations for such systems even for small changes of composition, as shown in Figure 1. Unfortunately, these data can't fully describe the principles in these 3-components system.

Figure 1. Analyses of 3-component cements (above the bars are shown the content of HAC)

The mathematical analysis of the data obtained was used for the determination of the principles and properties. This method required 10 experiments according to the following plan for 3-component systems (Table 3).

Table 3. The plan of 3-component experiments

Test No	Component PC500	Component HAC	Component GGBS	Rc, 1 day
1	0,000	0,333	0,667	15,8
2	0,667	0,333	0,000	24,3
3	0,333	0,333	0,333	10,1
4	0,333	0,000	0,667	4,2
5	0,000	0,667	0,333	58,3
6	0,000	1,000	0,000	54,1
7	0,333	0,667	0,000	45,8
8	0,000	0,000	1,000	5,4
9	1,000	0,000	0,000	10,3
10	0,667	0,000	0,333	9,2

After processing the early strength results, the following graphics model depicts the response surface for the 3-components composition.. Figure 2 shows the strength fields of the investigated systems.

Figure 2. The response surface # 1

This surface is described by the next regression equation, which was obtained after analyzing the data from Table 3.

$$\mathbf{Rc, 1\ day} = 9,8*\mathbf{Comp_A} + 58,9*\mathbf{Comp_B} + 1,2*\mathbf{Comp_C} + 3,3*\mathbf{Comp_A*Comp_B} + 5,6*\mathbf{Comp_A*Comp_C} + 31,7*\mathbf{Comp_B*Comp_C} - 477,1*\mathbf{Comp_A*Comp_B*Comp_C}$$

The observed relationship shows that the compression strength after 1 day depends on amount of component B (High Alumina Cement) and common action of components B (HAC) and C (Gypsum). Their estimated coefficients are accordingly 58,9 and 31,7. The estimated coefficient for common influence of the three components is negative and has very high value. This indicates weak interaction of those components for the compressive strength after 24 h. This fact is confirmed by the absence of peaks on the response surface in Figure 2, which has hollow behavior in the central area.

Improvement of the system reliability was obtained by combining all 21 recipes' results: the sum of the first 11 samples from Figure 1 and the other 10 from Table 3 (Figure 3). The new response surface has some differences from first one and the new regression equation is more complicated.

$$\mathbf{Rc, 1\ day} = 11,9*\mathbf{Comp_A} + 53,5*\mathbf{Comp_B} + 4,8*\mathbf{Comp_C} - 13,6*\mathbf{Comp_A*Comp_B} - 11,4*\mathbf{Comp_A*Comp_C} + 43,0*\mathbf{Comp_B*Comp_C} - 287,1*\mathbf{Comp_A*Comp_B*Comp_C} - 133,9*\mathbf{Comp_A*Comp_B*(Comp_A-Comp_B)} - 23,4*\mathbf{Comp_A*Comp_C*(Comp_A-Comp_C)} + 196,4*\mathbf{Comp_B*Comp_C*(Comp_B-Comp_C)}$$

Figure 3. The response surface # 2

Figure 4. The cantors of response surface # 2

The main activity in the investigated system belongs to component B (HAC) and compatible influence of components B and C (Gypsum). The estimated coefficients are accordingly 53,5 and 43,0. It should be noted that the compatible influence was increased by 25 %.

The obtained results were used as a base for continuance of researching new additives for reduction of the amount of HAC in the composite cement, but with the same early strength.

It is known that milled blast-furnace slag has a positive influence on the time-constant properties of HAC [6]. But thin layer applications demand information about the influence of slag on early strength development. The following results can give an answer on this question (Table 4).

Table 4. Properties of HAC-Slag admixtures

HAC, %	Slag, %	Water demand, %	Initial setting time, h-min	Final setting time, h-min	Compressive strength, MPa		
					1 day	7 days	28 days
100	-	25,20	3-40	3-45	49,7	58,8	68,7
95	5	25,10	3-50	3-55	48,1	56,4	67,2
90	10	24,45	3-50	4-00	49,6	55,2	64,7
80	20	24,01	4-10	4-20	52,4	57,1	65,6
75	25	23,75	4-10	4-25	50,2	56,0	62,3
70	30	23,10	4-15	4-30	48,2	50,1	54,6

These data show that adding of 20-25 % blast-furnace slag to HAC provides the optimum result: the strength of this cement with additive is 5-6 % higher than the pure cement. The setting time is a little elongated but with the same short term between initial and final setting time [6]. Together with this the influence of 30 % slag on the time-constant strength level is not confirmed. Probably, it could be explained by difference in raw materials.

Aluminium oxide Al_2O_3 was used as a chemical additive based on its strong impact on Portland cement. The recommend gel ratio is 1,0 - 1,5 % by the weight of Portland cement. As it follows from Tables 5 and Figure 5, the optimal amount of Al_2O_3 to HAC is 0,5; meanwhile with 0,25 % Al_2O_3 the result is similar

Table 5. The influence of Al_2O_3 on Alumina cement

High Alumina Cement, %	Al_2O_3	Compression strength, MPa After 1 day
100	-	49,7
99,95	0,05%	57,4
99,9	0,10%	61,8
99,75	0,25%	66,7
99,5	0,50%	67,8
99,25	0,75%	61,5
99,0	1%	59,4
98,0	2%	56,7
97,0	3%	55,8
95,0	5%	23,6

Figure 5. The influence of Al_2O_3 on Alumina cement

It could be expected that the combination of slag additives + Al_2O_3 reduces the quantity of HAC in composite cement. But, as it follows from table 5 the addition of Al_2O_3 increases the strength of alumina cement by 5-6 % more, and together with additive of 20 % slag the strength is reduce dramatically, even less then pure alumina cement.

The X-ray and differential thermal researches have shown that the slag retards the hydration of High alumina cement. This fact confirmed by significant quantity permanent CA ($d=0,471$; $0,297$; $0,242$ nm) and CA_2 ($d=0,307$; $0,279$; $0,206$ nm) after 24 h hardening at $20\pm 2^\circ C$. But in the composite system «Portland cement-High Alumina Cement-Slag-Gypsum» the slag function is more constructive, especially during the formation of $Ca(OH)_2$. So, in the system «Portland cement-High alumina cement-Gypsum» is observed the formation of C_3AH_6 ($d=0,776$; $0,568$; $0,390$ nm), which is known for its negative influence on binder composition. Meanwhile, the phase C_2AH_8 is forming ($d=0,350$; $0,288$; $0,269$; $0,256$ nm) and the phase C_3AH_6 is not identified. Probably, the formation of C_2ASH_8 and of $Al(OH)_3$ cause this positive effect. This way of hydration is confirmed by capture of heat on DTA: three-steps endothermic effect at $140^\circ C$, $175^\circ C$ and $280^\circ C$. This effect ended at the high temperature of $380-400^\circ C$.

It was roughly difficult to identify the products of hydration in the system «Portland cement-High alumina cement-Gypsum» with additive Al_2O_3 . But generally it is obvious that the hydration goes in the same way due to its developed specific surface. The phase C_2AH_8 is the most common in the products of hydration.

So, it could be two types of recipes with using the low amount of high alumina cement.

1. using 20-25 % of milled blast-furnace slag
2. using 0,25-0,5 of Al_2O_3

Figure 6 shows the hardening development of these binders. So, the most effective is using the chemical additive of Al_2O_3 from the technical and technological aspects. However, the binder with milled blast-furnace slag is cheaper and has acceptable strength.

Figure 6. The strength development of investigated composite cements

The deformation processes in this system have similar behaviors and their values are reasonable. Investigated composite cements were used in thin bed mortars for leveling compounds, which consisted of sieved fillers and organic additives.

Figure 7. The shrinkage development of investigated composite cements

Based on this investigation of composite cements the leveling compounds were prepared and tested. The properties of leveling compounds with the developed composite cements are given in Table 6.

Table 6. The properties of leveling compounds

Properties	The leveling compounds					
	M0	M1	M2	M3	L1	L2
Amount of slag, %	0	10	20	25	-	-
Amount of Al ₂ O ₃ , %	-	-	-	-	0,25	0,5
Flow properties, cm after 10 min	26,5	26,0	25,0	25,0	26,0	26,0
Working time, min	35	30	30	30	30	30
Initial setting time, min	54	62	65	66	52	50
Final setting time, min	62	70	72	75	58	55
Compression strength, MPa after 1 day	17,5	16,5	16,3	13,4	16,5	16,8
3 days	20,4	18,2	17,9	14,9	18,9	20,1
7 days	26,2	24,2	23,2	15,5	23,8	23,5
28 days	33,1	29,2	32,0	31,6	32,1	33,1

4. CONCLUSIONS

- Composite cement with Portland cements, High alumina cement and gypsum provide high early strength during hardening, when the optimal proportion of components is well adjusted.
- Beside the well known stabilizing influence of slag on HAC, it was shown that 20-25 % of lime-base milled blast-furnace slag has a beneficial effect on strength development of Alumina cement after 1 day. It permits reductions of the amount of expensive Alumina cement in composite cement without early strength reduction.
- It was determined that the influence of 0,5 % Al₂O₃ on the structure formation of HAC, is more effective than its influence on PC.
- The observed compounds are effective for using in thin layer applications in dry mixtures for leveling floors.

ABSTRACT

In the present study the pozzolanic behaviour of glass powder was investigated. Coloured container glass was crushed and milled in to two finesses. Mortars or pastes containing lime or cement and glass or fly ash were made. The structure of the pastes and mortars were analysed by SEM and the compressive strength of mortars was measured. Comparable investigations were made with a fly ash (PFA). At early ages CSH phases were detected on the surface of the glass particles. With similar particle size distribution the compressive strength from mortars with glass powder is lower than that of mortars with fly ash. To reach comparable compressive strength, glass powder must be ground very fine ($> 500 \text{ m}^2/\text{kg}$).

1. INTRODUCTION

Glass can be recycled many times to produce new glass. For this reason, in many countries used glass containers are collected and returned back to the glass producer. There are two cases in which waste glass can't be sent back to the glass producer: Firstly when there is a high content of impurities like ceramics in the recycled glass, secondly when there is a surplus of mixed coloured glass.

These cullet usually go to landfill or can be used as road material. Furthermore there are the possibilities for using waste glass in building materials for example as aggregate in concrete, cast stones or tiles. With glass as aggregate, special coloured effects can be obtained at the surface of the concrete or the tiles. However, by using glass as aggregate in concrete or cast stones often alkali-aggregate-reactions were observed [1], [2], [3].

Another way is the use of ground waste glass as pozzolanic addition for cements. Pozzolans (natural or industrial) are high in (reactive) SiO_2 and often also Al_2O_3 . Mixtures with water and CaO produce C-S-H at ordinary temperatures [4]. Well known and mostly used in the concrete production as pozzolan is fly ash (PFA). Until today, glass powder as pozzolan is only used on laboratory scale. In accordance to ASTM C 618, the chemical composition of glass meets the basic requirements ($\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3 \geq 70 \%$). Because of the high content ($\geq 10 \%$) of Na_2O it does not conform to the optional requirements.

Sugita et al. [5] produced mortars with OPC and glass powder addition up to 20 %. The final setting was prolonged and the strength after 28 days decreased. The addition of glass powder with a higher specific surface and 0.5 % NaOH caused a better strength and the average pore radius was lower. Sugita deduced that the glass cannot be activated under normal alkalinity of Portland cement hydration. Archibald et al. [6] used fine ground container glass as a partial pozzolanic replacement for normal Portland cement in various types of back fill. After 224 days slurry backfill materials

with ground glass showed equivalent or even better backfill strength characteristics. Dyer [7] determined that glass undergoes a pozzolanic reaction when combined with cement and the expansion caused by ASR can be reduced by using glass powder. Shao [8] also used fine ground glass as addition for concrete. The used glass was from fluorescent lamps and contained 1 % B_2O_5 . The glass was sieved in three size classes and the pozzolanic activity tested in accordance to ASTM C 593. Only the glass that was smaller than $38\ \mu m$ satisfied the requirements in compressive strength. The expansion by ASR was reduced by all glass fractions. By using fine ground glass and glass as aggregate in concrete, there was a strong expansion by ASR [1], [3]. Meland tested the long time durability above water in a closed container and Warianka at $40^\circ C/100\%$ humidity, while Dyer and Shao used the short time test according to ASTM C 1260 without glass as aggregate.

In the present study the pozzolanic behaviour of glass powder was investigated. Glass cullet from coloured container glass were crushed and milled into different finenesses. Investigations concerning the lime-pozzolan-reaction were made in accordance to the ASTM C 593 and to the German standard DIN 51043. Pastes from cement and glass powder were stored under water and analysed by SEM at different times. Key objective was the observation of the contact zone cement-glass and the condition from glass particles. Furthermore the strength development from mortars according to the German standard DIN EN 196 with a cement replacement up to 50 % by glass powder or fly ash and fine ground quartz as reference was investigated. Because of the small particle size of the glass powder a damaging alkali-silica-reaction must not be expected [9].

2. PHYSICAL AND CHEMICAL PROPERTIES

The physical and chemical properties of cement, glass powders, fly ash and quartz powder are shown in Table 1 and Table 2.

Figure 1. Particle size distribution

According to Blaine, glass powder 1 and fly ash have nearly the same particle size distribution and specific surface. The specific surface for fly ash according to BET is nearly four times higher than that of glass powder 1 and three times higher than that of glass powder 2.

Table 1. Physical properties

	Density	Specific surface		Average particle size
		Blaine	BET	
	[kg/m ³]	[m ² /kg]		[μm]
CEM I 42,5 R	3160	430	n.d.	10,8
Glass powder 1	2560	300	500	13,2
Glass powder 2	2560	540	700	7,1
Fly ash	2210*	310	1900	14,3
Quartz powder	2620	520	n.d.	6,6

3. EXPERIMENTS

3.1 Glass-Lime-Reaction

Mortars containing lime and glass powder or fly ash were made according to German standard DIN 51043. The mortars were stored 4 days at 20°C and 95 % humidity and after demoulding they were cured for 24 days in water of 20°C. The strength was measured after 24 days under water. Mortars with fly ash and lime disintegrated within the first hour. Investigations about the structure of the mortars were made with SEM. The results are presented in Table 3 and in Figures 2 to 6.

Table 3. Compressive strength from glass-lime-mortars according to German standard DIN 51043

mixture	flexural strength	compressive strength
	[N/pa ²]	
lime/fly ash	-	-
lime/glass powder 1	1,7	4,6
lime/glass powder 2	3,3	9,3

After 28 days the mortars must reach a minimum compressive strength of 5 N/pa. Mortars with glass powder reach 4.6 N/pa² and 9.3 N/pa². According to the German standard 51043 only glass powder 2 meets the requirements.

Also mortars containing lime (180 g), glass or fly ash (360 g) and German standard sand with a water-cement-ratio of 0.28 were made and cured according to ASTM C 593. Mortars with fly ash reached the highest values in compressive strength after 7 days storage at 54°C. The results are given in Table 4.

Table 4. Flexural and compressive strength from lime-glass-mortars after 7 days at 54°C

mixture	flexural strength	compressive strength
	[N/pa ²]	
lime/glass powder 1	1,6	6,7
lime/glass powder 2	2,3	9,2
lime/fly ash	3,1	11,3

Figures 2 and 3 show mortars with lime and glass or fly ash after the setting on air at 20°C and 95 % humidity. On the surface of the glass particles first CSH phases can be seen. On the surfaces of the spherical fly ash particles there are less or no CSH phases.

Figure 2. Mortar with lime and fly ash after 4 days at 20°C/95 % humidity

Figure 3. Mortar with lime and glass powder 1 after 4 days at 20°C/95 % humidity

Figure 4. Mortar with lime and fly ash after 4 d at 20°C/95 % humidity and 24 days under water

Figure 4 shows the reason for the decomposition of the lime/fly ash mortar. In some places there are no contact-zones between the lime and the fly ash. There is nearly no corrosion on the surfaces of the fly ash particles. The lime is carbonated and there are no CSH phases between lime and fly ash.

Figure 5. Mortar with lime and glass powder 1 after 4 days at 20°C /95 % humidity and 24 days under water

Figure 6. Mortar with lime and glass powder 2 after 4 days at 20°C /95 % humidity and 24 days under water

Figure 5 and 6 show mortars with lime and glass after 24 days under water. The surface of the glass particles is corroded and there are CSH phases on the surface or between the glass particles.

3.2 Glass-Cement-Reaction

Pastes of cement with 25 % replacement of cement by glass with a particle size from 90 to 125 μm were made. The particle size of the glass was selected to find easily the glass particles by SEM in the cement paste. The water-cement-ratio was 0.28. The pastes were stored one day at 20°C/95 % humidity. After demoulding they were stored under water. At different times a sample was dried and examined by SEM. The results are presented in the Figures 7-11.

Figure 7. Glass-cement-paste, 2 days

Figure 8. Glass-cement-paste, 2 days

At the age of 2 days there are a few CSH phases on the surface of the glass particles. The edges of the glass particles are sharp. Particular at rough edges accumulations of CSH phases can be found. At the age of 28 days there are more CSH phases on the surface of the glass particles. The surface of the glass particles is more corroded. The edges are lacerated.

Figure 9. Glass-cement-paste, 28 days

Figure 10. Glass-cement-paste, 91 days

At later ages often cracks between the glass and CSH phases are detected. Partially the cracks go through the glass particles. On the surface of the glass particles CSH phases can be detected, Figure 11 (1 = glass, 2 = CSH).

Figure 11. Glass-cement-paste, 182 days

3.3 Glass-Cement-Mortars

Mortar prisms according to DIN EN 196 part 1, were made with CEM I 42.5 and up to 50 mass-% cement replacement by glass powder or fly ash. After one day the specimens were demoulded. The specimens were cured under water. The compressive strength was measured up to the age of 365 days.

Water demand and setting time were measured according to DIN EN 196. The values for pastes with 25 mass-% cement replacement by glass powder or fly ash are given in Table 4. The water demand of the cements with the additions is not significantly different to that of the pure cements. The setting time is, as expected, higher for the cements with the additions. The final setting time of all binders was shorter than 12 hours.

Cement replacement by 25 % fly ash and glass powder 1 cause none or only a small increase of the mortar spread. Cement replacement by glass powder 2 gives a marked increase of 1 to 1.5 cm.

Table 5. Water demand, setting time and mortar spread of mortars with 25 mass-% cement replacement by glass powder or fly ash

	Water demand	Setting time	Mortar spread
	[%]	[min]	[cm]
CEM I	28,3	135	17,4
CEM I + fly ash	28,7	180	17,8
CEM I + glass powder 1	28,1	150	17,8
CEM I + glass powder 2	28,3	165	18,6

Figure 12. Compressive strength from mortars with 10 mass-% cement replacement by glass or fly ash

Figure 13. Compressive strength from mortars with 25 mass-% cement replacement by glass or fly ash

Figure 14. Compressive strength from mortars with 50 mass-% cement replacement by glass or fly ash

First of all the replacements of cement by fly ash or glass powder reduces the compressive strength. Up to the age of 90 days, mortars without cement replacement reach the highest values. At higher ages, mortars with 10 and 25 mass-% cement replacement by fly ash and glass powder 2 reach nearly the same or even better compressive strengths as mortars without cement replacement. Glass powder 1 reacts very slowly. After 180 days mortars with glass powder 1 reach about 90 % compressive strength of the mortar without replacement.

The compressive strength from mortars with 50 mass-% cement replacement is, up to 90 days, very low. After 180 days mortars with 50 mass-% glass powder 1 reaches 37 N/pa². Mortars with glass powder 2 and fly ash show nearly the same values (58 and 60 N/pa²) for the compressive strength.

However in contrast to mortars with 10 or 25 mass-% replacements, the mortar with glass powder 2 reaches higher values.

4. CONCLUSIONS

Fine ground container glass reacts as a pozzolan when combined with lime or cement. At early ages there are still reactions between the glass powder and the cement and lime respectively. CSH phases can be found on the surface and especially at rough edges of the glass particles. At later ages cracks are often found between the glass particles and CSH phases and particularly through the glass particles. A similar phenomenon was described by Pickel [10]. He used glass as aggregate for cast stones. These cast stones were damaged by ASR and loss of the bond between the glass particles and the cement as a result of corrosion of the glass was also detected. In the present case there is no damaging of the samples. So, it can be said that the shrinking during the drying period at 50°C probably causes the cracks.

Both, the reactivity and the strength depend on the particle size of the glass. To reach comparable compressive strength to mortars with fly ash, the glass powder must be ground very fine ($> 500 \text{ m}^2/\text{kg}$). Mortars with glass powder 1, which has a comparable particle size distribution to fly ash, reaches lower, but satisfactory compressive strengths at all ages. A reason can be the higher BET-surface of the fly ash and the higher amount of hydraulic components.

When mixed with lime, glass reacts pozzolanic at normal conditions. After four days storage at 20°C/95 % humidity glass-lime-mortars can be cured under water and are stable. The compressive strength depends on the particle size of the glass powder. With a heat treatment the compressive strength of glass-lime-mortars with coarse glass was improved.

The investigations show, that glass can be used as a pozzolanic material for concrete or lime mortars. At the present there are still some open questions concerning the influence of fine ground glass on ASR and chemical resistance on mortars or concrete. These questions are part of the current investigations.

ABSTRACT

This paper reports different aspects of the measurements of particle sizes of fine dispersed materials, like cement or mineral admixtures. The most important prerequisites for correct measurements of particle size distributions of these materials are the sampling and the complete dispersing. In the example of a fly ash, the specific features of the sampling of powders with very broad particle size distributions are explained. Because the mass of the sample is limited by the measuring technique the problem arises that the sample is not representative with regard to the coarse particles. To overcome this problem and to get a representative result, it is only possible if a lot of separate runs with an new sample is carried out. So the analysed quantity of sample is increased indirectly.

With regard to materials in the submicron range, the deagglomeration is the most important prerequisite for correct measurements. By a treatment with ultrasonic waves the agglomerates in the sample must be destroyed, thus to analyse the primary particles. The necessary duration of the treatment is reached if no further changes of the particle size are detectable. In the example of silica fume, the results of particle analyses based on light scattering agree with that of ESEM-analyses. With this example, it is shown that a complete deagglomeration can be achieved even for very fine powders which tend to the formation of agglomerates, provided that the sample is stressed by a suitable treatment.

Particle size analyses are also suitable to detect interactions in suspensions of different materials:

- In mixtures without interactions the measured particle size distributions must agree with those distributions calculated from the basic materials and the portions in the mixture.
- In mixtures where interactions occur, there is no agreement between measurement and calculation.

Furthermore, the changes of the particle size due to the reaction between water and cement in the early period of hydration can be observed in situ. Although not all measured effects are clear, a change of the particle size distribution and an increase of the mean particle size was found to be in agreement with the fact that the size of the hydration products is larger than the size of the original cement particles.

1. INTRODUCTION

The particle size distribution of cements and mineral admixtures is an important factor for the controlling of the properties of cement and concrete. Thus, the workability and the strength development can be influenced. Furthermore, a wide range of binders for different fields of application can be manufactured by the modification of the fineness.

The most usual method to describe the fineness of a cement is the measurement of the specific surface area. This surface area is an integral parameter and gives no information about details of the size distribution. That's why nowadays the particle sizes are characterised with complete distributions analysed with laser light diffraction or laser light scattering. Reliable results can be achieved if the influences of the sampling and the preparation of the sample are taken into consideration as shown in the first part of this paper.

The standard measurements do not exhaust the potential of the measuring technique. In the second part examples for sophisticated measurements are described. So it is possible to obtain changes of the particle size as a result of an interaction between components of a mixture or to observe the change of the size of the cement particles during the first stage of the hydration in situ.

2. EXPERIMENTAL PROCEDURES OF PARTICLE SIZE ANALYSES

2.1 Method of Analysis

The presented results of this paper were measured with the instrument COULTER® LS 230. This instrument analyses a range of particle sizes from 0,04 to 2000 μm without the need to make changes in the optical bench or the lens system. In the range above 0.4 μm the theoretical basis of the measurement is the Fraunhofer-theory of laser diffraction. In the range of particle sizes smaller than 0.4 μm the Mie-theory of light scattering is used (Figure 1). Altogether 116 size channels are available for the complete analysis with 151 detectors. The measurement is carried out in a liquid. This means that the sample must be dispersed in a suitable liquid before it is analysed.

Despite the continuously increasing automation of the particle size analyses it is possible to get different results in dependence of the preparation of the specimen. For coarse-grained materials the sampling and the splitting of the sample are the most important steps during the sample preparation. For fine-dispersed materials the process of disintegration of agglomerates is the key factor for reliable and reproducible results.

Figure 1. Standard measurement - particle size distribution of cement and different mineral admixtures

2.2 Sample preparation

The sample mass that is needed for the measurement of particle size distributions in general depends on the maximum particle size and the measuring method that is used or that is realised in the used instrument used. In the case of the measuring of broad distributions with the method of laser diffraction both effects have contrary tendencies. Broad distributions require a sufficient

quantity of sample, to ensure that coarse grains are also present in the sample in a representative manner. In contrast, the method of laser diffraction requires a very small sample, since it should reduce the total intensity of the laser light only slightly. Only so, it is possible to determine properly the signals at the various channels that correspond to the particle size. In the following example these influences are demonstrated and a strategy of minimising errors is explained.

In Figure 2, the particle size distribution of a fly ash of lignite is shown. The mass of the sample was about 50 mg. The sampling was done with the so-called “shovel method” since such a small sample cannot be obtained with sample dividers. The reason for the small mass of the sample follows from the high portion of fine material in this sample that causes a considerable reduction of the total light intensity. Therefore it is possible that the few coarse particles are not contained in the sample representatively.

This is the reason for the considerable deviations in the range above 400 μm between the single measurements with a new sample as shown in Figure 3. The differences depend on the random number of coarse particles in the sample. To overcome this effect and to obtain a representative result, it is only possible if a large number of separate runs with a new sample is carried out. So the analysed sample mass is increased indirectly.

Figure 2. Particle size distribution of a fly ash from lignite

Figure 3. Detail of particle size distribution - maximum and minimum deviations of the measurements from the mean value

For the measurement of the particle size distribution of fly ash in Figure 2, nine separate runs were done. The single results are the basis of summarized result calculated as an average. In addition, a sieve analysis was carried out in the particle range $> 400 \mu\text{m}$. This should always be done as confirmation of the results.

2.3 Dispersing of the sample

For fine-dispersed materials it is most important to deagglomerate them sufficiently. This means that the forces of attraction that act between the small particles and increase with decreasing particle size have to be overcome. Therefore a regime for the sample treatment with ultrasonic waves must be created for each material. Thus the particle size distribution of primary particles is obtained and a good reproducibility of the results is achieved.

For most of the fine bulk materials a treatment for 2 to 4 minutes with a disintegrator driven by ultrasonic waves is enough. For silica fume as the finest material with particle sizes below $1 \mu\text{m}$ that is used in the construction industry no distribution of the primary particles can normally be achieved. From extensive experiments with altogether 15 different samples of silica fume it was found that the silica fume has to be treated for 9 minutes with ultrasonic waves.

The deagglomeration of a sample volume of about 20 cm^3 was done with a power of about 42 W in intervals of 3 minutes. Thus a too large heat development could be avoided. The influence of the time of treatment on the different characteristic particle sizes x_{10} , x_{90} and the mean particle size x_m is shown in Figure 40 at the example of one sample of silica fume.

Figure 4. Influence of the time of ultrasonic treatment on the particle size distribution of silica fume

From this graph follows that the smallest particle sizes are measured after a treatment of 9 minutes. Then the particle size is unchanged also by the further input of power, i.e. the deagglomeration seems to be finished. In Figure 4, each point drawn is the mean of 3 separate runs for getting a sufficient statistical reliability.

Figure 5. Particle size distribution of silica fume measured by Laser light scattering and ESEM-images [3]

A comparison of two distributions is shown in Figure 5, on the one hand measured on the basis of the Mie-theory with laser light scattering, and on the other hand calculated on basis of ESEM-images by a particle count. The prerequisite for such a direct comparison is that the compared particles are spherical which is true for silica fume. From Figure 5, it follows that a complete deagglomeration can be achieved even for very fine powders, which tend to the formation of agglomerates, provided that the sample is stressed by a suitable treatment. Then the distribution of the real primary particles is measured.

3. STANDARD MEASUREMENTS OF PARTICLE SIZE DISTRIBUTIONS OF CEMENTS AND MINERAL ADMIXTURES

The properties of cements can be controlled by their fineness. Since this tool is most practicable in the cement manufacturing process, a considerable number of different cements is offered nowadays which mainly differs in the particle size distribution. In Figure 6, a selection of cements with different fineness is shown, and from the evaluation of a large number of further measurements, the ranges of particle size that are typical for different types of cements can be summarised below.

The mean particle sizes of cements are in the following ranges:

- for Ordinary Portland Cements 18 to 26 μm (CEM I+II 32,5R)
- for High-early-strength Cements 12 to 18 μm (CEM I 42,5R)
- for Very high-early-strength Cements 9 to 10 μm (CEM I 52,5R)
- for Special highly fine Cements, i.e. Microcem. 2.5; 3.1; 5.2; 8.0 μm

Figure 6. Particle size distributions of different cements [5]

As another possibility for the influencing of the properties of cement, the addition of blending materials or mineral admixtures must be named. The most important admixtures are industrial by-products that result in powders. These materials have particle sizes in the following ranges:

- Fly ash is characterized by particle sizes between 0.1 and 1000 μm , the mean particle size is between 23 and 67 μm .
- Silica fume is characterized by particle sizes between 0.02 and 1 μm ; the mean particle size is about 0.3 μm .

Limestone will be also interground or added as powder to the concrete. Added powders are characterized by particle sizes between 0,05 and 200 μm , the mean particle size is between 6 and 23 μm .

4. SOPHISTICATED MEASUREMENTS

4.1 Measurement of interactions between components of mixtures

In addition to standard measurements the measuring technique of particle sizes can be used also to check if interactions between components of mixtures take place.

If there are no interactions, then the measured particle size distribution must be the same as that which is calculated by mixing the distributions of the components. This is demonstrated by the example of a mixture from natural plaster plus REA-gypsum in Figure 7.

Figure 7. Particle size distribution of natural plaster and REA-Gypsum and a mixture of both with a ratio of natural plaster to REA-Gypsum of 1:1,5

If interactions between components take place, or reactions occur then the measured distribution does not agree with the calculated one. The example of a polymer-modified cement shows such considerable deviations between measured and calculated distributions as a result of an interaction. The particle size distributions of the separate components of polymer and cement are shown in Figure 8.

Figure 8. Particle size distribution of cement and polymer

Figure 9. Particle size distributions of polymer-modified cement - comparison of measurement and calculation [4]

The components were measured under the same conditions as the mixtures. The distribution of the mixture differs widely from the calculated distribution (Figure 9). A considerable coarsening takes place compared with the theoretically calculated mixture. Especially the first peak at 0,1 μm of the calculated distribution that is caused by the polymer does not appear in the measured distribution. It must be assumed that the polymer is fixed on the surface of the cement particle somehow.

4.2 Hydration of cement

The changes of the particle size distribution in the early period of hydration of cement can be observed in situ if the measuring regime is fitted to this special question. The most important difference compared with the standard measurements is the use of water instead of isopropanol as measuring liquid because the cement particles will react with the water in contrast to the standard measurements where such a reaction is not desired. Two different kinds of preparation methods were applied. For the one method a suspension with a water-cement ratio of 8 was used. Then the hydration could be observed for about 480 minutes. The other method was carried out with a paste with $w/c = 1$. Then the changes of the particle sizes due to the hydration could be measured for about 60 minutes, before the setting process began. The particle size of the Portland Cement at the starting point (time zero) was analysed in isopropanol in order to exclude reactions.

With the dynamic particle size measurements the following influences were examined:
fineness of cement:

- temperature of cement-suspension,
- water-cement ratio.

Figure 10 shows the changes of the mean particle size in dependence of the time of hydration of Portland Cements with different fineness and a water-cement ratio of 8. The first contact of the cement with the water results in an increase of the particle size. A period follows, while the particle size decreases. This period is finished after approximately 200 minutes. Then the mean particle size increases again.

Figure 10. Changes of the mean particle size of cement with different fineness during the early period of hydration, suspension with $w/c = 8$

If a finer or coarser cement is analysed, the shape of the plot “particle size versus time of hydration” is very similar. Only the height of the maximums is shifted.

The results of the particle size measurements can be explained with the theories of hydration known from the literature. A decrease of the particle size can be attributed to the through-solution mechanism assumed by Le CHATELIER. An increase may be caused by a topochemical reaction according to the hypothesis of MICHAELIS.

The observed influence of temperature on the growth of the particles can be noted in Figure 11. The acceleration of the process by increasing temperatures is no surprising effect. These results show that the method is able to make visible small differences.

In Figure 12, the results of the suspension measurements and the paste measurements are compared for three cements with different fineness. It follows that the paste measurements have systematically smaller mean particles than the suspension measurements. This difference increases with decreasing fineness. This effect statistically ensured by repeated runs can not be explained till now.

Figure 11. Changes of particle size in dependence of different temperature, PC CEM I 42,5 R, w/c = 8

Figure 12. Influence of different w/c – ratios to the hydration behaviour

5. CONCLUSIONS

In the first topic of the paper the performance of laser based measurements of the particle size distributions of fine-dispersed materials could be shown. If certain prerequisites of the sample preparation are fulfilled then reliable results are obtained even for problematic materials like powders with a very broad distribution or materials with very small particle sizes.

In the second topic new ideas were introduced for the application of particle size measurements and demonstrated by some examples. Obvious conclusions about interactions between the components of a mixture follow from the particle size distributions, measured in the separate components on the one hand and in the mixtures on the other hand.

The in situ measurements of cement suspensions or cement pastes point to a new possibility for the quantitative determination of changes of particle sizes in the early stage of hydration. In this field further investigations are necessary to improve the procedures of sample preparation, to prolong the period in which measurements are possible even in pastes, and to explain some of the measured effects. Furthermore a new method of evaluation must be figured out since the mean particle size as unit of the progress of the hydration is not expressive enough.

ABSTRACT

Mortar specimens were prepared using slag-modified Portland cement and 10% (by weight of mortar) of NaOH-treated rubber particles, smaller than 300 μm , from truck tyres (mainly SBR rubber). Water sorption by capillarity and by immersion, resistance to acid attack, surface of fracture analysis by scanning electron microscopy and flexural strength experiments were performed. Flexural strength was reduced with the addition of the rubber (3.6 ± 0.5 MPa for the specimens with rubber, 6.5 ± 0.8 MPa for the control). On the other hand, advantageous effects of the addition of the rubber were observed on the transport properties of mortar. Sorptivity coefficient was reduced from 0.29 (control) to $0.06 \text{ mm/min}^{1/2}$. By immersion, the amount of water absorbed by the specimens with rubber was reduced in 16 %. A significant decrease in the rate of weight loss by acid attack was observed for specimens with rubber. SEM micrographs showed the presence of microcracks in the specimens and closed pores in the specimens with rubber. These results show that small rubber particles can improve some mortar properties even when used in a high proportion.

1. INTRODUCTION

The ever-increasing volume of rubber waste in landfills from the disposal of used tyres has grown into a serious environmental problem. Because rubber waste does not biodegrade readily, even after long periods of landfill treatment, there is renewed interest in developing alternatives to disposal. One possible solution for this problem is to incorporate rubber particles into cement-based materials. Unfortunately, most research on using untreated tyre rubber in cement-based materials shows that the degree of adhesion is poor, i.e., the rubber-cement interface is weak, leading to poor mechanical properties. [1-7]

In a previous research, we studied ordinary Portland cement pastes with 10% of powdered tyre rubber (35 mesh maximum size). This rubber, a mixture of SBR, natural rubber, polybutadiene, oils, curatives, antioxidants, carbon black, among others, was used untreated and after surface-treatment with NaOH saturated aqueous solution. Mechanical properties such as flexural strength and fracture energy were improved with the addition of these rubber particles, and the decrease in the compressive strength observed was significantly lower than that described in the literature. The rubber-matrix adhesion was improved with the NaOH treatment as observed in the SEM

micrographs, rendering abrasion resistance and water absorption results significantly better than in pastes with the untreated rubber particles. [8]

Extending this work, the surface modification of tyre rubber after the treatment was investigated by HATR infrared analysis, potentiometric titration and contact angle measurements. Infrared analysis of the powdered treated rubber showed a decrease in absorption at 1540, 1450 and 1395 cm^{-1} . This decrease is attributed to the removal of zinc stearate, an additive present in tyre formulations that often migrates and diffuses to the surface, resulting in poor adhesion between the rubber and other materials. The potentiometric titration of the suspension of powdered rubber in 0.1M NaCl showed that more hydrochloric acid was consumed by the untreated rubber, most likely a result of the presence of basic groups on its surface due to the interaction between the zinc salt and the rubber. The contact angle of tyre pieces remained unchanged until 24 hours of exposure to NaOH. The decrease of the zinc stearate on the treated rubber surface can explain the improvement in the adhesion of this material to the cement matrix. [9]

The overall results of these works showed that the use of powdered rubber in cement composites is suitable for engineering purposes. Since cement paste is not commonly used in civil engineering and since ordinary Portland cement is unusual in Brazil, mortar was now prepared with the addition of NaOH-treated rubber to slag-modified Portland cement.

The use of tyre rubber as addition to cement paste (10% in weight of paste) showed satisfactory results in mechanical properties in our previous research [8]. In this work, 10% (in weight of mortar) of NaOH-treated tyre rubber was incorporated into the mortar, which represents roughly 35% of the cement content. This was the maximum amount of rubber that could be added to obtain a reasonable workability with a 0.6 w/c ratio, which is the maximum water amount for a mortar with reasonable mechanical properties. In other words, these mortars should be considered a case of ultimate powdered rubber addition.

2. EXPERIMENTAL

Powdered tyre rubber, supplied by Borcol Industria de Borracha Ltda, Sorocaba-SP, Brazil, 50 mesh maximum size (300 μm), was surface-treated with saturated NaOH aqueous solutions for 20-30 min, at room temperature, under stirring. The mixture was filtered and the rubber was rinsed with water until neutral pH and allowed to dry at room temperature.

Mortar test specimens were prepared with Brazilian slag-modified Portland cement (which contains 6 to 34% of blast-furnace slag), washed natural sand with 2.6 fineness modulus and water. The mixture composition was water/cement ratio = 0.6, sand/cement ratio = 2. For specimens with NaOH-treated rubber, 10% (by mass of mortar) was added to the mixture. The specimens were cured for 28 days at room temperature (25°C) and 100% relative humidity.

Water sorption by capillarity was followed gravimetrically. Cured cylindrical specimens measuring 100 x 60mm were dried at 50°C in an oven until constant weight and placed on a support grating in a dish supplied with a water leveler at room temperature. The water level was sufficient to wet only the lower surface of the test specimens, not more than 5mm or so above the base of the specimen. The lower parts of the sides of the specimens adjoining the inflow face were sealed with an adhesive to prevent absorption into the surface pores. Mass data of each specimen was obtained after several periods of time, until constant weight. Triplicate specimens were used.

Water sorption by immersion was measured using 45 x 30mm cured cylindrical specimens. The specimens were dried at 50°C until constant weight, and then immersed in water at room

temperature. Mass data of each specimen was obtained after several periods of time, until constant weight. Quintuplicate specimens were used.

For resistance to acid attack, cured cylindrical specimens measuring 45 x 30mm were dried at 50°C until constant weight and then immersed in HCl 5% (1.4M). Mass data of each specimen was obtained after several periods of time, until constant weight. The HCl solution was replaced once a day. Quintuplicate specimens were used.

For flexural strength experiments, prismatic test specimens measuring 150 x 25 x 25mm were used. A three-point bend test was performed. These measurements were performed in a MTS model 810 testing machine. A displacement rate of 10mm/min was used. A set of 46 control specimens and a set of 47 specimens with rubber were used.

Scanning electron microscopy (SEM) was used to characterize the bulk region of the mortar specimens prepared. Fractures were obtained from specimen fragments and the samples were sputtered with gold. The SEM micrographs were obtained in a Jeol JSM 840A microscope.

3. RESULTS AND DISCUSSION

The failure of cement materials is governed by a process of microcracking, mainly associated with the interfacial region between the cement and the aggregate particles. These internal cracks can arise, for example, from processing defects such as pores. The uniaxial strength in compression is commonly accepted as a general index of cement material strength. Nevertheless, the flexural test is usually preferred for quality control of pavements, where the cement material is loaded in bending rather than in axial tension.

Figure 1 shows the results of flexural strength for control and specimens containing NaOH-treated rubber. A set of at least 46 specimens was tested in order to calculate the Weibull modulus, the cumulative probability that a specimen fails during stressing in uniform tension (not shown in this work). A reduction of c.a. 45% in flexural strength was observed for specimens with rubber.

Figure 1. Flexural strength for mortar test specimens. In orange: control specimens, in green: specimens with 10% (by mass of mortar) of NaOH-treated tyre rubber particles. Dashed lines indicate the averages.

The high variability in strength shown is probably caused by the presence of a distribution of cracks and other flaws, both in size and position. In direct tension tests the entire volume of the specimen is under applied stress, whereas in the bending test only a small volume of the specimen near the bottom is subjected to high stresses. Figure 2 shows fracture surfaces of the specimens submitted to bending stress, after failure. It is interesting to note that control specimens with different bulk characteristics (a and b) showed the same strength value (5.5 MPa). For specimens with rubber a better value of flexural strength (4.1 MPa) was obtained for a specimen with more defects (c) when compared with the value 3.5 MPa obtained for a more homogeneous specimen (d).

Figure 2. Fracture surfaces of specimens submitted to bending stress, after failure. (a) and (b): control specimen; (c) and (d) specimen with NaOH-treated rubber particles.

In cement technology, strength is the commonly specified property. However, the strength of a hardened cement material is by no means its only important characteristic. Properties such as elastic modulus, impermeability, and resistance to weathering agents including aggressive waters, are directly related to durability.

The amount of water absorbed is related to the porosity of the test specimens and gives a picture of the internal microstructure. An understanding of moisture transport in concrete and mortar is important to estimate their application as a building material and to improve their quality. The primary transport mechanisms by which aggressive substances enter cement materials are diffusion and capillary action, but capillary transport is the dominant entry mechanism. In this sense, the smaller the capillarity, the higher the durability. Figure 3 shows that the addition of rubber particles lowers radically the amount of water absorbed.

Figure 3. Water sorption by capillarity as a function of time, for mortar test specimens with 10% (by mass of mortar) of NaOH-treated tyre rubber particles. Control: mortar only. Room temperature. Results of triplicate specimens.

The sorptivity coefficient (S) characterizes the tendency of a porous material to absorb and carry water by capillarity, and can be obtained by considering the application of Equation 1, where Δw is the increase in weight, A is the cross-sectional area, ρ is the density of water and t is the time. A finite (generally small, positive) intercept, b , is usually found. The origin of this arises from the filling of open surface porosity on the inflow surface and along the sides of adjacent faces. [10, 11]

$$\frac{\Delta w}{A \cdot \rho} = S t^{1/2} + b \quad (1)$$

Figure 4 shows the water sorption per unit area of inflow surface as a function of the square root of the time, as obtained from Figure 3. For the control specimens, a sorptivity coefficient of $0.29 \text{ mm/min}^{1/2}$ was calculated, and for the specimens with the rubber particles, $0.06 \text{ mm/min}^{1/2}$.

Figure 4. Water sorption per unit area of inflow surface as a function of time for mortar test specimens with 10% (by mass of mortar) of NaOH-treated tyre rubber particles. Control: mortar only. Results of triplicate specimens.

This behavior arises from the hydrophobicity of the rubber particles. In channels in which a rubber particle is exposed, a hydrophobic barrier arises, which can even stop capillary ascension, increasing the local interface tension between water and the channel surface. The probability that a rubber particle is in the surface of a channel is roughly the same as that of a sand particle (regarding the mass ratio) since the particle fineness is inside the sand fineness.

Figure 5 shows the results of the sorption of water by immersion, which is also related to the open porosity of the specimens tested. However, water sorption by immersion is always higher than by capillarity, since capillary ascension takes place only in open pores of relatively small diameter. A 17 % reduction in the amount of water absorbed is found for the rubber-containing specimens, meaning that they have fewer pores or that fewer pores are reachable by the water (closed pores or very narrow capillaries). Since the hydrophobic effect is not expected to be prominent in this case, and since the microstructure of both, with or without rubber, mortar specimens shows detachments at interfaces, this effect arises probably from occluded pores.

Figure 5. Water sorption by immersion, at room temperature, as a function of time for mortar test specimens with 10% (by mass of mortar) of NaOH-treated tyre rubber particles. Control: mortar only. Results of quintuplicate specimens.

Figure 6 show micrographs of a typical fracture surface bulk region of a control test specimen (a) and specimens with rubber (b and c). Microcracks are observed in the rubber or sand -matrix interface (transition zone). During early hydration periods, the transition zone is weak and vulnerable to cracking due to differential strains between the cement paste and the aggregate induced generally by drying shrinkage, thermal shrinkage, and externally applied load. [12] Supporting our hypothesis, the presence of closed pores is observed in the specimens with rubber.

The durability of a cement-based material relates to its service life under given environmental conditions. The hydrated cement paste is alkaline and, therefore, acidic waters are expected to be particularly harmful to these materials. Deleterious chemical effects of this acidic attack include leaching of the calcium hydroxide. Acidic fluids will also increase the porosity, thus making the material more vulnerable. Under these conditions, impermeability becomes a primary factor in determining durability.

Figure 6. SEM images of fracture surface of mortar test specimens. (a) Control: mortar only; (b) and (c) with 10% (in weight of mortar) of NaOH-treated rubber particles. Bars: 100 μm . A: sand particle. B: rubber particles. Arrows: detachments or closed pores.

The effect of the addition of rubber on the acid resistance was investigated. Results displayed in Figure 7 show that the rubber particles have a positive effect on the acid resistance. A faster surface

leaching was observed for the specimens without rubber. In this case, the rubber particles act by shielding the mortar inner parts from the incoming acid.

Figure 7. Acid resistance, as a function of time, for mortar test specimens with 10% (by mass of mortar) of NaOH-treated tyre rubber particles. Control: mortar only. Results of quintuplicate specimens.

4. CONCLUSIONS

Very few papers describe the properties of mortars with small rubber particles. In every case, only mechanical properties are measured, which worsens [2,7]. We have shown that the addition of 10% (by weight of mortar) of NaOH-treated tyre rubber particles in mortar reduced the sorptivity significantly, and enhanced the resistance to acid attack, demonstrating the favorable effects of the rubber on the transport properties despite the reduction in flexural strength observed in the specimens.

ABSTRACT

Chloride penetration into concrete is the main cause of the corrosion of steel in concrete structures exposed to chloride-rich environments. Protective surface coatings are increasingly being applied to concrete structures to reduce chloride penetration. In this study, the performance of various surface coatings was evaluated. Most coatings showed good results for the various tests of the performance evaluation. Surface coatings can effectively delay deterioration such as chloride-induced reinforcing bar corrosion.

1. INTRODUCTION

Large-scale concrete structures directly exposed to seawater such as SeoHae Grand Bridge are increasingly being constructed along the coast in Korea. Chloride ingress into concrete followed by reinforcement corrosion and deterioration of concrete is a major problem for many structures under chloride attack. Previous experience emphasized the need for high quality concrete for the assurance of long-term durability[1]. In the case of high quality concrete structures, the typical protection methods against chloride attacks consist of thickening the cover thickness of concrete, using cathodic protection, applying a coating layer on the surface of concrete to reduce the penetration of chloride ions, and using non-corrosive materials, such as epoxy coated re-bars, FRP, corrosion inhibitors etc.

Currently, various types of protective surface coatings are increasingly introduced to reduce chloride penetration into concrete. In applying these materials, however, we have few reasonable standardized programs of tests for evaluating them. Therefore, in this study, the performance of surface coatings for protecting chloride ingress was evaluated, and proper test methods were investigated.

2. EXPERIMENTAL PROGRAM

2.1 Coating Materials

As shown in Table 1, five kinds of surface coating materials have been prepared to investigate the performance of coating materials effectively. Free films and surface-coated specimens were prepared. Free films were prepared by painting only with intermediate and top coating without substrate, and surface-coated specimens were prepared by painting on the substrate. Their painting methods were based on the manufacturer's recommendation. The specimens were cured in open air in the laboratory at room temperature for 28 days (standard condition). For investigation of the performance after accelerated deterioration, the specimens were exposed to the QUV accelerated weathering for 250 hours, seawater(3% NaCl) for 15 days and alkaline solution (saturated Ca(OH)₂) for 15 days.

Table 1. Type of Coating Materials

Specimen	Chemical Component of Coating System				Thickness (μm)**
	Primer	Putty	Intermediate Coat	Top Coat	
AS	epoxy	epoxy	acrylic silicone	acrylic silicone	50
EP	epoxy	epoxy	epoxy	epoxy	250
UR	polyurethane	PCM*	polyurethane	polyurethane	125
AC	acrylic	PCM*	acrylic	acrylic	400
AU	acrylic urethane	acrylic urethane	acrylic urethane	acrylic urethane	100

*Portland Cement Mortar **Intermediate coat + Top coat

2.2 Experimental methods

Various tests employed in this study are summarized in Table 2.

2.2.1 Water penetration test

The water penetration test for surface-coated specimens was performed according to JIS A 1404. 3kgf/cm^2 of water compressive force was applied.

2.2.2 Vapor penetration test

The vapor penetration test for free films was carried out according to ASTM D 1653. Desiccant used was calcium chloride. The specimens were put in the test chamber of $23 \pm 0.6^\circ\text{C}$, and 50–20% R.H., and the weight of specimen was measured every 24 hours for 3 weeks until it became constant.

2.2.3 Chloride penetration test

70–70mm of free films were fixed on diffusion cells. 3% NaCl solution was filled in the one side of the cell and distilled water was also filled in the other side of the cell. The test set-up was kept for 30 days at 20°C in laboratory. After 30 days, chloride ion concentration was analyzed in the distilled water.

2.2.4 Bond strength test

The bond strength test of coatings with concrete was performed in accordance with ASTM D 4541. Bond strength tests under wet conditions were also performed to evaluate the effect of water contained on the concrete surface. The specimens were stored in water for 10 days and then cured for 48 hours in a dry condition before testing.

Table 2. The Tests Used in This Study

Test Method	Specimen Type	Condition*	Remarks
Water Penetration	Surface-coated Concrete	S, AW, N, A	$\sigma_{28}=24\text{N/mm}^2$
Vapor Penetration	Film	S, AW, N, A	
Chloride Penetration	Film	S, AW, N, A	
Bond Strength	Surface-coated Concrete	S, AW, W, N, A	$\sigma_{28}=45\text{N/mm}^2$
Crack-Bridging	Surface-coated Mortar	S, N, A	W/C=0.5
Accelerated Cl^- Ion Diffusion	Surface-coated Concrete	S	$\sigma_{28}=24\text{N/mm}^2$
Freezing-Thawing	Surface-coated Concrete	S	
Carbonation	Surface-coated Concrete	S	

*S : Standard, AW : QUV Accelerated Weathering for 250 hours, W : Wet Condition(JIS A 6909 5.8.3)

N : Seawater(3%NaCl) Immersion for 15 days

A : Alkaline Solution(Saturated $\text{Ca}(\text{OH})_2$) Immersion for 15 days

2.2.5 Crack-bridging test

The crack-bridging test for surface-coated specimens was conducted using Japan Highway's method. The specimens used were one face-coated mortar prisms. The specimens were extended at a speed of 5mm/min. The test was carried out at 20 °C.

2.2.6 Accelerated chloride diffusion test by applying electrical potential

To determine the chloride diffusion coefficient of surface-coated concrete specimens, the rapid test method proposed experimentally by Tang & Nilsson[2] was employed. The effective chloride diffusion coefficient was calculated using equation (1) proposed experimentally as follows:

$$D_{eff} = \frac{RTL}{ZFU} \frac{X_d - \alpha \sqrt{X_d}}{t} \quad (1)$$

D_{eff} : effective chloride diffusion coefficient determined by non-steady state migration test

Z : absolute value of ion valence F : Faraday constant t : test duration

U : absolute value of potential difference R : gas constant T : temperature

L : thickness of the specimen X_d : chloride penetration depth

2.2.7 Freezing-thawing test and accelerated carbonation test

The freezing-thawing test for surface-coated concrete specimens was conducted according to ASTM C 666. Accelerated carbonation tests for surface-coated concrete specimens were carried out at 40 °C, 60% R.H., 10% CO₂ concentration for 4 weeks.

3. RESULTS AND DISCUSSIONS

3.1 Water penetration and vapor penetration

Most coating materials except acrylics had no water penetration. Also, water penetration was not shown after accelerated deteriorating tests such as QUV accelerated weathering (AW), seawater immersion(N) and alkaline solution immersion(A). Acrylic coating materials showed 0.17~0.83ml of water penetration after accelerated deteriorating test (Figure 1).

Figure 2 showed the vapor penetrations of surface coating membranes. The vapor penetration of acrylic coating membrane was much greater than that of the other types. And the results showed larger penetration after accelerated deterioration tests.

Figure 1. Water penetration of acrylics after accelerated deteriorating tests

Figure 2. Vapor penetration of coatings after accelerated deteriorating tests

Figure 3. Cl⁻ ion penetration of various coatings after accelerated deterioration tests

Figure 4. Bond strength of coatings with concrete

3.2 Chloride ion penetration

The results of the chloride penetration test is given in Figure 3. As can be seen, chloride ion penetration increased in accelerated deterioration tests. Especially, the effect of accelerated weathering and alkaline solution immersion was remarkable.

3.3 Bond strength

Figure 4 shows the bond strength of the coatings with concrete. Except for acrylics, most coatings showed over 4N/mm² of bond strength. The results of bond strength tests were similar to those of the water, vapor and chloride penetration tests. Acrylic coatings exhibited much lower bond strength, and the reduction rate after accelerated deterioration tests was more than the other types of materials. The results from accelerated weathering and alkaline solution immersion had a tendency to show less bond strength than those of seawater immersion.

3.4 Crack-bridging test

Figure 5 showed the results of crack-bridging test for various surface-coated specimens. The test results showed that the polyurethane type of coating exhibited much greater tensile strength than any other types, and elongation was much larger for the acrylic type although its tensile strength was very low. The reduction of tensile strength and elongation after seawater and alkaline solution immersion were not so great.

Figure 5. Elongation of coatings after accelerated deterioration tests

3.5 Accelerated chloride diffusion test by applying electrical potential

Figure 6 illustrates the effective diffusion coefficients which took into account the combined effect of coating materials and concrete specimens. Surface-coated specimens showed 10~20 times lower diffusion coefficients than plain specimen without surface coating treatment.

3.6 Freezing-thawing test and accelerated carbonation test

Figures 7 and 8 show the results of freezing-thawing and accelerated carbonation tests for surface-coated concrete specimens, respectively. The surface-coated concrete specimens were found to have good resistance to freezing-thawing and carbonation. The carbonation depth, especially, decreased greatly for surface-coated concrete specimens.

3.7 Discussion

Most coatings showed good results for the various performance evaluation tests. Their performance depended upon the types of coating materials[3]. In this study, acrylics showed poor performance in various accelerated penetration tests. Although the film thickness of acrylics was larger than the other coatings, the results of various accelerated penetration tests were poorer. It seemed that the penetration properties of coatings were affected much more by material characteristics than coating thickness. Figure 9 shows the relationship between chloride penetration and vapor penetration. Good relationship between protecting performances such as chloride penetration and vapor penetration for coating materials was given in this study($R^2=0.83$).

However, acrylic coatings revealed lower bond strength with concrete and protection performance, but larger elongation. It was regarded to be a typical result for elastic material such as acrylics[4]. Protection properties of the films from various harmful factors showed the reverse to the crack-bridging property. Therefore, it is necessary to do further studies to obtain reasonable standardized values for protection and crack bridging properties.

The performance of surface coatings was reduced after accelerated deterioration tests. Figure 9 shows that 250-hours accelerated weathering influenced the penetration performances of coatings very greatly in this study. However, the field test results for coating materials were limited, the ranking of coating materials according to the results from this study cannot be supported. For correlations with field testing, the field test for surface coating materials were conducted in a marine environment.

4. CONCLUSIONS

- (1) Most coatings showed good results for the various performance evaluation tests. The degree of performance depended upon the types of coating materials.

Figure 6. Effective diffusion coefficient of surface-coated concrete specimens

Figure 7. Relative dynamic elastic modulus of surface-coated concrete specimens

Figure 8. Accelerated carbonation depth of surface-coated concrete specimens

Figure 9. Relationship between Cl⁻ penetration and vapor penetration

- (2) Surface-coated specimens showed 10~20 times lower chloride diffusion coefficients than plain specimen without surface coating treatment. Surface coatings can effectively delay deterioration such as chloride-induced reinforcing bar corrosion effectively.
- (3) Acrylics showed poor performance in various accelerated penetration tests. It seemed that the penetration properties of coatings were affected much more by material characteristics than by coating thickness.
- (4) The performance of most surface coatings was reduced after accelerated deterioration tests. However, the field test results for coating materials were limited, the ranking of coating materials according to the results from this study cannot be supported. It is necessary to study further for correlating accelerated testing with field testing.

ABSTRACT

This study was undertaken to investigate the immobilization of Cr(VI) by cement hydrates, the behavior of the sorption of CrO_4^{2-} for cement hydrates and the leaching from cement hydrates after sorption. The hydrates were ettringite, monosulfate hydrate and the mixture of C-S-H and $\text{Ca}(\text{OH})_2$. The solutions for sorption were prepared to use $\text{CaCrO}_4 \cdot n\text{H}_2\text{O}$ and the pH of solutions were adjusted with $\text{Ca}(\text{OH})_2$ to the equilibrium pH of each hydrate in water. The leaching of CrO_4^{2-} from the hydrate after sorption was also determined.

The relation between equilibrium concentration of Cr and amount of sorption of Cr for CH and CSH was analysed using Freundlich's adsorption isotherm. Test results agreed well with the relation of Freundlich's adsorption isotherm. On leaching, this relationship was found. The CrO_4^{2-} is only slightly adsorbed on ettringite. The amount of Cr sorption on monosulfate hydrate was very large and CrO_4^{2-} was incorporated into monosulfate hydrate.

1. INTRODUCTION

The heavy metals in industrial waste have been immobilized by hardened cement, and a lot of studies on this subject have been carried out. In recent years, the leaching of trace elements from mortar or concrete was studied from environmental standpoint [1].

In trace elements, hexavalent chromium is easy to be leached from cement [2]. CrO_4^{2-} is fixed as a solid solution of ettringites containing CrO_4^{2-} during the hydration of C_3A [3]. But, the sorption of CrO_4^{2-} for cement hydrates has been studied sufficiently.

For the purpose of investigating the mechanism and the influence of various ions on immobilizing and leaching of CrO_4^{2-} , the fundamental behavior on the sorption of CrO_4^{2-} for cement hydrates was examined in this study.

2. EXPERIMENTAL

2.1 Hydrates

The hydrate(ETT) corresponding to ettringite(Aft) and the hydrate(MSH) corresponding to monosulfate hydrate(AFm) were synthesised by the hydration of C_3A and gypsum. The mixture(CSH-CH) of C-S-H and $\text{Ca}(\text{OH})_2$ as obtained through the full hydration of C_3S . After each hydrate was placed in acetone, it was dried in an aspirator at room temperature. And each hydrate was ground to pass 150 μm .

2.2 Measurement of equilibrium pH of each hydrate in water

After 0.5g of each hydrate was stirred in 50ml of fresh distilled water at 25°C for 1 hour, the hydrate was filtered through a 0.45 μ m membrane filter. The pH of the filtrate was measured.

2.3 Solutions for sorption

The solutions for sorption were prepared by dissolving $\text{CaCrO}_4 \cdot n\text{H}_2\text{O}$ in fresh distilled and deionized water. The amount of Cr was about 1/10, 1/100 and 1/1000 mol for each hydrate. And, the pH of the solutions were adjusted with $\text{Ca}(\text{OH})_2$ to the equilibrium pH of each hydrate in water at 25°C

2.4 Measurement of amount of sorption

The method of sorption and leaching is shown in Figure 1. After 0.5g of the hydrates was stirred in 50ml of solution for sorption at 25°C for 1, 2 and 4 days, the hydrates were filtered through a 0.45 μ m membrane filter. The concentration of Cr solution for sorption is shown in Table 1. The amount of Cr in the filtrate was determined by ICP-AES.

Table 1. The concentration of Cr of solution for sorption

Hydrate	Solution (mg/l)		
	I	II	III
CH	183.5	18.35	1.835
CSH-CH	183.5	18.35	1.835
MSH	76.7	7.67	0.767
ETT	36.8	3.68	-

2.5 Measurement of amount of leaching from hydrates after sorption

After the 0.4g of hydrates after sorption was stirred in 40ml of fresh distilled and deionized water which were adjusted with $\text{Ca}(\text{OH})_2$ to the equilibrium pH of each hydrate in water at 25°C for 1day, the hydrates were filtered through a 0.45 μ m membrane filter. The amount of Cr in filtrate was determined by ICP-AES.

Figure 1. The method of sorption and leaching

3. RESULTS AND DISCUSSION

3.1 Hydrates and equilibrium pH of each hydrate in water

The compositions and the equilibrium pH of hydrates are shown in Table 2. The amount of CSH in CSH-CH was calculated by the content of SiO_2 . The amount of CH in CSH-CH was determined by thermal analysis (TG). MSH contained a small amount Aft, and ETT contained 0.288(mmol/g) of gypsum.

Table 2. Compositions and equilibrium pH of hydrates

Hydrate	Compositions (mmol/g)					equilibrium pH
	CH	CSH	AFm(*)	AFt(**)	CaSO ₄ ·2H ₂ O	
CH	13.5	—	—	—	—	12.5
CSH-CH	3.14	3.58	—	—	—	12.5
MSH	—	—	1.35	0.05	—	11.8
ETT	—	—	—	0.713	0.288	10.8

(*) C₃A·CaSO₄·12H₂O

(**) C₃A·3CaSO₄·32H₂O

3.2 Concentration of Cr in solution at various pH

Solutions (Cr:305mg/l) were adjusted with Ca(OH)₂ at various pH, and they were stirred for 1 day at 25°C. The concentration of Cr in solution after stirring is shown in Figure 2. This figure shows that CrO₄²⁻ does not precipitate at high pH.

Figure 2. The influence of pH of solution to the concentration of Cr

3.3 Sorption of CrO₄²⁻ for CH and leaching

The concentration of Cr in solution after sorption for CH is shown in Figure 3 and the amount of sorption of Cr for CH is shown in Figure 4. The sorption of Cr for CH reached the equilibrium at 1 day. The amount of sorption of Cr for CH depends on the initial concentration of Cr in solution.

The relationship between the equilibrium concentration of Cr and amount of sorption of Cr for CH was analysed with Freundlich's adsorption isotherm [Equation (1)]. The result is shown in Figure 5 and it agreed well with the relation of Freundlich's adsorption isotherm. The correlation equation is Equation(2).

$$v = aP^{1/n}$$

$$\ln(v) = \ln(a) + (1/n)\ln(P)$$

where, v : amount of adsorption

P: equilibrium concentration

(1)

$$\ln(v) = 1.394 + 0.572\ln(P)$$

(2)

On the leaching of Cr from CH(s), the relationship between the equilibrium concentration of Cr and amount of sorption of Cr for CH(l) agrees with the relation of Freundlich's adsorption isotherm also (see Figure 5). These results show that CrO₄²⁻ is absorbed on CH with Freundlich's adsorption isotherm.

Figure 3. The concentration of Cr in solution after sorption for CH

Figure 4. The amount of sorption of Cr for CH

Figure 5. The relation between equilibrium and Cr and amount of sorption of Cr for CH

3.4 Sorption of CrO_4^{2-} for CSH and leaching

In the calculation of the amount of sorption of Cr for CSH, the amount of sorption of Cr for CH was corrected.

$$\begin{aligned}
 &[\text{amount of sorption for CSH}] = \\
 &[\text{amount of sorption for CSH-CH}] - [\text{amount of sorption for CH}] \\
 &\text{where, } [\text{amount of sorption for CSH-CH}]: \text{measured} \\
 &[\text{amount of sorption for CH}]: \text{calculated with equation (2)}
 \end{aligned} \tag{3}$$

The amount of sorption of Cr for CSH is shown in Figure 6. The sorption of Cr for CSH reached the equilibrium at about 2 days. And, the amount of sorption of Cr for CSH depends on the initial concentration of Cr in solution, too. The relation between equilibrium concentration of Cr and amount of sorption of Cr for CSH was analysed with Freundlich's adsorption isotherm. The result is

shown in Figure 7 and it agreed well with the relation of Freundlich's adsorption isotherm. The correlation equation is Equation(4).

$$\ln(v) = 3.303 + 0.717\ln(P) \quad (4)$$

On the leaching of Cr from CSH(s), the amount of sorption of Cr for CH was corrected with equation (2). The relation between equilibrium concentration of Cr and amount of sorption of Cr for CSH(l) was agreed with the relation of Freundlich's adsorption isotherm (see Figure 7).

These results show that CrO_4^{2-} is absorbed on CSH with Freundlich's adsorption isotherm similarly to CH, and the CrO_4^{2-} is not incorporated into CSH.

In comparison with equation (2) and (4), the amount of adsorption of Cr for CSH is about 20 times as large as CH.

Figure 6. The amount of sorption of Cr for CSH

Figure 7. The relation between equilibrium of Cr and amount of sorption of Cr for CSH

3.5 Sorption of CrO_4^{2-} for ETT

The concentration of Cr in solution after sorption for ETT is same as initial concentration. From this result, it is considered that the CrO_4^{2-} is hardly adsorbed on ettringite. Isozaki *et al.* found that the Cr^{3+} was incorporated into ettringite, but Cr^{6+} was not incorporated into ettringite [4]. But, this ETT contained considerable gypsum, and it is necessary to discuss the influence of SO_4^{2-} .

3.6 Sorption of CrO_4^{2-} for AFm and leaching

As mentioned in 3.1 and 3.5, the content of AFt in MSH is small and CrO_4^{2-} is hardly adsorbed on AFt. So, it is considered that all sorption of Cr is the sorption for AFm. The amount of sorption of Cr for AFm is shown in Figure 8. The sorption of Cr for AFm reached the equilibrium at 1 day, and the ratios of sorption were 98.0 – 99.5% regardless of initial concentration. In the leaching of Cr from MSH(s) on condition that the initial concentration of Cr was 76.7 mg/l and the sorption time was 4 days, the amount of leaching of Cr is 0.8%. These results show that CrO_4^{2-} is hardly adsorbed

on AFm, but CrO_4^{2-} is incorporated into AFm. The XRD patterns of MSH and MSH(s) are shown in Figure 9. In comparison with MSH, the intensity of AFt of MSH(s) is larger and the intensity of AFm is less. From this result, it is considered that the SO_4^{2-} in AFm is replaced by CrO_4^{2-} in solution, and the reaction of the released SO_4^{2-} and AFm formed AFt. The illustration of these reactions is shown in Figure 9. The sorption capacity of CrO_4^{2-} for AFm is very large, and AFm fixes CrO_4^{2-} strongly.

Figure 9. The XRD patterns of MSH and MSH(s)
(X-ray : CuK β)

Figure 10. The illustration of sorption of CrO_4^{2-} for AFm

4. CONCLUSIONS

The results in the present study are summarised as follows:

- (1) The $\text{Ca}(\text{OH})_2$ and CSH adsorbed CrO_4^{2-} according to Freundlich's adsorption isotherm. CrO_4^{2-} is not replaced in the structure of C-S-H. The amount of adsorption of CrO_4^{2-} for CSH is about 20 times as large as CH.
- (2) Ettringite hardly adsorbed CrO_4^{2-} in solution. This result shows that the CrO_4^{2-} can be fixed in ettringite during the hydration process.
- (3) The sorption of Cr for monosulfate hydrate reached the equilibrium within 1 day, and the ratios of sorption were 98.0 – 99.5% regardless of initial concentration. The amount of leaching is small. SO_4^{2-} in monosulfate hydrate is replaced by CrO_4^{2-} , and CrO_4^{2-} is not leached into water.

PHASE ASSEMBLAGES RELEVANT TO CALCIUM ALUMINATE CEMENTS IN THE MULTICOMPONENT PHASE DIAGRAM, $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-Fe}_2\text{O}_3\text{-MgO-TiO}_2$

Sorrentino, F.P. and Castanet R.

Lafarge, Laboratoire Central de Recherche, 95 rue de Montmurier 38291 St Quentin Fallavier Cedex, France; E-mail: francois.sorrentino@lafarge.com

ABSTRACT

The increase of minor elements, such as MgO and TiO_2 in the raw materials of calcium aluminate cements leads to the crystallisation in large quantities of phases such as $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$ and calcium ferro-titanate. To account for the presence of these phases, the results for phase assemblages found in the system $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-Fe}_2\text{O}_3$ have been extended to the multi-component systems containing MgO and TiO_2 . Experimental data obtained at the laboratory scale allows a description of the compatibility between the phases CaAl_2O_4 , $\text{Ca}_2\text{Al}_2\text{SiO}_7$, $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$, Ca_2SiO_4 , $\text{Ca}_4\text{Al}_2\text{Fe}_2\text{O}_{10}$ and calcium ferro-titanate. Ti replaces Fe in the calcium aluminoferrite and when the amount increases, calcium ferro-titanate is formed. Monocalcium aluminate crystallises in significant quantity (up to 20%) in most of the samples containing $\text{Ca}_2\text{Al}_2\text{SiO}_7$, $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$, Ca_2SiO_4 , $\text{Ca}_4\text{Al}_2\text{Fe}_2\text{O}_{10}$ and calcium ferro-titanate.

1. INTRODUCTION

Control of the cement manufacturing process firstly requires knowledge of the chemistry and the mineralogy of the clinker (i.e. the identity and the percentage of individual phases).

To achieve the optimum mineralogy of a clinker, it is then necessary to calculate the proportion of raw materials. This calculation uses predictive methods that correlate the chemistry with the mineralogy, with assumptions for the process conditions.

The analytical methods for the phase determination are similar for Portland cement and high alumina cement. The methods used are X-ray diffraction [1,2], microscopical point counting (ASTM C 1356), selective dissolution [3], or scanning electron microscopy coupled with EDS analyses [4]. In the case of high alumina cement (HAC), the presence of crystal intergrowths between certain phases results in a major analytical problem for phase identification. This is the case for the phases $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$ with C_2AS [5,6] and for calcium ferro-titanate with calcium aluminoferrite [7].

Concerning Portland cement (OPC = Ordinary Portland Cement), the predictive method is essentially the well known "Bogue calculation" based on the knowledge of the phase diagram $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2\text{-Fe}_2\text{O}_3$ with the assumption of equilibrium conditions and very limited solid solutions (ASTM C 150).

The prediction of the phase percentage is more complicated in the case of HAC, which is produced by melting due to the following reasons: i) the range of compositions for HAC is wider than that for OPC clinker; ii) a wide range of solid solutions exists; iii) the equilibrium conditions are not reached; iv) the presence of minor elements, such as TiO_2 and MgO have a major effect. These reasons render the tentative phase calculation difficult for applications at the industrial scale [8].

A few years ago, we studied the area in the phase diagram $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ and Fe_2O_3 that is relevant to HAC, [9,10]. From these results, it was possible to define different phase assemblages and to calculate the mineralogical composition of HAC. The assumption of equilibrium and the restrictive hypothesis of specific combination of MgO however limited this model of calculation [11]. The non-equilibrium conditions are mainly due to the melting temperature and the rate of cooling, which leads to the presence of variable quantities of glass in the final solid. These conditions have been assessed by theoretical studies and applied industrially [12,13].

The following step is to take into account the influence of minor elements such as MgO and TiO_2 . It is known that Mg is an essential constituent of $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$ (called Q phase) [14]. It must be noted that 1% of MgO (which is common in a HAC) forms 25 % of the Q phase. In addition, the isomorphous replacement of MgO by FeO also contributes to the increased amount of the Q phase.

Titanium (as Ti^{4+}) substitutes Fe^{3+} in calcium aluminoferrite [15,16] and, at higher concentrations, calcium ferro-titanate can form. An average chemical composition of HAC cement made by melting is (as weight %): Al_2O_3 =38.9%, CaO =38.4%, SiO_2 =3.8%, Fe_2O_3 =12.2%, FeO =3.7%, TiO_2 =2%, MgO =1%, represented by a mineralogical composition of CA =44%, C_{12}A_7 =3%, C_2AS =1%, C_2S =5%, Q =2%, glass=8%, calcium ferrite =37%. Therefore, the percentage of TiO_2 , which can be expected in the ferrite phase, is between 5 and 6%

The objective of this paper is to obtain experimental data to describe the compatibility between the phases, $\text{Ca}_2\text{Al}_2\text{SiO}_5$ (C_2AS), $\text{Ca}_4\text{Al}_2\text{Fe}_2\text{O}_{10}$, (C_4AF), CaTiO_3 (CT) and $\text{Ca}_{20}\text{Al}_{32-2n}\text{Mg}_n\text{Si}_n\text{O}_{68}$ (Q) at the solidus temperature. Figure 1 shows the volume (regions of the phase diagram) that has been studied ;

Figure 1. Regions of the phase diagram explored in this study

2. EXPERIMENTAL PROCEDURE

Mixtures have been chosen to cover the phase combinations of the phases shown in Figure 1, i.e assemblages of two phases (CT/Q , $\text{C}_2\text{AS}/\text{Q}$, $\text{C}_2\text{AS}/\text{CT}$, $\text{C}_2\text{AS}/\text{C}_4\text{AF}$, $\text{C}_4\text{AF}/\text{CT}$, $\text{C}_4\text{AF}/\text{Q}$), assemblages of three phases $\text{C}_2\text{AS}/\text{CT}/\text{Q}$, $\text{C}_4\text{AF}/\text{CT}/\text{Q}$, $\text{C}_4\text{AF}/\text{C}_2\text{AS}/\text{CT}$, $\text{C}_4\text{AF}/\text{C}_2\text{AS}/\text{Q}$, assemblages of four phases C_2AS , C_4AF , CT , Q .

The mixtures were prepared by two methods:

- 1) The first method synthesises the phases C_2AS , C_4AF , CT, Q from pure oxides (Merck reagent Fe_2O_3 or Prolabo Al_2O_3 , SiO_2 , light MgO and rutile) and 'Analar' calcium carbonate respectively at $1500^\circ C$, $1350^\circ C$, $1300^\circ C$ and $1250^\circ C$ (the phase Q, $Ca_{20}Al_{32-2n}Mg_nSi_nO_{68}$ was prepared with $n = 3$).

After checking the purity of the phases by X-ray diffraction, the phases are mixed by cogrinding in ethanol (mixtures prepared by this method are named by a single letter in Table 1, ex A, B, C).

- 2) The second method uses the pure oxides, Al_2O_3 , SiO_2 , Fe_2O_3 , MgO, TiO_2 and calcium carbonate as starting material; they are mixed by cogrinding in water for the first mixing and in ethanol for the successive further grinding. (mixtures prepared by this method are named by a double letter eg. AA, BB, CC, .. etc in Table 1)

The prepared mixtures are pressed into pellets and burned in a muffle kiln for 12 hours at the temperatures shown in Table 1. The temperatures are chosen to prevent the formation of liquid but nevertheless to have a kinetic, which enables reasonably fast combination (few hours). After the heat treatment the samples are examined by X-ray diffraction. If the results obtained by the two methods (pure phases or oxides) are different, the mixtures are reground and the procedure is reapplied (pellets/ heat). If the results obtained by X ray diffraction are the same, an examination of polished sections is undertaken using SEM associated with EDS analysis. With the analysis of each phase and the bulk composition, it is then possible to calculate the phase percentages.

3. RESULTS

The results are presented in Table 2 and discussed as follows: (Note: the stoichiometry of the phases is related to one mole of CaO)

Assemblage A, AA: (CT/Q)

At 1285°C and 1320°C, the same result is obtained for A and AA. By XRD and SEM, the major phases found are CT and the Q phase in quantity of 54% and 37%. There is a small amount of CA (5%), C₂S (3%) and C₂AS (1%). The phase percentage is calculated from the mass balance between the chemical composition of the bulk (X-ray fluorescence analysis) and the individual phases analyses by EDS (SEM).

Assemblage B, BB: C₂AS /Q

At 1350°C, the same result is found for B and BB. By XRD and SEM, the major phases found are C₂AS and the Q phase but a small quantity of CA is also detected. The lack of accuracy of the chemical analyses of the C₂AS and Q crystals due to their intergrowth prevents their percentage calculation. As it has been already noted [5], such intergrowths vary in thickness from a few nanometers to a few micrometers. It is thus not possible to have a reliable analysis for these individual phases by SEM/EDS techniques.

Assemblage C/CC: C₂AS /CT

At 1420°C, the results are the same for C and CC. Two phases C₂AS (51%) and CT (49%) are found. The proportion is modified from the starting material (50%/50%) due to the atomic exchange between Ti which enters C₂AS and for Al and Si which substitute the perovskite.

Assemblage D/DD: C₂AS / C₄AF

At 1280°C and 1320°C, the same result is found for D and DD. C₂AS (50%), and C₄AF (43%) are detected as major phases, accompanied by C₂S (2%) and CA (3%). Iron oxide enters the gehlenite (C₂AS) as a probable substitution for alumina, while silica is detected in the calcium ferrite.

Assemblage E/EE: C₄AF /CT

At 1300°C E and EE give the same results. By SEM techniques, only one phase is detected, corresponding to the bulk reaction :

By SEM technique, it was not possible to separate the different phases and thus not possible to know if there is a real solid solution of titanium with the calcium ferrite or an intergrowth of several phases as described in [7].

By XRD, the main peaks of the ferrite phase C₄AF disappear [17] and an additional calcium titane phase is detected : Ca₃ Ti (Fe Al)₂O₁₃ (20%) in combination with CT (80%). Traces of CaFe(Ti₂O₆) are also detected. The solid solution of Ti in ferrite C₄AF gives a series of complex changes that have been previously studied and published [16]. The authors found an extensive range of 14Å body centred solid solutions which become more disordered at higher Ti contents and lead to a formula close to that of Ca₅Fe₄TiO₁₃. The present results are in agreement with these findings although our composition is higher in TiO₂ than that published. Conversely we do not find an increase in free lime for TiO₂ contents higher than 18% as it is claimed [18].

Assemblage F/FF: C₄AF /Q

At 1270°C and 1290°C, by XRD and SEM, C₄AF (43%) and Q (55%) are the phases found in the samples F and FF. The difference in the composition between the starting proportion of 50/50 compared to 43/55 after the heat treatment is due to the modification of the solid solution composition from the starting composition. For example, the decrease from 3% to 2% of the percentage of MgO measured in the Q phase leads to an increase in the % of the Q phase formed.

During the burning period, the molar ratio MgO/SiO₂ of the Q phase varies from 1 to 0.9

Assemblage G/GG: C₂AS /CT/Q

At 1350°, G and GG give the same results. XRD detects the following phases Q (15%), C₂AS (35%), CT (37%) and CA (13%). SEM techniques do not however detect the Q phase. This is

probably due to the intimate intergrowth between C_2AS and the Q phase that prevents the separation of these phases by SEM. To calculate the % of phases, we have used the composition of the Q phase given by its stoichiometry for $n=3$. The occurrence of CA in these samples is consistent with the results obtained in the sample B (C_2AS/Q) and A (Q/CT).

Table 2: Results of the mineralogical determination by XRD and SEM/EDS techniques

Quaternary K/KK ($C_2AS/C_4AF/CT/Q$)	C_2AS , C_2S , CA, Q, $Ca_3TiFe_2O_8$	$CA_{0.49}S_{0.51}$ (C_2AS) $CA_{0.62}F_{0.03}S_{0.11}M_{0.08}$ (Q) $CA_{0.96}F_{0.043}$ (CA) $CA_{0.12}F_{0.09}S_{0.04}M_{0.02}T_{0.54}$ (FT)

Assemblage H/HH: $C_4AF/CT/Q$

At $1300^\circ C$, by SEM, three main phases are detected in H and HH ; Q phase (16%), calcium ferro-titanate (54%), CA (23%), and small quantity of C_2S (4%) . By XRD, it is possible to separate the calcium ferrite (24%) from calcium ferro-titanate (31%). In this case the crystals of calcium ferrite and ferro-titanates are probably intergrown with a thickness lower than the detection limit of the SEM as previously described in [7].

Assemblage I/II: C₄AF / C₂AS /CT.

At 1300°C, the same result is obtained for I and II ; three phases are detected by SEM , C₂AS (23%) CA (7%) and calcium ferro-titanate (70%). By XRD, the peaks of calcium ferrite disappear, meaning that there is a transformation of the calcium ferrite and not an intergrowth of two separated phases.

Assemblage J/JJ: C₄AF/ C₂AS /Q.

At 1280°C, 4 phases are detected by SEM techniques i.e Q (55%), C₂AS (14%), C₄AF (26%) and C₂S (4%) in J and JJ. XRD does not confirm the presence of C₂S.

Figure 2. Connection between the mono and divariant assemblages in the diagram CASFMT

Assemblage K/KK: C₄AF / C₂AS /CT/Q .

At 1285°C and 1320°C SEM shows the presence of Q (25%), C₂AS (16%), calcium ferro-titanate (48%) and the occurrence of CA (8%) and traces of C₂S (2%). XRD confirms the presence of these phases and the almost total disappearance of the calcium ferrite phase.

In the phase diagram CaO-Al₂O₃-SiO₂-Fe₂O₃-MgO-TiO₂, (CASFMT), a maximum of six phases can be found together at a given temperature. This senary phase diagram is formed itself by 6

quinary diagrams, CASFM, CASFT, CASMT, CSFMT, ASFMT and CAFMT, issued from 15 quaternary diagrams. The connection is shown in Figure 2.

The starting phase assemblages, which have been studied here fall into the quinary and quaternary shown in the colour blue: quinary diagram CASFM for the samples B, F, J, CASFT for the samples I, CASF for the samples D, CAST for the samples C, CAFT for the samples E, The samples A, G, H and K fall into the senary diagram CASFMT.

The phase assemblages found in this study are summarised in Figure 3 as follows (in bold)

Figure 3. Assemblage found experimentally (bolt, FT= calcium ferro-titanate)

4. CONCLUSIONS

- The simultaneous use of XRD and SEM techniques in combination with calculations from the mass balance overcomes the difficulties in identifying C_2AS and Q phase or calcium ferro-titanate and calcium ferrite due to the intergrowth of these phases.
- The starting phase assemblage C_2AS , C_4AF , CT and Q phases, is modified in the following way:
 - i) diminishing and disappearance of the ferrite phase when the % of titanium increases
 - ii) appearance of calcium ferro-titanate
 - iii) decrease of the amount of the Q phase
 - iv) occurrence of CA and C_2S
 - v) modification of the solid solution composition and the percentage of the phases
- When the amount of titanium increases, the phase assemblage C_2AS , C_2S , Q, CA and calcium ferrite becomes C_2AS , C_2S , Q, CA, solid solution of calcium ferrite with titanium, and finally C_2AS , C_2S , Q, CA and calcium ferro-titanate.

ABSTRACT

Among the residues and by-products waiting for a sustainable valorisation, steel slags present the most interesting potential because of their chemical and mineralogical composition. In spite of that, the degree to which steel slag is used remains limited because of the quantity of free lime contained in this type of slag. Many processes have been tried to solve this problem but their economic balance has been limited by the quality of the final product and has prevented industrialization. Two processes, however, have a significant potential for industrial application. These involve treatments under oxidising or reducing conditions and a modification of the chemistry and the mineralogy by a mineral addition (addition of silica or alumina) between the converter and the slag discharge process step ('Upstream' process modification).

With such modifications, it is possible to eliminate the free lime and to obtain sound aggregates or a product with cementitious properties similar to or better than a blast furnace slag. In this study, we compare the mineralogy of the final "modified slags" obtained by these processes and its impact on the reactivity. The best results are obtained by the addition of alumina and lime under oxidising conditions. The iron rich cement produced has a similar reactivity to that of a Portland cement with potential advantages in terms of durability thanks to the absence of alkalis.

1. INTRODUCTION

The steel industry produces several types of by-products (slags, dusts, slurry, scraps etc...), generated during the successive stages of the process that starts with the iron ore going through to the final steel. The steel manufacturing process consists mainly of three stages; reduction, steel making and secondary metallurgy stage. Pig iron and blast furnace slag (B.F. slag) result from the reducing stage. From the transformation of pig iron into steel, result the steel and the basic oxygen process slag (BOP slag, or LD slag) and the electric arc furnace slag (EAF slag) and finally from the secondary metallurgy processes result the "SMP" slag. BF slag is air cooled, granulated or pelletised. BOP, EAF, SMP slags are air-cooled. Most of the slag that is produced is either BF slag or BOP steel slag.

The BF slag is widely used as aggregate when it is crystallised and crushed or as cementitious additive when it is glassy and finely ground. The steel slags have not found a real valorising destination, mainly because of their high level of free lime content but also because they contain undesirable elements such as Mn, Ti or Cr in the case of stainless steel.

Steel slags are produced during the refining of iron to obtain steel. The transformation occurs by blowing oxygen into the molten pig iron and lime, limestone or dolomite is added to entrap the impurities. During this process, the current practice is to add more lime than the stoichiometry would require in order to improve the efficiency of the refining. Hence a large amount of free lime

is found in the final slag, with the consequence of expansion when these types of products are used as aggregates or cement or concrete additives.

The increasing cost of landfill, due to environmental constraints generates research to find ways of valorising steel slags [1,2,3] and old studies, that a few years ago were abandoned because of lack of economic advantages are arousing new interest [4,5]. Nevertheless, when looking at the methods for valorising by-products, attention must be paid to the process and to its evolution.

In the past, the steel slag was the by-product of the transformation of high-phosphorus basic Bessemer pig iron and it could be used as a fertiliser (Thomas type phosphate slag). Today low phosphorus pig iron is almost exclusively produced and the use of slag as fertiliser is reduced.

The different ways of using steel slags can be deduced from the process itself, which can be summarised in three steps:

Input material: Pig Iron, Oxygen, Lime

STAGE 1	CONVERTER
Operation	separation by density
Output material	Steel, Steel slag

STAGE 2	TRANSFER VESSEL
Operation	deferrisation
Output material	recovered steel, deferrised steel slag

STAGE 3	DUMPING
Operation	classification, beneficiation
Output material	sieved , treated steel slag

Any utilisation or treatment of slag can be carried out during one of these three stages.

The treatment during stage 3 is certainly the easiest as the slag is already cold and the treatment does not interfere with the steelmaking process. On the other hand, the levers of these treatments are limited and the cost probably high. The steel slags are mainly used as aggregates for the civil (road, railway ballast) and water construction [6,7]. Physical strengths, resistance to frost and constant volume are the principal qualities required for these products. The presence of large quantities of free lime in the steel slag is the main limitation when using these slags as aggregates for roads or concrete [8]. Also due to the quantity of free lime, the addition of ground steel slags to clinker is not allowed (same practice as for BF slag). Classification of the different sizes of the slag according to their free lime content and the use of the lowest lime content slag is a solution.

Another solution is to water or to carbonate the slag in order to transform the free lime into $\text{Ca}(\text{OH})_2$ and CaCO_3 , which are innocuous.

The addition to the raw material in the manufacture of cement is an interesting option, although limited because of the high iron content of the slag. The steel slag provides lime and iron oxide and acts as a mineralizer in the clinkering process [9].

The most promising processes are based on the modification of the chemistry and the mineralogy of the slag, mainly by the addition of silica to neutralise the free lime. The slag can be treated during the first or second stage of steel manufacture.

During stage 1, it is possible to modify the thermodynamic path of the slag composition to prevent the formation of dicalcium silicate shell around the lump of lime and to decrease the quantity of free lime. The study of the primary crystallisation fields of CaO, C₃S, and C₂S in the system CaO-iron oxide-SiO₂ in air shows that the slags that are saturated with CaO at 1650°C will be in equilibrium with CaO when the SiO₂/iron oxide is less than 21/79. In the system CaO-iron oxide-SiO₂ in equilibrium with metallic iron, the ratio becomes 24/76 [10,11]. The question of how far the range over which the saturated slag coexists with lime can be extended at steelmaking temperature has been solved by the use of oxide addition such as bauxite or calcium aluminate [12,13,14].

During stage 2, the liquid slag can be treated in different ways. By reduction of the steel slag, it is possible to recover iron as metal and to obtain a slag of a defined composition, provided that the raw material composition is adjusted [15]. This process requires an external energy, supplied as electricity. During the treatment, iron (Fe²⁺ and Fe³⁺) are reduced to iron metal and are separated from the slag. (Other oxides are also reduced, depending on the efficiency of the reducing agent and the conditions of treatment). If there is no mineral addition during the treatment, the final product will contain a high amount of lime, its melting point will be too high for it to become a liquid at the furnace temperature (1500°C), and thus the process will stop. If silica is added, the chemical composition can be adjusted to obtain a liquid phase at the furnace temperature. The final product contains very little iron oxide and its chemical composition is similar to that of a BF slag. As for a BF slag, this can be used crystallised or it can be quenched to increase its reactivity when it is used as cementitious addition. This treatment, difficult to achieve on a laboratory scale, has been studied at pilot plants and is now being tested on an industrial scale.

By oxidation (injection of oxygen) and addition of silica, it is possible to obtain a sound aggregate [16]. During oxidation, divalent iron oxide (wüstite, or magnesiowüstite), and iron metal oxidise to give Fe₂O₃. This exothermic reaction produces sufficient energy for the dissolution of minerals such as silica.

The added silica combines with the free lime to produce calcium silicates and finally, calcium silicates and calcium ferrite crystallise. In this case, the final product contains the same elements as the starting material, plus the mineral additions. It contains the iron in its maximum oxidation state.

In this paper, we propose a new treatment in which the slag is oxidised but instead of adding silica, we add alumina or an alumina containing compound [17]. The slag displays a new type of mineralogy and interesting hydraulic properties described below.

Figure 1 shows the different compositions of modified slags, which can be obtained by adding silica (path 1), or alumina (path 2)

Figure 1. Chemical modification of steel slag

2. EXPERIMENTAL PROCEDURE

In this study, we have used an industrial steel slag as the raw material (chemical composition given table 1) which has been submitted to different treatments in the laboratory:

- 1) Oxidation at 1500°C,
- 2) Reduction at 1500°C,
- 3) Mixing with silica and oxidation
- 4) Mixing with silica and reduction
- 5) Mixing with alumina and lime and oxidation

The quantity of silica added is calculated in order to obtain a liquid slag at 1500°C with a minimum of residual free lime (respectively 5% and 15 % in the treatment by oxidation and reduction). The addition of alumina and lime is calculated to obtain a potential phase assemblage that is able to generate hydraulic properties and that is compatible with the constraints of the process (30% alumina 15 % lime).

Pilot plant tests have been performed in a similar way to the oxidation process with the addition of silica but with additional quenching of the final product [15].

Free lime was analysed after the different treatment processes.

Table 1. Chemical composition of the industrial steel slag

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	TiO ₂	MnO	P ₂ O ₅	FeO	Free lime
15.22	1.68	11.06	50.03	6.59	0.7	2.38	2.06	11.61	10.40

Polished sections have been studied by SEM techniques associated with EDS measurements and the crystallography controlled by X ray diffraction.

A comparison of the reactivity has also been performed for samples produced under oxidising conditions in the laboratory and for those produced in reducing conditions in pilot trials. The reduction process and the addition of silica gave a product whose composition is similar to a BF slag. It is known that the reactivity of slag is increased when the degree of vitrification (% of glass) is high. The degree of vitrification required is obtained by a quenching system, which is possible on an industrial but not on a laboratory scale. This is not the case with oxidising conditions where the quenching can be carried out on a laboratory scale. In terms of reactivity, the most reactive products available at present have been compared.

Experiments 3 and 4 corresponding to silica additions have been described in more detail elsewhere (18) and are therefore only summarised in this paper.

3. RESULTS AND DISCUSSION

The experimental results obtained by SEM associated with the X Ray diffractograms are compared with the phases composition calculated from the chemical composition, and a mass balance which assumes an assemblage of probable phases that exist.

Figure 2 shows the micrograph obtained on a polished section of the industrial steel slag before the treatment (SEM, backscattered electrons mode). The phases detected are: solid solution of dicalcium silicates, magnesio wüstite, calcium ferrite, and free lime. The experimental and calculated results are consistent and in good agreement with the published studies [19, 20]. The entire indexation of the X-Ray diffractogram of the steel slag represented Figure 4 is well known and has been published [18]. We show here only the main peaks in order to highlight the evolution of the phases during the transformation

Figure 2. Micrograph of industrial steel slag (polished section, BEI)

After oxidation, magnesio-wüstite disappears (oxidation of divalent iron) and the magnesium oxide precipitates as periclase. The main phases are then solid solutions of dicalcium ferrite (containing Mn, Al, etc.), dicalcium silicate solid solution (containing large amounts of phosphate) and periclase. The occurrence of periclase, the disappearance of lime and wüstite and the increase of calcium ferrite are clearly shown by X-ray diffraction.

After reduction and silica addition, bright particles of iron metal and tricalcium silicate are found by SEM in large quantities. Small particles of free lime have also been detected. After this treatment, the sample is sintered due to its chemical composition

After oxidation and with silica addition, the main crystallised phase is dicalcium silicate surrounded by a phase containing iron oxide and eutectoid precipitation that is difficult to identify by SEM (particles less than 1 μm). Even by theoretical consideration, it is not easy to identify the interstitial phase. An X-Ray diffractogram shows the presence of merwinite and akermanite and traces of enstatite and perovskite.

With the addition of 15% silica under reducing conditions, the calculated phase assemblage (system $\text{CaO-SiO}_2\text{-MgO}$ with a very small amount of Al_2O_3) indicates the presence of merwinite (C_3MS_2), dicalcium silicate, and wollastonite. The results from SEM micrographs and the XRD indicate the presence of dicalcium silicate, periclase and iron metal.

The results of the free lime analysis and phase assemblage are shown in Table 2.

Table 2. Comparison of the experimental and predicted phase assemblage

		Phases
Steel Slag Untreated	theoretical	magnesio wüstite (24%), calcium ferrite (23%), dicalcium silicate (43%)
	experimental	dicalcium silicate, magnesio wüstite, calcium ferrite, free lime (10%)
Oxidised	theoretical	Dicalcium silicate (46%), calcium ferrite (46%), periclase (6%)
	experimental	tricalcium and dicalcium silicate, iron, periclase free lime (1%)
Oxidised + Alumina + lime	theoretical	monocalcium aluminate (20%), dicalcium silicate (25%), calcium ferrite (43%)
	experimental	monocalcium aluminate, dicalcium silicates, calcium ferrite, Q phase, free lime (< 0,5%)

In the case of the slag oxidised with alumina and lime addition, the micrograph (Figure 3) shows the presence of monocalcium aluminate (CA), dicalcium silicate, (C_2S), calcium ferrite (C_4AF), gehlenite (C_2AS) and the phase $C_{20}A_{16-x}(Mf)_xS_x$ also called Q phase [21]. This finding is in good agreement with the calculated mineralogical composition. The presence of Q phase is explained by the presence of MgO.

Figure 3. Micrograph of industrial steel slag (polished section, BEI) treated with oxygen, alumina and lime - slow cooling

The results obtained by SEM are confirmed by X-ray diffraction in Figure 4 where the evolution of the mineralogy, due to the oxidation and the addition of alumina is evidenced (only the major peaks are quoted).

Figure 4. X ray diffractogram of the industrial steel slag (bottom) and steel slag modified by oxidation and alumina and lime addition (above) l (lime), w (wustite) , (b) C_2S , (f) calcium ferrite , (a)calcium aluminate, (g) gehlenite (C_2AS),(Q), Q phase

The reactivity of the cementitious additive is based on the measurement of the reactivity index (RI), standardised by ASTM C 989 978b. The reactivity index is the ratio of the compressive strengths obtained with a mixture of 50% slag 50% cement to the compressive strengths obtained with 100% cement.

Four slags have been used for the test:

N°1 An industrial BF slag, ground at 400 m²/g

N°2 The slag produced under oxidising conditions and with addition of 5% SiO₂. This slag has been produced on a laboratory scale and it is crystallised.

N°3 The slag produced under reducing conditions and with addition of 15% SiO₂. It has been produced at the pilot plant scale, in order to have a glassy product.

N°4 The crystallised slag produced on a laboratory scale by addition of alumina and lime

Figure 5 shows the evolution of the reactivity index versus time for these slags.

Figure 5. Reactivity index versus time

These results show that the slag N°2 (Figure 5), produced under oxidising conditions and with silica addition is less reactive than the industrial BF slag N°1 (Figure 5). The slag produced under reducing conditions N°3 (Figure 5) behaves like an industrial BF slag. The addition of alumina and lime, under oxidising conditions gives the best results (N°4 Figure 5) and with 50% substitution, the same performance as a pure cement (RI=100%) or even better (early strength) is obtained. Nevertheless, the reactivity of the slag is only one factor determining the choice between these processes and the final decision must take into account other parameters such as the presence of toxic elements in the slag (different in both processes) and the thermal balance. The economic balance also involves the cost of the energy and the mineral additions.

4. CONCLUSIONS

- The "upstream" process modification to the chemistry and mineralogy of the steel slag is a viable solution that can be used to transform this by-product into a valuable product.
- Each process (oxidising or reducing conditions) gives products with a mineralogical composition favourable for use as an addition to OPC clinker.
- These processes are technically feasible (the oxidising process is under development) and the reducing process has been tried at a pilot plant.
- The reactivity of the slag produced under reducing conditions is similar to that of BF slag, while the reactivity of the slag produced under oxidising conditions and with the addition of silica is lower.
- The best results, especially at an early age are obtained in oxidising conditions and addition of alumina.
- The reactivity, expressed as a reactivity index is only one criterium determining the choice of process and some other technical aspects (trace of heavy metals, heat of hydration, grinding energy, etc.) and economic aspects (transport, cost of landfill,) must be kept in mind.

Address : 7 Garnier street 69330 Meyzieu (FRANCE)

Degree: Chemist engineer (Grenoble 1964) D.Sc Material science (Grenoble 1969) Ph.D; Thermodynamic (Aberdeen 1972)

Scientific background : thermochemistry, thermodynamic, high temperature chemistry

Technical background : analytical method (SEM, TEM, thermal analysis, XRD, XRF)

Professional experience : Material science (cement, ceramics, glass, metallurgy) author of more than 100 refereed papers , 4 chapters , 10 international patents.

Actual Position : Senior scientist (Lafarge) , member of the scientific council of University Lyon 1 (France)

Michel Gimenez:

is a chemical engineer and has followed his PhD studies in Physical Chemistry in Brussels dealing with non-linear phenomena in various chemical and physical systems.

He then joined the plastics & cement industries where he occupied positions in Research, Process, Quality and Production management. He is currently in charge of R&D for Cementitious materials within the Lafarge organisation.

CHARACTERISATION OF INTERSTITIAL TRANSITION ZONE (ITZ) OF HIGH PERFORMANCE CEMENT BY NANOINDENTATION TECHNIQUE

ABSTRACT

The evolution of the performance of concrete achieved during the past years is mainly due to the improvement of our understanding of the microstructure of the cement paste and especially of the interstitial transition zone (ITZ). The ITZ of very high performance concrete only extends to a few microns from the inclusions (anhydrous cement, aggregates, fibers, silica fume) and required the development of new techniques of investigations such as nanoindentation.

With this technique it is possible to measure, in a composite material, the mechanical properties (elastic modulus, hardness) of particles having a size of a few cubic micrometers. This technique is based on the record of the load versus displacement curve at a very low load (less than 50mN). In a first step, the mechanical properties (elastic modulus) of the pure components of the clinker (C₃S/C₂S/C₄AF/C₃A) and of the cement paste (CH, C-S-H) have been studied. Then nanoindentation was applied to the high performance concretes.

The results show that the values of the elastic modulus obtained for the different constituents in the concrete are in agreement with those for the same constituents taken independently at constant porosity. In this study, the creep behaviour of the C-S-H is also highlighted. Associated to classical SEM and EDS analysis, the nanoindentation technique can be used as a "micro-mechanical probe" to scan the surface of hardened cement paste.

1. INTRODUCTION

The quality of hardened concrete (mechanical strengths, dimensional variations, resistance to the aggressive conditions, ...) depends on the concrete mix design (proportion, type of cement, quality of the aggregates, etc.), on the processing and curing. Because the microstructure of hardened concrete depends also on the same parameters, it can be assumed that there is a correlation between the microstructure and the bulk properties of concrete.

Based on this concept, researches have been undertaken to describe the microstructure of the concrete. The results of these researches have been at the origin of the improvement achieved during the last decade moving from ordinary concrete to high performance concrete (HPC), to very high performance concrete (VHPC), reactive powder concrete (RPC) and the new concrete *Ductal*[®] [1,2,3].

In the final state, the microstructure of the hardened concrete is determined by the characteristics of the different constituents, the residual clinker, the cement paste, the aggregates, the fibers and their bond (Interstitial Transition Zone). According to many researchers, the interstitial zone appears to be the weakest part of the concrete (reviewed in [4]). In ordinary concrete, the thickness of the ITZ is about 40-50 μ m. The pore distribution, the chemistry and mineralogy of the ITZ differ from the bulk of the cement paste. The influence of the ITZ on the mechanical properties of the concrete has been investigated according to two approaches. In the first approach, the bulk elastic modulus of concrete is measured and compared to a calculation based on the data of the elastic modulus of each constituent linked by different models [5, 6, 7]. The second approach is based on the measurement of the mechanical properties (elastic modulus, hardness) of the interfacial zone by microhardness testing (nanoindentation techniques) [8, 9,10, 11,12]. After the description of the microstructure, it is necessary to use a model to link the data obtained at different scales.

The techniques of indentation have been developed to allow a measurement of mechanical characteristics at the micro-scale. These techniques, well known in the polymer industry, in metallurgy, electronic and ceramics, [13,14,15] are based on forcing an indenter into the surface of the material by a dynamic or static loading and determining the response of depth of penetration or size of indentation.

There are many techniques of indentation, classified according to the load applied to the sample: i) macrohardness when the load is higher than 10 Newtons (N), ii) microhardness when the load is between 0.05 and 10N, iii) nanohardness, also called nanoindentation or deep sensing micro-indentation, when the load is around 50mN. The microhardness technique is standardized [16, 17] and has been widely used in the cement field [8,9,10,11,18,19], but it has many disadvantages:

- a) it cannot be applied to study the ITZ of high performance concrete, because the thickness of the ITZ is the same as the size of the indent (10 μ m) and consequently, it is necessary to have a smaller indent (1 μ m).
- b) the load is too high to keep the stress/strain curve in the elastic part, and to measure the fine layer of compound in a heterogeneous matrix.
- c) optical measurement of the trace of the indents is necessary, inducing an important standard deviation of the measurement.
- d) The size and shape of the indenter (most often Vickers type) are not always adapted to the problem and cannot be easily modified.

The main difference between the microhardness technique and the nanoindentation technique comes from the measurement of the displacement. In the microhardness, the size of the print of the indenter in the cement paste must be measured, but in that case, because of the intensity of the load, this print is visible through an optical microscope or in SEM. In nanoindentation, the size of the print of the indenter is no longer useful to determine the displacement, but it is necessary to identify which phase has been measured, in the case of a heterogeneous material such as a cement paste. Because of the low intensity of the load (few mN), the print of the indenter is hardly visible. The technique to locate the trace of the indents in cement paste has been used successfully in experiments and reported in published works. [19, 20].

In this work, we first measured the elastic modulus of the clinker phases and of the main hydrates i.e. CH and C-S-H of different ratio C/S. In the second step, we measured the elastic modulus of a heterogeneous sample such as a high performance concrete.

EXPERIMENTAL PROCEDURES

2.1 Description of the equipment

The experiments at microscopic scale by nanoindentation were performed using a nano indenter TM II shown schematically in figure 1. The complete description of the equipment can be found elsewhere [19] and is summarised below. The instrument continuously monitors the displacement of the indenter by a capacitance gauge as a load is applied. The load and displacement resolution of the apparatus are respectively 75 nN and 0.04 nm. The measurements of elastic modulus were obtained using a Berkovich indenter, i.e. three-sided pyramid diamond, with the same nominal area to depth relationships as the standard Vickers pyramid.

Figure 1. A schematic representation of experimental equipment used to perform the indentation experiments.

Experiments were performed using a load-time sequence that is shown in figure 2. The indenter was first loaded and then unloaded three times at a constant rate of loading. In order to insure that the contact was maintained between the specimen and the indenter, the load reached at the end of unloading is 10 % of the maximum load (i.e if the maximum load is 40 mN, the minimum is 4 mN, see figure 2). The multiple loadings and unloadings are necessary to check the reversibility of the deformation and thereby to make sure that the unloading data used for analysis purpose are mainly elastic. Every three unloading, the load was held constant for a period of 100 seconds ("hold" period) at 10 % of the peak value while the displacement was carefully monitored to establish the ratio of displacement produced by thermal expansion in the system.

The system is thermally regulated from its surrounding and from the room within which it is housed. The room is temperature controlled within 1°C. Following the "hold" period, the specimen was loaded for a fourth and final time, with another 50 second "hold" period during the peak load, to avoid plastic effects, and finally the specimen was fully unloaded.

The simultaneous measurement of the load and the displacement during the indentation allows a direct measurement of the elastic modulus and the hardness without direct imaging of the indentation using the method described by Oliver and Pharr [21, 22] and developed by Boudouka for ceramics [15].

The formula used to obtain the effective indentation modulus E_r , from the measured data is:

$$S = \frac{dP}{dh} = \beta \frac{2}{\sqrt{\pi}} \sqrt{A} E_r \quad (1)$$

Where S is the contact stiffness, P is the peak load, h is the displacement, A is contact area, and β is a correction factor (approximately equal to 1.034 for the Berkovich indenter [21]). For the indentation data studied in this paper, 90% of the unloading curve was fitted to the relation described by Oliver and Pharr [21, 22] used to determine the contact stiffness S .

Figure 2. Typical load-time sequence

The equation (1), which follows an analytical solution derived by Sneddon [23], for the penetration of an elastic half space by an axisymmetric indenter of arbitrary smooth profile, relates the experimental stiffness and the contact area to the effective elastic modulus.

From the measurement of the effective modulus, E_r , the elastic modulus of the material, E , is obtained using the equation:

$$\frac{1}{E_r} = \frac{1 - \nu^2}{E} + \frac{1 - \nu_i^2}{E_i} \quad (2)$$

where ν_i and E_i are the Poisson coefficient and the elastic properties of the diamond indenter and ν is the Poisson coefficient of the measured phase.

The methods used to compute the effective indentation modulus E_r , from the measured data, are published elsewhere [23].

2.2 Sample preparation

2.2.1 Pure Phase

The preparation of pure phase of Portland cement [tricalcium silicate (C_3S), dicalcium silicate (C_2S), tricalcium aluminate (C_3A), calcium aluminoferrite (C_4AF), C-S-H, or CH can be found in [24, 25]. The structure and the purity of the synthesised phases were checked by X-Ray diffraction.

The samples for the nanoindentation tests are pressed. The pellets are embedded in a low viscosity epoxy resin and polished by using, at first, abrasive papers of 400, 600 and 1200 grade and then diamond suspensions (6, 3, 1 and 0.25 μm). The quality of the surface of the sample (flatness, cracks and scratches) is an important parameter to insure the reproducibility of the small penetration of the indenter. The chemical homogeneity is checked by SEM/EDS (after carbon coating of the polished section). The pressure is used to densify the particles in order to obtain a polished section to check the chemical homogeneity and to minimise the standard deviation of the results of E (elastic modulus). It is more difficult to carry out these experiments on powders. The volume of

matter which is concerned for the nanoindentation test is about $5\mu\text{m}^3$ (the order of magnitude of the volume analysed by the electron beam in SEM). In this case it is not necessary to have a large pellet of high bulk density but dense particles of a few millimetres are recommended.

2.2.2 Heterogeneous matrix. (cement paste and concrete)

This experimental technique is described in detail elsewhere [19] and summarised here ;

- 1) A mortar containing 33 % OPC type I, 10% ground sand, 10 % silica fume, 47 % of sand ($< 1\text{mm}$) is prepared at $W/C = 0.2$ and 1.4 % of polyphosphonate admixture is added to insure a good workability.
- 1) After 28 days, the samples are embedded in a low viscosity epoxy resin and polished as described previously.
- 2) A copper grid is pasted on the polished surface (this grid is commonly used as sample holder in transmission electron microscopy). The sample is coated with gold or gold palladium (same technique as for SEM preparation).
- 3) The grid is removed leaving its trace on the sample.
- 4) The quality of the sample is checked by SEM.
- 5) The nanoindentation is started by 2 indents separated by 50 to 150 μm (depending on the sample). These indents correspond to a relatively important load, in order to leave a print, visible by optical microscopy SEM. These two indents are necessary to identify the area where the measurements are carried out, but the figures found for these 2 indents are not taken into account. We called them "locating indents".
- 6) Between these "locating indents", a few indents are carried out corresponding to a given distance (5 to 15 μm).
- 7) The sample is removed from the nanoindenter and the identification of the phases which have been indented, as well as their chemical analysis are carried out by SEM (EDS).

The grid helps to identify the right zone to be explored. The presence of the "locating indent" helps to locate the phases where the indents have been printed and allows their chemical analysis

2. RESULTS

3.1 Elastic modulus of the clinker phases

The elastic modulus of C_3S , alite, C_2S , belite, C_3A , C_4AF , are measured by nanoindentation at penetration depths of about 300 nm and 500 nm. Figure 3 presents the typical load-displacement curves at applied penetration of 500 nm for C_3S . For this penetration depth, corresponding to applied forces ranging between 40 mN and 50mN, this phase exhibits first an elastoplastic behaviour during the first loading, and then during the successive cycles an hysteresis loop occurs. No creep phenomenon is observed at constant force. The hysteresis behaviour corresponds to energy dissipation (damping phenomenon) probably due to a viscoelastic behaviour appearing after plastic deformation.

However, this effect can be neglected in order to calculate the elastic modulus (the elastic modulus is measured by using the last unloading curve). Table 1 shows the elastic moduli of the phases of Portland cement, measured at two depths of penetration. These values are an average of ten to twenty experiments and are calculated using an approximate Poisson's ratio of 0.3 for all constituents.

We checked that the samples were homogeneous as the elastic moduli values do not vary with the penetration depth. The elastic moduli are similar to each other in the range of 125 GPa to 145 GPa. The comparison of moduli between a pure C_3S phase and alite shows clearly that the influence of minor element included as solid solution in C_3S is not significant. The same conclusion stands for the pure C_2S and belite. The standard deviation of the measurement is about 10 %, except for C_2S and C_4AF . In the first case, this greater scatter can be explained by the polymorphic transformation

during the cooling generating microcracks in the matrix and in the second case by the presence of microcracks generated by the indenter during the first loadings.

Table 1. Elastic modulus of the clinker phases

	C ₃ S	alite	C ₂ S	belite	C ₃ A	C ₄ AF
Elastic modulus (GPa)	135	125	130	143	145	125
Standard deviation	7	7	20	10	10	25

Figure 3. Load versus Displacement curve for C₃S

3.2 Case of calcium silicate hydrates

Figure 4 shows (as example) the load displacement curve for a C-S-H of C/S=1. In this case, creep occurs. The elastic moduli of C-S-H (C/S from 0.5 to 1.76) and CH are given in the Table 2.

Table 2. Elastic modulus as function as C/S for CSH

	CH	C-S-H C/S=0.5	C-S-H C/S=0.6	C-S-H C/S=0.7	C-S-H C/S=0.8	C-S-H C/S=1	C-S-H C/S=1.13	C-S-H C/S=1.2	C-S-H C/S=1.76
Elastic modulus (GPa)	34	22	19	24	24	28	34	29	28
Standard deviation	2	2	3	4	3	2	4	2	2

Figure 4. Load versus displacement curve for CSH of C/S=1

3.3 Case of heterogeneous sample, cement pastes

The micrograph (Figure 5) shows a polished section of a powder reactive concrete (PRC) sample (SEM, back scattered electrons). Particles of quartz aggregates, residual clinker, and cement paste are easily recognized.

Figure 5. Powder reactive concrete (polished section, Backscattered electrons)
The straight line shows the explored area

The distance between two particles (quartz/residual clinker, quartz/ quartz or clinker/clinker) rarely exceeds 20 μm and consequently, the number of measurements in the paste is limited to 2 to 3. Table 3 shows, as an example, the results of the elastic moduli and the analysis by SEM (EDS) of the corresponding area.

Table 3. EDS analysis and Elastic modulus determination

Point	1	2	3	4	5	6	7
C/S ratio	2.45	2.2	0.85	1.50	1.34	0	0
Elastic modulus (GPa)	135	120	40	47	45	75	80

The points 1 and 2 correspond to the clinker, the points 6 and 7 correspond to the quartz. The points 3, 4, 5 correspond to the cement paste. Many linescans of this type have been carried out and can be summarized in table 4

Table 4. Elastic modulus in concrete , average

	Residual clinker	Cement Paste	Quartz aggregates
Elastic modulus (GPa)	100 to 140	30 to 45	70 to 90

3. DISCUSSION

It is difficult to find reliable figures for the elastic moduli of the constituents of cement (anhydrous or hydrate phases) in the literature

Granju [26] measured the elastic moduli of clinker on polished blocks. He found an elastic modulus for the clinker ranging between 60 and 300 GPa. The scatter of the results was due to the cracks introduced during the preparation of the sample.

Boumiz [27] measured the elastic modulus of compacted powder of C_3S by the acoustic method. He prepared cylindrical samples with a density of the same order as the density of C_3S grains (3.14g

/cm²). He found that the elastic modulus of C₃S was equal to 117 GPa. that is consistent with the values obtained in the present work. There is also a good agreement between the values obtained by nanoindentation and those obtained at the macroscopic scale by other techniques such as resonance techniques [23]

The elastic modulus of Portlandite has been measured by Monteiro [28] and Wittman [29] and Beaudouin [30]. The figures obtained range from 35,2 to 48 against 34 GPa for nanoindentation measurement. The discrepancy could come from the porosity of the sample

In the case of concrete (table 3), there are together, quartz grains, residual clinker, cement paste, and some other constituents such as silica fume or fibers. Elastic moduli of pure C₃S, SiO₂, CH, C-S-H, are respectively 135GPa, 78GPa, 34GPa and between 22 and 34GPa depending on the C/S ratio of C-S-H. These values stand for a non-porous material and a decrease could be expected when the porosity increases.

In a cement paste (or C₃S paste) the range of the porosity extends from a few Angströms (for the gel pores) to a few microns for the capillary porosity. Consequently, in the volume concerned by the nanoindentation test (a few microns), it is possible to have some capillary pores. This could explain the low value of the elastic modulus obtained for some constituents.

The results obtained at the microscopic scale come from the measurement of the elastic properties of small particles (a few μm^3). At this scale and being given the method of the preparation of the sample, it is easy to check that the porosity of the particles can be taken at zero (the density of the particles close to the theoretical mass density of the compound). If the porosity was different from particle to particle, the standard deviation of the measurement would be very high.

The elastic modulus varies from 22 to 34 GPa for the CSH with a ratio C/S varying from 0.5 to 1.76 (Table 2) . The figure of 34 GPa is in agreement with the findings of Beaudoin et al [31] who did not highlight the variation of the elastic modulus with the ratio C/S of the CSH. This discrepancy is due to the lack of accuracy of the method of measurement (extrapolation to zero porosity of a result obtained by a static method)

In the case of concrete (table 3), the high moduli represent the location of the indent in quartz aggregate or in clinker. The low moduli represent the measurement in the cement paste. The elastic modulus is constant for the sample with a C/S varying from 0.8 to 1.9 (corresponding to inner or outer C-S-H, or a mixture of C-S-H and Portlandite) and higher than those obtained for pure C-S-H. Probably this phenomenon is due to the presence of fine silica intimately mixed with C-S-H.

From these measurements, it is difficult to see a difference of elastic modulus versus the distance from an aggregate or a particle of clinker, and thus to evidence the presence of ITZ in this type of concrete.

4. CONCLUSIONS

The results found at the microscopic scale by nanoindentation show that:

1. The elastic moduli of C₃S, C₂S, C₃A, C₄AF, are similar and range between 125 GPa to 145 GPa. These results obtained at the microscopic scale by nanoindentation are in good agreement with those obtained at the macroscopic scale by frequency resonance technique.
2. The elastic modulus of C-S-H varies as a function of the ratio C/S from 22 to 34 GPa. The creep behavior of C-S-H has been shown.

The technique used to locate the indents in heterogeneous material allows us the identification of the area which has been indented and consequently, the nanoindentation can be applied to cementitious material to study in situ the mechanical properties of the cement or concrete matrix.

The results obtained by the nanoindentation technique with a sample of a hardened cement paste, show that the elastic moduli of the different constituents in the paste are in agreement with those obtained for the same constituents independently, provided the porosity of the particles is taken into account.

There is no significant difference of the elastic modulus between inner and outer C-S-H. No evidence of a difference of the elastic modulus has been found close to the particles, and consequently the ITZ, if it exists in this case is less than 1 to 5 μm (for this type of material)

Associated to SEM and EDS analysis, the nanoindentation technique can be used as a "micro-mechanical probe" to scan the surface of hardened cement paste and to obtain information on i) the microstructure and mineralogy of such concrete. ii) the elastic modulus of the constituents of the cement "in situ", iii) the elastoplastic behavior and the occurrence of creep phenomenon iiiii) the mechanical properties of the cement paste in UHPC and *Ductal*[®].

APPLICATION OF NEW FINE PARTICLE CHARACTERIZATION TECHNIQUES TO CONCRETE DURABILITY

R.I. Malek

Director, Particle Characterization Laboratory, Materials Research Institute, The Pennsylvania State University, 109 MRL Building, University Park, PA 16802, USA. E.mail: rqm@psu.edu

ABSTRACT

Concrete durability as well as its failure is directly related to the physical nature of the fine particle fraction. Concrete technology has become so sophisticated that the simple techniques are no longer suitable for cement particle characterization. The problem becomes more complicated with blended cement where a variety of particles with diverse properties are mixed together. The unique particle characterization laboratory at Penn State University compiles a variety of state-of-the-art instruments for complete particle characterization. It includes atomic force microscope, zeta potential analyzers (Zeta PALS and DELSA), particle size distribution (Micron Air Jet sieve, centrifugal, wet and dry laser diffraction and ultra fine particle size analyzers), BET and mercury intrusion porosimetry, rheometry, thermal analysis (DSC, DTA, TGA and TMA). The application of these techniques to cement and concrete has led to better understanding of the physical properties of cementitious particles. The purpose of this paper is to present the state-of-the-art capabilities in fine particle characterization techniques and their applications to solve durability problems.

1. INTRODUCTION

Particulate material in concrete plays a significant role in defining its durability. Concrete durability as well as its failure is directly related to the physical nature of the fine particle fraction. The current techniques of cement particle characterization are no longer appropriate for the modern performance of concrete. Concrete technology has become so sophisticated that the simple techniques are no longer suitable for cement particles characterization. The problem becomes more complicated with blended cement where a variety of particles with diverse properties are mixed together. The unique particle characterization laboratory at Penn State University compiles a variety of state-of-the-art instruments for complete particle characterization. The application of these techniques to cement and concrete has led to better understanding of the physical properties of cementitious particles.

2. THE PARTICLE CHARACTERIZATION LABORATORY FOR CEMENT AND CONCRETE APPLICATIONS

The Particle Characterization Laboratory at Penn State University is a core facility for physical characterization of fine particles. It includes:

- Digital Instruments multimode atomic force microscope.
- Brookhaven Zeta PALS zeta potential analyzer by electrophoretic light scattering.
- Coulter DELSA 440SX zeta potential analyzer.
- Electroacoustophoresis zeta potential analyzer.
- Horiba CAPA 700 centrifugal sedimentation particle size analyzer.
- Malvern Mastersizer S-wet and dry laser diffraction

- MicroTrac UPA 150 ultra fine particle size analyzer.
- Hosokawa Micron Air Jet sieve.
- Micromeritics GIMINI 2375 surface area analyzer.
- Micromeritics Autopycnometer 1320
- Pascal 140, and 440 Mercury Intrusion Porosimeter.
- CSL TA Instruments Rheometer
- TA Instruments Thermal Analysis system.
 - Differential Scanning Calorimetry (DSC)
 - Differential Thermal Analysis (DTA).
 - Thermogravimetric Analysis (TGA)
 - Simultaneous DSC/TGA – DTA/TGA (SDT).

2.1 The Atomic Force Microscope

The atomic force microscope (AFM) is operated in such a way that a thin tip (mounted on a cantilever) scans the surface of a sample. The attractive and repulsive forces between the tip and the surface move the cantilever vertically for a distance proportional to these forces, and in turn, on surface structure. This movement is recorded through the deflection of a laser beam (centred on the tip of the cantilever) on a mirror and piezoelectric elements. An image of the surface structure of the sample can be obtained by the signals sent from the piezoelectric elements. AFM can be used to investigate the fabric of cement and clinker surfaces.

The AFM was used to investigate the degree of coverage of a curing compound on the surface of cement particles. The contact mode of Scanning Probe Microscope (SPM), a new development in the AFM technology was used [1, 2]. Fresh cement particles were spread on a freshly cleaved mica surface. The mica disc was then placed together with the AFM scanning head inside a glove box flooded with nitrogen gas to prevent the effect of moisture. The curing compound was sprayed over the cement particles and the mica disc was placed on the scanning head of the microscope. The microscope was operated over an area of 25 μm x 25 μm . The image, shown in Figure 1, was obtained for the surface of a single particle. The colour hue of the image was arbitrarily chosen to reflect a better contrast. It is noticed that the curing compound is concentrated in certain areas. That this preferential distribution is related to the heterogeneous surface composition is the subject of an ongoing investigation.

Figure 1. AFM image of curing compound over the surface of a single cement particle.

2.2 Zeta PALS Zeta Potential Analyzer

Modern instruments for the determination of zeta potentials by Electrophoretic Light Scattering (ELS) are very easy to use and much more accurate than traditional microelectrophoresis. They have achieved a widespread use in many research and applied fields. Their ultimate use is for materials with very low mobility such as cementitious materials. The low mobility of cementitious material is due to the compression of Stern double layer as a result of high ionic strength of the medium. The Brookhaven Zeta PALS is used. The Zeta PALS determines zeta potential using Phase Analysis Light Scattering: a technique that is up to 1,000 times more sensitive than traditional light scattering methods. The Zeta PALS utilizes phase analysis light scattering to determine the electrophoretic mobility of charged, colloidal suspensions. Unlike its cousin, Laser Doppler Velocimetry (LDV) (sometimes called Laser Doppler Electrophoresis (LDE)); the PALS technique does not require the application of large fields which may result in thermal problems because in the measurement of phase shift, the particles need only to move a fraction of their own diameter to yield good results. In this technique, an alternating current is applied and the amplitude of oscillation of particles is measured, which is related to the composition of the double layer and zeta potential. In salt concentrations up to 3 molar and with electric fields as small as 1 or 2 V/cm enough movement is induced to get excellent results. In addition, the Autotracking feature compensates for thermal drift. The excellent agreement of the three runs in experiments involving cementitious materials is an evidence of excellent reproducibility.

The Zeta PALS was used to study the stabilization of expansive clays. Expansive soils cause annual damage to manmade structures resulting in an estimated \$9 billion in losses. Lime and Portland cement were used as stabilisers in the mid-1930' and expanded with many applications in World War II. Use of cement as a treatment of expansive clay soils continues on a limited basis today. Lime treatment was first used for this purpose by the Texas Highway Department in the mid-1940's. Soil stabilisation products are available on the market today. Some of them work on the principle of substitution of a cationic species in the clay lattice for a sodium ion. The cationic species is generally selected such that its radius of hydration is less than that of the sodium ion, hence resulting in less swelling when the clay comes in contact with a foreign fluid. More recently, polymers containing 400 to 7500 cationic sites are used. In order for the polymer to "desorb" from the clay, all of these cationic sites must simultaneously be displaced. The probability of this occurring is negligible, hence stabilising the soil. The disadvantage of these stabilisers is due to the physical size of the molecule preventing its migration through the formation pores. It is crucial that the surface charge of the soil be adjusted for maximum interactions with the stabilisers. The Zeta PALS was used to determine the isoelectric point (point of zero charge) of stabilised clay (Figure 2).

Figure 2. The change in zeta potential as a function of pH of stabilized clay.

2.3 Coulter DELSA 440SX Zeta Potential Analyzer

The DELSA (Doppler Electrophoretic Light Scattering Analyzer) analyzes data from 4 angles (7.5° , 15° , 22.5° , and 30°). The simultaneous multi-angle analysis simplifies data interpretation by giving information similar to that obtained with consecutive measurements made at different electric field strengths on a single angle instrument. It also distinguishes between particle charge heterogeneity and diffusion effects over a wide range of particle sizes. The instrument is automated and provides a simple analysis which can detect small charges. It also measures particle size distribution. The DELSA zeta analyzer is particularly useful in studying the changes that take place during the hydration of blended cements.

2.4 Electroacoustophoresis Zeta Potential Analyzer

Electroacoustic effects are defined as the generation of electric fields by sound waves or conversely, the generation of sound waves by electric fields. An alternating electric field is applied at a single frequency of about 1MHz. The generated electroacoustic signals are received by means of a dip-type probe placed in direct contact with the sample. It has been demonstrated that the electroacoustic signals are related to both the zeta potential and the size of particles of the colloidal suspension. The major advantage of the electroacoustics over the electrokinetic and particle sizing methods is that the technique does not involve the passage of light through the sample. The use of sound waves instead of light means that optical clarity of the sample is not required, hence concentrated suspensions (such as cement slurries) may be studied in their original formulations i.e. without dilution. One other advantage is the ability to analyze very large particles that may otherwise cause opacity in light scattering techniques.

The electroacoustic technique was used to study the variation of surface charge of silica fume particles as a function of hydration time. Paste containing 35% by volume of silica fume in saturated lime was prepared. The paste was left to hydrate in the electroacoustic sample holder. At designated times, the sample holder was placed in the electroacoustic device and an alternating electric field is applied at a single frequency of about 1MHz. The generated electroacoustic signals are received by means of a dip-type probe placed in direct contact with the sample. The zeta potential of silica fumes particles (before mixing) was found to be -24mV . The zeta potential of the mixture shows a sharp change to more positive potentials during the first few minutes of reaction due to adsorption of Ca^{++} ions on the surface particles (Figure 3). Then a slight decrease toward less positive potentials at 1 hour is noticed, due to the chemisorption of OH^- ions and the start of hydrolysis process. This is followed by a gradual increase to reach a plateau at 3 hours.

Figure 3. Electroacoustic Zeta potential of silica fume/lime mixture with and without superplasticizer.

The zeta potential and electrophoretic mobility of the superplasticized mixture (sulfonated naphthalene-formaldehyde condensate) show that the surfaces of superplasticized particles acquire an initial charge (Figure 3). This is attributed to the adsorption of superplasticizer molecules on the surface of particles. The sulfonated naphthalene-formaldehyde condensate molecule has a strong electrophilic sulfonate group which allow the hydrophobic organic chain to adhere to the particle's surfaces with SO_3^- group projecting outwards. This leads to an increase in the negative charge of the particles. The negative zeta potential (and mobility) of the superplasticized silica mixtures decreases gradually then converts to a positive charge and resumes the normal course of change as the pastes without superplasticizer. The conversion to positive charge is due to the hydrolysis of superplasticizer molecules under the effect of the strong alkaline medium and continuous conversion to CSH gel.

2.5 Particle Size Distribution

Over the past two decades, the development of miniaturized computers and monochromatic laser light sources has prompted particle size distribution analysis to a sophisticated level involving mathematical modelling and statistical analysis. The equipment design has made the analysis rapid and routine provided that the material being analyzed adheres to certain assumptions regarding particle morphology and optical characteristics. The particle size distribution techniques are divided into two categories: the light scattering methods and the sedimentation method. Almost all the zeta potential analyzers that use light scattering can also be used for particle size distribution. In addition, other light scattering equipment is specifically dedicated for particle size distribution. These include:

(1) Malvern Mastersizer S- wet and dry laser diffraction particle size analyzer

The mastersizer has the advantage of analyzing dry powders which have the ability of fast agglomeration when placed in contact with liquid medium. It analyses particle sizes up to 900 μm .

(2) MicroTrac UPA 150 ultra fine particle size analyzer

The MicroTrack has the advantage of analyzing very fine particles in the nanometer range.

(3) Horiba CAPA 700 centrifugal sedimentation particle size analyzer

The method is based on the sedimentation of particles (under the influence of centrifugal force) in a liquid medium, optical transmission and application of Stokes law. The method assumes spherical morphology of the particles.

Cement particles have a lognormal distribution curve and acquire a non spherical shape. The shape factor can be derived by comparing the average particle diameter from the two techniques, light scattering and sedimentation. The principle is to determine the divergence of the particle shape from the sphericity assumed by the sedimentation technique. Therefore, a shape factor can be derived from the ratio of average diameter from the light scattering to that from the sedimentation (1). The shape factor is 1 for a sphere and increases from this value with increasing divergence from sphericity.

2.6 Particle Classification and Analysis

Separation of fine particles into size fractions is an important aspect of research and development in cement and concrete. We utilized the Hosokawa Micron Air Jet sieve in which the particles are separated into size fractions down to 5 μm fraction. These studies help understand the grindability of different components of the clinker. Particle surface area is determined with the 5-point BET nitrogen adsorption with surface area analyzer. The true density of particles, as determined by helium pycnometer, help to understand the internal porosity of cementitious particles and its effect of hydration and performance. The internal porosity and pore size distribution of cementitious particles are determined with Pascal 140, and 440 Mercury Intrusion Porosimeter. In this technique the intrusion data from the low pressure stage (140 MPa) and high pressure stage (440 MPa) are

combined. The packing density of particles is used to calculate the internal porosity of particles. In addition, rheometer is used to assess the rheological properties of pastes.

2.7 Thermal Analysis

Thermal analysis instruments are very useful in obtaining quantitative data on components of the hardened pastes. An example is obtaining quantitative data on gypsum, hemihydrate and ettringite using DSC. The difficulty arises from the fact that their endothermic peaks are superimposed. We can omit the ettringite peak by methanol treatment (Figure 4) and we can use hermetic sample pan to separate the hemihydrate from the dehydrate peaks (Figure 5).

Figure 4. An example of removing ettringite peak using methanol treatment.

Figure 5. High resolution DSC using hermetic pan.

3. CONCLUSIONS

New particle characterization techniques offer a unique opportunity in the area of cement and concrete applications. They include: atomic force microscope, zeta potential analyzers (Zeta PALS and DELSA), particle size analyzers (Micron Air Jet sieve, centrifugal, wet and dry laser diffraction

and ultra fine particle size analyzers), BET and mercury intrusion porosimeters, theometers, and thermal analysis instruments (DSC, DTA, TGA and TMA). The application of these techniques to cement and concrete can lead to a better understanding of the physical properties of cementitious particles. The information gained from such analyses is a significant step towards joining the research community in exploring fine particle characteristics, which will be crucial in cement and concrete technology.

University Park, PA 16802, USA. E-mail: rqm@psu.edu, and mns3@psu.edu.

ABSTRACT

The purpose of this paper is to report on the application of a new technique that studies the changes in surface charge of cement and fly ash particles during hydration. The new technique is superior to other techniques in that concentrated suspensions (such as cement slurries) may be studied in their original formulations i.e. without dilution. The mechanism of hydration was monitored by x-ray diffraction at various ages. Solid state ²⁹Si magic angle spinning nuclear magnetic resonance spectroscopy (MAS NMR) was used to characterize the detailed structure of hydration products after 28 days. The new technique represents a step towards exploring the actual changes in surface charge during hydration.

1. ELECTROACOUSTICS

Electroacoustic effects are defined as the generation of electric fields by sound waves or conversely, the generation of sound waves by electric fields [1]. The former effect is termed the Ultrasonic Vibration Potential (UVP), while the latter is known as the Electronic Sonic Amplitude (ESA). The UVP was first investigated in 1933 by Debye [2] in an attempt to determine the hydration number of ions in electrolyte solution. Only in 1985 was the ESA discovered [3]. It is based on the principal that when an alternating electric field is applied to a suspension, the particles move backwards and forwards between the electrodes because of their surface charge. This motion generates pressure changes which propagate in the medium as a sound wave. The UVP and ESA effects have been shown theoretically by Obrien [1, 4, and 5] to be linked by the reciprocal relation:

$$ESA = QK * UVP \quad (1)$$

where the ESA is in Pascals per unit field strength (Vm^{-1}), the UVP is in volts per unit pressure gradient ($Pa.m^{-1}$), Q is an instrument constant, and K^* is the complex conductivity of the suspension. By the late 1980's, and early 1990's, Obrien et al demonstrated that the electroacoustic signals are related to both zeta potential and the size of the particles [6]. By 1995, a new instrument has been commercialized which enabled the estimation, simultaneously, of the zeta potential and size distribution of suspended particles [6]. The major advantage of the electroacoustics over the electrokinetic and particle sizing methods is that the technique does not involve the passage of light through the sample. The use of sound waves instead of light means that optical clarity of the sample is not required, hence concentrated suspensions (such as cement slurries) may be studied in their original formulations i.e. without dilution. One other advantage is the ability to analyze very large particles that may otherwise cause opacity in light scattering techniques.

Several investigators have determined the zeta potential of cementitious materials by the traditional microelectrophoresis [7, 8, 9, and 10] or the more advanced light scattering techniques [11]. These

techniques require infinitely diluted suspensions. Infinite dilution of cementitious materials reduces the ionic strength and expands the double layer giving rise to interfacial properties that are totally different from the real situation in pastes. The electroacoustic technique is applied on highly concentrated suspensions where the interfacial properties of particles are not different from the real situation in pastes.

2. EXPERIMENTAL

Type-I cement (Keystone cement, Pennsylvania, USA), silica fume, and class-F fly ash (Pennsylvania Power and Light Co., USA) are used in this study. Pastes containing 35% by volume of cement in water, silica fume in saturated lime and fly ash in saturated lime were prepared. The pastes were left to hydrate in the electroacoustic sample holder. At designated times, the sample holder was placed in the electroacoustic device and an alternating electric field is applied at a single frequency of about 1MHz. The generated electroacoustic signals are received by means of a dip-type probe placed in direct contact with the sample. The technique has been used to study the changes in surface charge, as a function of hydration time, of concentrated cement, silica fume/lime, and fly ash/lime slurries. A diagram of the electroacoustic device is presented in Figure 1.

Figure 1. Electroacoustic device

X-ray diffraction was used to monitor the phase changes in hydration products as a function of time. A computerized search/match program was used to identify the nature and quantity of each hydration product. The solid state ^{29}Si magic angle spinning nuclear magnetic resonance spectroscopy (MAS NMR) was used to characterize the detailed structure of hydration products after 28 days. The NMR spectra were referenced to tetramethylsilane (TMS). The signals due to ^1H were decoupled so that the signals due to Si-O-Si and Si-O-Al connectivities are not affected by the proton signals.

3. RESULTS AND DISCUSSION

The zeta-potential of cement, silica fumes and fly ash particles (before mixing) were found to be: -10mv, -24mv and -27mv, respectively. The zeta-potential of the cement/water, silica fume/lime, and fly ash/lime mixtures show a sharp change to more positive potentials during the first few minutes of reaction due to adsorption of Ca^{++} ions on the surface particles (Figures 2, 3 and 4). The mixtures containing cement/water and silica fume/lime show a slight decrease toward less positive

potentials, at 24 hours and 1 hour, respectively, due to the chemisorption of OH^- ions and the start of hydrolysis process. This is followed by a gradual increase to reach a plateau at 72 hours and 3 hours for cement and silica fume, respectively. The mobility and zeta potential show minor changes afterwards.

The x-ray patterns of the solid reaction products of cement after 7 days and silica fume after 6 hours show the presence of portlandite crystals and CSH as evidenced by the broad peaks at 3.04 \AA , 2.97 \AA , and 1.83 \AA .

Figure 2. Electroacoustic zeta potential of cement with and without superplasticizer.

Figure 3. Electroacoustic zeta potential of silica fume/lime mixture with and without superplasticizer.

Figure 4. Electroacoustic zeta potential of class F fly ash/lime mixture with and without superplasticizer.

Figure 5. Variation of x-ray peak intensity vs. time of class F fly ash/lime mixture.

The zeta potential of the fly ash/lime mixtures show the initial sharp change to more a positive potential during the first few minutes due to adsorption of Ca^{++} ions on the surface particles (Figure 4). It does not, however, show the subsequent decrease toward less positive potentials, and the change in zeta potential reaches a plateau which continues unchanged afterwards.

The zeta-potential and electrophoretic mobility of the superplasticized mixtures (sulfonated naphthalene-formaldehyde condensate) show that the surfaces of superplasticized particles acquire an initial negative charge (Figures 2, 3, and 4). This is attributed to the adsorption of superplasticizer molecules on the surface of particles. The sulfonated naphthalene-formaldehyde

condensate molecule has a strong electrophilic sulfonate group which allow the hydrophobic organic chain to adhere to the particle's surfaces with SO_3^- group projecting outwards. This leads to an increase in the negative charge of the particles. The negative zeta-potential (and mobility) of the superplasticized silica mixtures decrease gradually then convert to a positive charge and resume the normal course of change as the pastes without superplasticizer. The conversion to positive charge is due to the hydrolysis of superplasticizer molecules under the effect of the strong alkaline medium and continuous conversion to CSH gel.

The x-ray analysis of Fly ash/lime mixture (Figure 5), show that Portlandite continues to diminish with time. C_4AH_{13} forms within the first few days of hydration and continues to increase up to 7 days then it converts to the more stable phases, hydrogarnet and C_3ASH_4 (an AFm phase). CSH is detected at 3 days and continues to increase in intensity. The mechanism of hydration can be explained as follows. The first step is the adsorption of Ca^{++} ions from solution on the surface of the negatively charged fly ash particles. This is immediately followed by an attack on the Al_2O_3 - SiO_2 framework in the glassy phase of the fly ash by the OH^- ions resulting in the breakdown of the Al-O and Si-O bonds. The breakdown of the aluminosilicate frame work will release alkali ions (K^+ and Na^+) into solution. The immediate product is likely to be an amorphous material with K^+ and Na^+ as the dominant cations. The abundant supply of Ca^{++} and the lower solubility of CSH are an indication that the CSH gel is the first intermediate product formed. Afterwards, due to the removal of Ca^{++} and depression of solubility of lime under the effect of increasing alkali concentration in solution a low Ca/Si ratio CSH is expected to form. The addition of Al ions in solution will promote the formation of C_4AH_{13} . This is an intermediate metastable compound which later converts to hydrogarnet and AFm phase (C_3ASH_4). Sersale [14] argues that there exists a strong dependency of the breaking down of the glass phase on the alkalinity of solution which becomes significant only after few days which may explain the early incubation period in fly ash hydration. This incubation period is decreased with temperature due to increased solubility of the glass. In addition, the reactivity of fly ash/lime mixtures increases by optimization of the fine particle range, due to two factors: enlargement of the reaction surface area and the enrichment of chemically active constituents. The relative concentrations of CaO, SiO_2 and Al_2O_3 define the nature of hydration products formed. Therefore, low concentrations of CaO and high concentrations of SiO_2 and Al_2O_3 favours stratlingite formation whereas high concentrations of CaO, SiO_2 and low concentration of Al_2O_3 favours the formation of C_4AH_{13} [14]. The later compound converts with age to more stable AFm phases Hydrogarnet and C_3ASH_4 .

The solid state ^{29}Si magic angle spinning nuclear magnetic resonance spectroscopy (MAS NMR) of the dried mixtures after 28 days of hydration were obtained. The signals due to ^1H have been decoupled so that the signals due to Si-O-Si and Si-O-Al connectivities are not affected by the proton signals. It should be noticed that, Q^0 , Q^1 , Q^2 , Q^3 , Q^4 correspond to a SiO_4 tetrahedron connected to 0, 1, 2, 3, and 4 SiO_4 tetrahedra, respectively, whereas, $\text{Q}^n(0 \text{ Al})$, $\text{Q}^n(1 \text{ Al})$, $\text{Q}^n(2 \text{ Al})$, $\text{Q}^n(3 \text{ Al})$, $\text{Q}^n(4 \text{ Al})$, correspond to Si tetrahedron connected to 0, 1, 2, 3, and 4 Al tetrahedra, respectively. The solid state ^{29}Si MAS NMR spectrum of cement showed the presence of Q^0 doublet, at ~ -71.5 ppm characteristic of the unreacted C_3S . On the other hand, the spectrum of silica fume/lime mixture showed the presence of Q^4 peak at ~ -111.5 ppm, characteristic of unreacted silica fume. The two spectra contain Q^1 and Q^2 peaks, at ~ -79 ppm and at ~ -85 ppm, respectively, characteristic of CSH, with various C/S ratios. The deconvoluted peak areas were calculated and the average chain lengths were calculated from the formula (Richardson, et al, 1999 [12]).

$$\text{Av. Chain Length} = \frac{1/2 Q^1 (0 \text{ Al})}{Q^1 (0 \text{ Al}) + Q^2 (0 \text{ Al}) + Q^2 (1 \text{ Al})} \quad (2)$$

It was found that the average chain length of the CSH is 3.5 and 4 for cement and silica fume, respectively.

The NMR pattern of fly ash/lime mixture shows a small peak at -107 ppm which is assigned to the unreacted fly ash. In addition, peaks at ~ -79 ppm and ~ -85 ppm are attributed to $Q^1 (0 \text{ Al})$ and $Q^2 (0 \text{ Al})$ species, respectively. That is terminal and middle (unbranched) silicon tetrahedra, respectively. An additional peak at ~ -81 ppm is assigned to $Q^2 (1 \text{ Al})$. The deconvoluted peak areas are used to calculate average Al/Si from the formula [12 and 13].

$$\text{Al/Si} = \frac{1/2 Q^2 (1 \text{ Al})}{Q^1 (0 \text{ Al}) + Q^2 (0 \text{ Al}) + Q^2 (1 \text{ Al})} \quad (3)$$

The Al/Si ratio was found to be 0.24. The average chain length is 10 units. The presence of Al as \sim one fifth of the Si in a chain length of 10 units suggests that Al tetrahedra may be present in bridging positions.

4. CONCLUSIONS

A new technique that studies the changes in surface charge of particles in pastes has been used. An alternating electric field was applied at a single frequency of about 1MHz, on each paste, which generated an electroacoustic signals that are received by means of a dip-type probe placed in direct contact with the paste. The electroacoustic signals are used to calculate the zeta potential of particles in the paste. The technique has been used to study the changes in surface charge, as a function of hydration time, of concentrated cement, silica fume/lime, and fly ash/lime slurries. The new technique is superior to other techniques in that concentrated suspensions (such as cement slurries) may be studied in their original formulations i.e. without dilution. The mechanism of hydration monitored the changes in phase composition by x-ray diffraction at various ages. Solid state ^{29}Si magic angle spinning nuclear magnetic resonance spectroscopy (MAS NMR) was used to characterize the detailed structure of hydration products after 28 days. The new technique represents a step towards exploring the actual changes in surface charge during hydration.

ABSTRACT

Eco-cement is made from municipal waste incinerator ash, which contains large amounts of Al_2O_3 and Cl^- . Consequently, Eco-cement contains greater quantities of calcium aluminate and ferrite phases and Cl^- than OPC. Although 20 to 40 mass% of Cl^- in Eco-cement dissolved into free water within 3 hours of the start of hydration, Cl^- concentration decreased rapidly after that. When Cl^- content in cement was adjusted to 0.1 mass% (added as NaCl), almost all of Cl^- in free water was bound as Friedel's salt in mortars made with Eco-cement, OPC and Blast furnace Slag Cement. The value of $[\text{Cl}^-/\text{OH}^-]$ molar ratio of free water in each mortar was under 0.6 at 28 days, so steel corrosion is not likely to occur. When Cl^- content was increased to 1.0 mass%, Eco-cement bound more Cl^- than other cements by producing a large amount of Friedel's salt. The Remaining Cl^- in free water, which was not bound as Friedel's salt, was sorbed in hydrates such as C-S-H.

1. INTRODUCTION

Municipal waste, the main waste product of domestic life, reaches 50 million tons a year in Japan. Most of it is usually reduced in volume (to about 1/10 of the original volume) by incineration and disposed in landfill sites without being recycled. Therefore, treatment and disposal of waste materials are becoming a serious social problem. The cement industry in Japan has accepted many kinds of waste materials from other industries and uses 2,800 million tons of them as raw materials or fuels every year. Based on this information, it is expected that the cement industry will become a solution provider to waste problems, in addition to being a provider of basic construction materials as it has been [1]. Eco-cement has been developed in response to this trend [2][3][4][5].

Eco-cement is a new type of Portland cement made from municipal waste incinerator ash as main raw material. Incinerator ash generally includes much larger amounts of Cl^- and Al_2O_3 than natural raw materials such as clay. Therefore, using incinerator ash at about 50% of raw materials leads to an increase Cl^- and calcium aluminate and ferrite phases in cement. Taking this into consideration, two types of Eco-cement are produced [4][6]: (1) normal type that contains 500 ppm Cl^- , and (2) rapid-hardening type that contains about 1 mass% Cl^- .

The behavior of Cl^- in concrete has been investigated by many researchers because it has a potential to accelerate steel bar corrosion. However, there are few papers on behavior of Cl^- , incorporated into cement clinker, in concrete. Cl^- in concrete is classified into free Cl^- in free water (pore solution) and bound Cl^- by cement hydrates [7][8]. It is thought that the former directly associates with the steel corrosion. Since Eco-cement has a different mineral composition and Cl^- content from Portland cements, the concentration of free Cl^- in free water is probably different from that in Portland

cements.

In this study, the dissolution of Cl^- incorporated into cement clinker is investigated by using Eco-cement that contains much greater quantities of Cl^- and calcium aluminate and ferrite phases than Portland cement. Also, the Cl^- binding mechanisms and Cl^- binding capacity of Eco-cement are investigated as compared with ordinary Portland cement and blastfurnace slag cement.

2. EXPERIMENT

2.1 Materials used

Normal Eco-cement (EC), rapid hardening Eco-cement (ECR), ordinary Portland cement (OPC) and blastfurnace slag cement (BB) were used for experiment. Their chemical compositions, mineral compositions, densities and Blaine specific surface areas are listed in Table 1. For mineral composition, EC contains much greater quantities of calcium aluminate and ferrite phases (15 mass% C_3A and 12 mass% C_4AF) than OPC. ECR contains 16 mass% calcium chloro-aluminate ($\text{C}_{11}\text{A}_7\cdot\text{CaCl}_2$), due to its higher content of Cl^- (8,900ppm). BB contains more Al_2O_3 (8.4 mass %), originated from blastfurnace slag, and less Fe_2O_3 (2.1 mass%) than OPC.

Table 1. Chemical composition, mineral composition, density and specific surface area of cement used

2.2 Experimental methods

2.2.1 Sample preparation

Cement pastes were prepared at w/c of 0.5, 20°C. Free water in cement paste was expressed by centrifugal separator at 30 min, 1, 3, 6 hours. The free water (pore solution) in ECR paste was expressed by a pore expression device [9] at all ages.

The total Cl^- content (added as NaCl) in cement used for mortar was adjusted to 0.1, 1.0, 3.0 and 5.0 mass% (by mass of cement). Mortar specimens were prepared at w/c of 0.5, s/c of 1.0 and 20 °C. Toyoura sand was used as fine aggregate. The Mortar was cast into 5cm diameter, 20cm height cylindrical molds that were tightly sealed. The free water in mortar was expressed by a centrifugal separator at 0.5, 1, 3, 6 and 12 hours, and by a pore expression device at 1, 3, 7, 28 days. Free water in mortar with ECR was expressed by a pore expression device at all ages.

At the same age as expression of free water from mortar, hardened mortar was cut into approximately 5mm cubes. These cubes were immersed in acetone to terminate the hydration and dried by D-drying or in the atmosphere with the RH of 11%. They were used for hydration analysis.

2.2.2 Analysis

The concentration of Cl^- in free water was determined with ion chromatography. The concentration of OH^- was determined by titration against standard NaOH of 0.01N using phenolphthalein as indicator. Amount of Friedel's salt ($\text{C}_3\text{A}\cdot\text{CaCl}_2\cdot 10\text{H}_2\text{O}$) was determined according to Shirasaka et.al. [10] in such way that it is determined by using heat absorption peak around 330 °C measured by DSC. Non-evaporable water of D-dried hardened mortar was determined by ignition loss according to JIS R 5202. Specific surface area was determined by BET.

3. RESULT AND DISCUSSION

3.1 Dissolution of Cl^- from clinker

Dissolutions of Cl^- into free water in cement paste were determined by ion chromatography. As shown in Figure 1, the concentration of Cl^- in free water in EC paste reached a maximum of 300 mg/l at 3 hours. If it is assumed that free water to cement ratio was 0.5 at 3 hours, this result means that about 23 % of Cl^- in EC was detected in free water. The concentration of Cl^- in EC paste decreased gradually after 3 hours and became almost equal to OPC paste at 12 hours.

The concentration of Cl^- in free water in ECR paste was highest of all pastes. Although, about 40 % of Cl^- in ECR paste was detected in free water at 3 hours at the maximum, the concentration of Cl^- in ECR paste decreased gradually after 3 hours as same as EC paste. These results indicate that the amount of Cl^- bound by cement hydrates of EC and ECR exceeded that dissolved from them after 3 hours.

3.2 Cl^- binding capacity

As mentioned above, Cl^- in hardened cement is classified into free Cl^- in free water and Cl^- bound by cement hydrates. It is considered that the latter one doesn't participate in the steel corrosion process as far as cement hydrates that bind Cl^- do not decompose by carbonation or other degradation mechanisms. Some techniques are proposed for determination of free Cl^- : extraction free Cl^- with water or ethyl alcohol (Leaching technique), press out pore water by pore expression device, etc. Trithart [11] reported that a pore expression device is suitable for expression of free water to determine the amount of free Cl^- and leaching technique is likely lead overestimation of free Cl^- . From consideration of this, the concentration of Cl^- in free water was determined by using expressed pore water in this experiment. Cl^- in free water is called "free Cl^- ", and other Cl^- is called "bound Cl^- ".

The Cl^- binding capacity of cement depends on the mineral composition and the type of blending materials used in the mixture. For example, cements with high calcium aluminate and ferrite phases or blast furnace slag are able to bind large amounts of Cl^- [7][12]. For cement hydrates, it is thought that Friedel's salt that binds Cl^- chemically and C-S-H that has high specific surface area are closely related to binding capacity of Cl^- . It is expected that the Cl^- binding capacities of EC and ECR are higher than OPC because of higher content of calcium aluminate and ferrite phases. In this section, Cl^- in cements were adjusted to 0.1-5.0 mass% by NaCl for comparison of the Cl^- binding capacity between cements.

Figure 1. Concentration of Cl^- in free water in cement paste

Figure 2. Concentration of Cl^- in mortar with cement with 0.1 mass% Cl^-

3.2.1 Cement with 0.1 mass% Cl^-

(1) Concentration of Cl^- and SO_4^{2-} in free water

The concentrations of free Cl^- and SO_4^{2-} in free water in mortars with 0.1 mass% Cl^- from 30 min to 12 hours are shown in Figure 2 and Figure 3. At 30 min, the concentration of free Cl^- in OPC, BB and EC mortar were 2,050, 2,030 and 960 mg/l, respectively. The amounts of free Cl^- at this age were almost equal to the total sum of Cl^- dissolved from cement (as shown in Figure 1) and those added as NaCl. The concentration of free Cl^- in each mortar increased slightly from 1 to 3 hours. After that, it started decreasing gradually. This result indicates that the amount of Cl^- bound by cement hydrates exceeded the amount of Cl^- dissolved from cement in each mortar after 3 hours.

At 30 min, the concentrations of SO_4^{2-} in free water in OPC, BB and EC mortar were 5,900, 5,430 and 1,700 mg/l, respectively. That in EC mortar was lower than those in OPC and BB because of the lower content of alkali sulfate in EC. The concentration of SO_4^{2-} in EC and OPC mortar decreased earlier than that in BB because they contain high amounts of calcium aluminate and ferrite phases that react with SO_4^{2-} at early age. The concentration of free Cl^- in EC and OPC mortar decreased rapidly with decreasing concentration of SO_4^{2-} after 6 hours. This result suggests that Friedel's salt is related to binding amount of Cl^- at early age.

The concentrations of free Cl^- in free water in mortars are shown in Figure 4. The concentration of free Cl^- in BB mortar was higher than others at 12 hours. It decreased rapidly from 12 hours to 1 day and became 40 mg/l at 7 days. The concentration of free Cl^- in OPC mortar decreased slowly after 12 hours. It decreased to 80 mg/l at 28 days. The concentration of free Cl^- in EC mortar decreased earlier than others. It decreased to 30 mg/l at 3 days and hadn't increased at 28 days.

Figure 3. Concentration of SO_4^{2-} in mortar with cement with 0.1 mass% Cl^-

Figure 4. Concentration of Cl^- in mortar with cement with 0.1 mass% Cl^-

(2) Proportion of bound Cl^- to total Cl^-

It is assumed that water in mortar, except for non-evaporable water shown in Figure 5, is free water. In that case, the amount of free water (FW) in mortar is calculated by using Equation (1). The amount of bound Cl^- (BCL) is calculated by using Equation (2). The proportions of bound Cl^- to total Cl^- (BCLR), calculated by using Equation (3), are shown in Figure 6. The proportions of bound Cl^- in each mortar increased rapidly from 6 hours to 3 days. At 3 days, almost all the free Cl^- in each mortar was bound. The proportions of bound Cl^- in EC, OPC and BB at 28 days were 99, 91 and 95 mass%, respectively.

$$FW = W - C * BW / 100 \quad (1)$$

$$BCL = TCL - FCL * FW / C \quad (2)$$

$$BCLR = (BCL / TCL) * 100 \quad (3)$$

where FW: Unit amount of free water (g/cm^3), W: Unit amount of water (g/cm^3), C: Unit amount of cement (g/cm^3), BW: Non-evaporable water (mass% to cement), BCL: Amount of bound Cl^- (ppm to

cement), TCL: Total amount of Cl^- (ppm to cement), FCL: Concentration of free Cl^- in free water (mg/l), BCLR: Proportion of bound Cl^- (mass% to total Cl^-)

Figure 5. Non-evaporable water in mortar with cement with 0.1 mass% Cl^-

Figure 6. Proportion of bound Cl^- in mortar with cement with 0.1 mass% Cl^-

3.2.2 Cement with 1.0 mass% Cl^-

(1) Concentration of free Cl^- in free water

When Cl^- content in cement was 0.1 mass%, the concentration of free Cl^- in free water in EC mortar decreased earlier than OPC and BB as described in section 3.2.1. However, there was not a significant difference between the proportions of bound Cl^- to total Cl^- of 3 mortars at 3 days. In this section, the same examination as in section 3.2.1 was done by using cement with 1.0 mass% Cl^- for investigation of the Cl^- binding capacity of each cement. The concentrations of free Cl^- in free water in mortar are shown in Figure 7. For EC, OPC and BB, concentration of free Cl^- at 1 day was about 20,000 mg/l. This result means that only a little amount of free Cl^- was bound by sorption into hydrates. From 1 to 3 days, the concentration of free Cl^- in each mortar decreased rapidly. The Cl^- concentration in EC mortar decreased earlier than that of OPC and BB. At 28 days, that of EC, BB and OPC mortar was 4,130, 6,600 and 12,500 mg/l, respectively. That of ECR mortar was much lower than the other mortars from an early age. This result is attributed to the un-hydrated $\text{C}_{11}\text{A}_7\cdot\text{CaCl}_2$ still remaining in ECR mortar and to the higher binding capacity of ECR due its higher content of calcium aluminate and ferrite phases.

(2) Proportion of bound Cl^- to total Cl^-

The proportions of bound Cl^- to total Cl^- in mortars with 1% Cl^- (by mass of cement) are shown in Figure 9. These results were calculated by using Equation (1) to (3), and the results of Cl^- concentration and non-evaporable water are shown in Figure 7 and Figure 8, respectively. The proportions of bound Cl^- to total Cl^- increased rapidly from 1 to 3 days. At 3 days, the proportions of bound Cl^- to total Cl^- of EC, ECR and OPC were 81, 92 and 52 mass%, respectively. The proportion of bound Cl^- in each mortar decreased with increasing total amount of Cl^- . The proportion of bound Cl^- in ECR mortar was much higher from an early age. At 28 days, that became almost the same value as EC mortar.

Figure 7. Concentration of Cl^- in mortar with cement with 1.0 mass% Cl^-

Figure 8. Amount of non-evaporable water in mortar with cement with 1.0 – 5.0 mass% Cl^-

Figure 9. Proportion of bound Cl^- in mortar with cement 1.0 mass of Cl^-

Figure 10. Relationship between Cl^- content in EC and amount Cl^- (28d)

3.2.3 Cement with 3.0 to 5.0 mass% Cl^-

As mentioned above, when Cl^- content in cement was adjusted to 0.1 to 1.0 mass%, EC has a higher Cl^- binding capacity than OPC and BB. In this section, Cl^- in EC was adjusted to 3.0 and 5.0 mass% by NaCl and concentrations of Cl^- in mortar with the cement at 28 days were measured to investigate the Cl^- binding capacity of EC. Figure 10 shows that the amount of bound Cl^- calculated by using Equation (1) and (2), and non-evaporable water is shown in Figure 8. Proportion of bound Cl^- to total Cl^- of EC decreased with increasing total Cl^- in cement. When Cl^- content in EC was adjusted to 5.0 mass%, about 2.8 mass% of Cl^- bound in cement hydrates. According to the results of Someya et.al. [12], when Cl^- content in OPC was adjusted to 3.0 mass%, the amount of bound Cl^- in OPC mortar at w/c of 0.5 and 28 days was 1.2 mass%. In the same condition, EC bound 2.1 mass% of Cl^- is shown in Figure 10. Therefore, it is considered that the Cl^- binding capacity of EC is much higher than that of OPC. This is attributed to the fact that the amount of calcium aluminate and ferrite phases in EC is much higher than that in OPC.

3.3 Cement hydrates

The relationship between the proportion of bound Cl^- to total Cl^- and the amount of Friedel's salt was investigated. The amount of Friedel's salt was expressed as mass% to cement revised by using loss of ignition.

3.3.1 Cement with 0.1 mass% Cl^-

The amounts of Friedel's salt from 6 hours to 3 days are shown in Figure 11. In general, after SO_4^{2-} in free water decreases with proceeding of hydration, monosulfate hydrate is produced. When Cl^- is in free water, Friedel's salt is produced instead of monosulfate hydrate. For OPC in this study, Friedel's salt was detected after 12 hours and 0.7 mass% at 3 days. For BB that contains relatively smaller amounts of calcium aluminate and ferrite phases, Friedel's salt was detected after 1 day and 0.8 mass% at 3 days. This result means that blastfurnace slag that contains large amounts of Al_2O_3 reacted after 1 day. EC produced much greater amounts of Friedel's salt than OPC at 12 hours. Friedel's salt in EC was 0.8 mass% as same as OPC at 3 days. This is attributed to the much higher content of calcium aluminate and ferrite phases (27 mass%) in EC. It can be noticed in Figures 6 and 11 that the increase of the proportion of bound Cl^- and the increase in the amount of Friedel's salt occurred at the same period, suggesting a correlation between the two.

3.3.2 Cement with 1.0 to 5.0 mass% Cl^-

The amounts of Friedel's salt in mortar are shown in Figure 12. Friedel's salt in OPC increased gradually from 1 to 7 days. At 28 days, it was 2.9 mass%. Amount of Friedel's salt in BB mortar was more than OPC at 3 days and 5.3 mass% at 28 days. For ECR which indicates the high proportion of bound Cl^- to total Cl^- , the amount of Friedel's salt was more than the other cement types and it was 5.1 mass% at 28 days. Similar to the case of cement with 0.1 Cl^- the proportion of bound Cl^- to total Cl^- and the amount of Friedel's salt increased at the same period as shown in Figures 9 and 12.

As shown in Figure 12, the amount of Friedel's salt at 28 days increased up to 3.0 mass% of total Cl. Therefore, it is considered that for this range of Cl⁻ content in cement, Cl⁻ was mainly bound by Friedel's salt. For the range of 3.0 mass% or more of Cl⁻ in cement, however, the amount of Friedel's salt didn't increase with increasing total Cl⁻ in cement. This result indicates that the amount of bound Cl⁻ by hydrates except Friedel's salt increased when Cl⁻ content in cement was 3.0 mass% or more. Maybe this is because the amount of un-hydrated calcium aluminate and ferrite phases was not enough to produce more Friedel's salt and OH⁻ was saturated in free water. That is, when Friedel's salt is produced according to Equation (4), OH⁻ in Ca(OH)₂ substitutes for Cl⁻ in free water and OH⁻ saturated in free water. In this case, further production of Friedel's salt will be prevented [13].

Figure 11. Amount of Friedel's salt in mortar with cement with 1.0 mass% Cl⁻

Figure 12. Amount of Friedel's salt in mortar with cement with 1.0 – 5.0 mass% Cl⁻

3.4 Cl⁻ binding mechanisms

From these results, it is considered that the Cl⁻ binding capacity is closely related to the production of Friedel's salt. In this section, Cl⁻ binding mechanisms were considered.

3.4.1 Cl⁻ in Friedel's salt

When Cl⁻ content in cement was adjusted to 0.1 mass%, 91 to 99 mass% of Cl⁻ was bound to cement hydrates at 3 days. At same age, Cl⁻ bound as Friedel's salt was 780 to 910 ppm. These results mean that most of Cl⁻ (1,000 ppm) in cement was bound as Friedel's salt in mortar. It is reported that C-S-H, which is main cement hydrate, also binds Cl⁻ by sorption [14]. When Cl⁻ content in cement was less than 0.1 mass%, however, Cl⁻ was bound by mainly Friedel's salt until 3 days [10].

When Cl⁻ content in cement was 1.0 mass%, the proportions of bound Cl⁻ to total Cl⁻ were 52 to 92 mass% at 28 days. This result means that much of the Cl⁻ remained in free water. Cl⁻ in hardened mortar at 28 days is classified into free Cl⁻ and bound Cl⁻ as shown in Figure 13. Bound Cl⁻ is classified again into Cl⁻ in Friedel's salt and Cl⁻ in other cement hydrates. Bound Cl⁻ was determined in the same way as in 3.2.2. The amount of Cl⁻ in Friedel's salt was determined by using stoichiometric calculations from values in Figure 12. When Cl⁻ content in cement was 1.0 mass%, 0.38 mass% of Cl⁻ was bound into Friedel's salt in OPC. This value agrees with the result obtained by Richartz [7]. EC and ECR bound more Cl⁻ (about 0.7 mass%) as Friedel's salt than OPC. Therefore, it is considered that the amount of calcium aluminate and ferrite phases is closely related to the amount of Friedel's salt. For BB, the amount of Cl⁻ bound in Friedel's salt was 0.43 mass%, a little more than OPC. This result is attributed to the contribution of Al₂O₃ in blastfurnace slag to produce Friedel's salt. On the other hand, the amount of Cl⁻ bound into other cement hydrates in OPC was higher than others. This result tends to suggest that Cl⁻ sorbed into other cement hydrates increases with decreasing amount of Cl⁻ bound in Friedel's salt.

For EC with 3.0 to 5.0 mass% Cl^- , amounts of free and bound Cl^- obtained in same manner as in Figure 13 are shown in Figure 14. The amount of bound Cl^- and Cl^- in Friedel's salt increased with increasing total Cl^- . When Cl^- content in cement was 3.0 mass% or more, however, the amount of Cl^- in Friedel's salt was little increased with increasing total Cl^- . That is, in this range of Cl^- , the proportion of Cl^- in other cement hydrates to total Cl^- increased with increasing total Cl^- .

Figure 13. Free Cl^- and bound Cl^- in mortar with cement with 1.0 mass% Cl^- (28 days)

Figure 14. Free Cl^- and bound Cl^- in mortar with cement with 0.1 – 5.0 mass% Cl^- (28 days)

3.4.2 Cl^- binding mechanisms

When Cl^- content in cement was 0.1 mass%, Cl^- was mainly bound as Friedel's salt. This result was true for all tested cements. When Cl^- content in cement was 1.0 mass%, however, there were significant differences in the proportion of bound Cl^- to total Cl^- among the different types of cements. It tended to increase with an increasing amount of Friedel's salt. These results suggest that Cl^- binding mechanisms vary with the types of cements and the total Cl^- content.

The amount of Cl^- bound as Friedel's salt depends on the amount of calcium aluminate and ferrite phases and gypsum, and their reaction ratio [15]. Cl^- in other cement hydrates is bound by sorption. Therefore, it is considered that the amount of Cl^- in other cement hydrates depends on the concentration of Cl^- in free water. Figure 15 shows that the relationship between the concentration of Cl^- in free water (shown in Figure 7) and the amount of Cl^- sorbed in other hydrates per surface area of mortar. The amount of Cl^- sorbed in other cement hydrates per surface area is calculated by using the amount of Cl^- sorbed in cement hydrates (shown in Figure 13 and Figure 14) and the value of BET specific surface area. With increasing the concentration of Cl^- in free water, the amount of Cl^- sorption per surface area increased regardless the types of cement and the amount of total Cl^- .

From these results, the Cl^- binding process is considered as follows: although Cl^- sorption starts just after mixing with water, the amount of Cl^- sorption at early age is a little because of the smaller amount of cement hydrates. On the other hand, Friedel's salt is produced vigorously from 6 hours to 7 days and binds Cl^- . Sorption of Cl^- has a relationship to the concentration of Cl^- in free water as shown in Figure 15. Therefore, it is considered that the sorption of Cl^- increases with increasing free Cl^- in free water, which isn't bound as Friedel's salt. When Cl^- content in cement is 0.1 mass% or less, each cement contains enough calcium aluminate and ferrite phases to produce Friedel's salt. Therefore, the amounts of Friedel's salt and bound Cl^- in all cements were almost equal. However, when Cl^- content in cement was 1.0 mass% or more, the amount of calcium aluminate and ferrite phases is not enough to bind all Cl^- as Friedel's salt. Therefore, EC, which contains large quantities of calcium aluminate and ferrite phases, produces much more Friedel's salt. Consequently, the concentration of Cl^- in free water in EC mortar decreases from an early age.

Figure 15. Relationship between the concentration of Cl^- in free water and the amount of Cl^- sorbed into hydrates in mortar with cement with 0.1 – 5.0 mass% Cl^-

Figure 16. $[\text{Cl}^-/\text{OH}^-]$ molar ratio in free water in mortar with cement 0.1 – 1.0 mass% Cl^- (28 days)

3.5 Molar ratio of $[\text{Cl}^-/\text{OH}^-]$ in free water

The most serious problem of Cl^- in concrete is the initiation and propagation of steel corrosion. Generally, the steel bar in concrete is protected by the high alkaline environment. However, when Cl^- exist in concrete and $[\text{Cl}^-/\text{OH}^-]$ molar ratio in free water excess 0.6, the oxidized layer on steel bar becomes unstable [16]. Kawai et.al. [17] investigated the relationship between $[\text{Cl}^-/\text{OH}^-]$ molar ratio and corrosion speed of steel bar and reported that the corrosion speed of steel bar depends on $[\text{Cl}^-/\text{OH}^-]$ molar ratio, rather than the concentration of Cl^- in free water. And in water with $[\text{Cl}^-/\text{OH}^-]$ molar ratio of 0.01 or less, the steel corrosion didn't occur [17].

$[\text{Cl}^-/\text{OH}^-]$ molar ratios in free water in mortar with cement with Cl^- of 0.1 and 1.0 mass% are shown in Figure 16. When Cl^- content in cement was 0.1 mass%, $[\text{Cl}^-/\text{OH}^-]$ molar ratio in OPC was highest in all cements. However, $[\text{Cl}^-/\text{OH}^-]$ molar ratio in OPC was under 0.01 and much lower than 0.6 of the threshold of corrosion. In consideration of the result of Kawai et.al. [17], the steel corrosion in each cements are not likely to occur. When Cl^- content in cement was 1.0 mass%, $[\text{Cl}^-/\text{OH}^-]$ molar ratio of EC and ECR, which bound much more Cl^- , was lower than those of OPC and BB. $[\text{Cl}^-/\text{OH}^-]$ molar ratio of OPC a little exceeded 0.6. These results mean that $[\text{Cl}^-/\text{OH}^-]$ molar ratios are different from the mineral composition of cement even if total Cl^- in cements is constant.

4. CONCLUSIONS

Eco-cement, made from municipal waste incinerator ash as main raw material, contains greater quantities of calcium aluminate and ferrite phases and Cl^- than OPC. Eco-cement is classified into normal type (EC) that contains about 500 ppm Cl^- and rapid hardening type (ECR) that contains 1.0 mass% Cl^- . In this study, the dissolution of Cl^- from EC and ECR were investigated. The Cl^- binding capacity of EC and ECR was also investigated as compared with OPC and BB by adjusting Cl^- in cement by NaCl. The results obtained are as follows:

- (1) The concentration of Cl^- in free water in EC and ECR paste was highest at 3 hours. At that age, the proportion of Cl^- detected in free water in EC and ECR paste were about 20 and 40 mass% of total Cl^- content, respectively. The Cl^- concentrations decreased rapidly after that.
- (2) When Cl^- content in cement was adjusted to 0.1 mass%, the concentration of Cl^- in free water in EC mortar decreased earlier than others. At 3 days, almost all the Cl^- in each mortar was bound mainly by Friedel's salt. $[\text{Cl}^-/\text{OH}^-]$ molar ratio in free water in each mortar was much lower than the corrosion threshold of steel.
- (3) When Cl^- content in cement was adjusted to 1.0 mass%, EC and ECR bound much more amount

of Cl^- than OPC and BB. Hence, the concentrations of Cl^- in free water in EC and ECR mortar decreased earlier than OPC and BB mortar.

- (4) When Cl^- content in cement was adjusted to 3.0 mass%, EC mortar bound about twice the Cl^- of OPC. The Cl^- binding capacity of EC is considered to be higher than OPC.
- (5) At early ages, Cl^- in free water is mainly bound as Friedel's salt produced by hydration of calcium aluminate and ferrite phases. The remaining Cl^- that isn't bound as Friedel's salt, is sorbed by other cement hydrates. The amount of Cl^- sorption increased with increasing concentration of Cl^- in free water.

1. INTRODUCTION

According to German technical specification a PCC is a cement mortar or a concrete with a maximum particle size of 8 mm which is modified with polymer additives. Usually, mortars made with Portland cement are used for PCC's. The function of the polymer additive depends on its type and amount, e.g. it could be serve as a plasticiser, a bonding aid or a binding material. If polymers are added to conventional mortars, one expects that such an additive improves the properties of fresh mortar (e.g. consistency, water retention capacity) and/or the properties of the hardened one (e.g. tensile bending strength, modulus of elasticity, adhesive power) in a special way and to a larger degree than common additives [1, 2]. The main component of such modifier is a thermoplastic polymer or a polymer mixture usual in the trade as a dispersion, as redispersible powder or a thermosetting system. Because of the easier handling of the former, dispersions are widely used, whereas thermosetting epoxy resins are designed for special applications according to its higher inherent stability and its temperature resistance. The quality control of these materials requires the identification and quantification of the polymer additives in dry mortar mixtures just as much as in hardened mortars or concrete. Therefore, four different polymer additives were investigated as a raw additive and also as a component of hardened mortars using FTIR spectroscopy and simultaneous thermal analysis.

2. EXPERIMENTAL

All investigated mortar samples were prepared using the same Portland cement (CEM I 42,5R) and standardised aggregate in constant amounts, but with different polymer : cement ratios, water : cement ratios and storage conditions because of the adjustment of the workability and of its use for further investigations [2]. Sample markings, preparation and storage conditions are summarised in Table 1. The samples aged for a half year were manually crushed, edge areas were removed and the remaining pieces were milled for 10 seconds at 1400 r.p.m. in a disk vibration mill.

Vinyl acetate-versatic acid vinylester-copolymers (PA), styrene-acrylate-copolymers (SA) and thermosetting epoxy resins (EP) are the most frequently used polymer additives for PCC's in Germany [3]. According to this, four commercial products based on these systems were used in this work, two of them as redispersible powders (RP) and the others as an aqueous dispersion (DI) or thermosetting emulsion (CU). One redispersible powder (SA-RP) and one dispersion (SA-DI) based on the same main component, a styrene-acrylate-copolymer.

The real polymer content within the hardened mortars deviates from the values resulting from the

amounts of the single components, because of the moisture exchange with the environment and the carbonation. Therefore, the polymer contents were corrected using the total mass change of the concrete up to 1000 °C according to equation 1.

$$w_{\text{pol}} = \frac{m_{\text{pol}}}{m_{\text{cement}} + m_{\text{aggregate}}} \cdot (1 + \Delta m_{\text{total}}) \quad (1)$$

The as-corrected polymer contents are also listed in Table 1.

The infrared transmission measurements were carried out on a Fourier transform spectrometer BioRad FTS 175C within a wavenumber range of 4000 cm⁻¹ to 400 cm⁻¹ with a resolution of 2 cm⁻¹. The hardened polymers and the PCC's were milled with a surplus of KBr (x 130) and pressed to cylinders in a conventional manner. Polymer solutions were dropped on quadratic pieces of a Silicon wafer, so that the solvent evaporates within some seconds. Each Silicon piece was measured for background correction before the polymers were deposited.

A reliable identification of small polymer contents nearly or below 1 w.-% is complicated because of the mortar peaks covering weak polymer infrared peaks. Therefore, polymer additives were enriched by reflow extraction using a Soxhlet extractor related to EN ISO 6427 standard [4]. The extractions were carried out with 20 g PCC and 100 ml Acetone, a full extraction cycle took place within 2 or 3 minutes. Approximately a third of the total polymer content was typically extracted within 8 hours.

A simultaneous thermal analyser Setsys 16/18 by Seteram SA was used for the thermal analysis. The measurements were carried out with a heating rate of 10 K/min in a flowing atmosphere (appr. 1 l/min) of purified air or Argon. The sample mass varied from 8 to 25 mg, open corundum crucibles with a volume of 100 µl were used. All measurements were corrected for buoyancy.

Because of the significant differences of the expected and the experimental mass changes caused by polymer decomposition, mixtures of a cement paste with hardened polymer additives SA-RP and

PA-RP were prepared. The cement paste (CS) was made from a CEM I 42,5R, hardened and stored in a closed vessel for one year. The cement paste and all mixtures were prepared and milled for 30 seconds in a vertical vibration ball mill just before measurement. The total handling time in air was comparable for all these samples to prevent different carbonation.

3. RESULTS AND DISCUSSION

3.1 Infrared measurements

The IR spectra of the reference mortar CC-0 and of the hardened polymers are depicted in Figure 1. The polymer-free mortar shows wide valence vibrations of the inorganic groups $[\text{SiO}_4]^{4-}$ and $[\text{CO}_3]^{2-}$ at 993 cm^{-1} and 1486 cm^{-1} , respectively. The sharp peak at 3645 cm^{-1} corresponds to a free O-H valence vibration, the wide peak at 3442 cm^{-1} is assigned to associated OH groups.

Plain hints for organic additives in cement mortars should be given by the presence of $\nu\text{-C-H}$ vibrations in the range from 2840 to 3110 cm^{-1} . Surprisingly, two small peaks below 3000 cm^{-1} (at 2922 and 2852 cm^{-1}) point to organic impurities in the polymer-free mortar, just as in the Portland cement (not shown) itself which was used for the mortars. We assume that these organic impurities came from a milling agent usually used in the cement production process.

Nevertheless, the called range is very meaningful for the identification of the additives. All additives excepting PA-PR show peaks between 3020 and 3120 cm^{-1} which were assigned to $\nu\text{-C-H}$ vibrations of aromatic compounds. Correspondingly, the sole polymer without aromatic components should be the vinyl acetate-versatic acid vinylester-copolymer built up of aliphatic monomers only.

Another important range for the identification of polymer additives in cement mortars is enclosed

Figure 1. IR spectra of the CC-0 reference and the hardened polymer additives

by the wavenumbers 1700 up to 2000 cm^{-1} . The absence of the strong $\nu\text{-C=O}$ vibration at 1720 - 1750 cm^{-1} excludes ester groups, this is valid for the EP-CU epoxy system in the present work. Moreover, the accurate wavenumber of the $\nu\text{-C=O}$ vibration peak top makes it possible to distinguish between the vinyl acetate-versatic acid vinyl ester-copolymer PA-RP with 1745 cm^{-1} and the styrene-acrylate-copolymer (SA-RP, SA-DI) with 1732 cm^{-1} . Additional weak peaks were observed for SA-DI above the $\nu\text{-C=O}$ vibration. These peaks were assigned to C-C combination vibrations of the aromatic core.

The comparison of the IR spectra in Figure 1 shows clearly that a lot of polymer peaks of PCC's should be overlapped by vibrations typical for cement mortars. In fact, the polymer peaks in the IR spectra of PCC's are mostly covered for wavenumbers below 1700 cm^{-1} . Besides, small polymer contents nearly or below 1 w.-% results in very weak polymer peaks preventing a reliable polymer identification.

Therefore, polymer additives were removed from the PCC's and enriched by reflow extraction and deposited on silicon wafer pieces as described above. The IR transmission spectra on polymer films deposited from polymer solutions in acetone are compared in Figure 2 for PA-RP and the related PCC3. No significant differences between the absorption peak positions were observed for this example or for the other polymer additives. According to that, the reflow extraction makes possible a reliable identification of hardened polymer additives. A reactive conversion of the polymers can be excluded for the described storage conditions.

Figure 2. IR spectra on films deposited from PA-RP solution and from PCC3 extracts

3.2 Thermal analysis

3.2.1 Characterisation of polymers and PCC's

Thermoanalytic measurements were carried out in atmospheres of purified air and argon, respectively. Corresponding measurements on PCC4-15 are shown in Figure 3 for example. The thermogravimetric curve (TG) and its first derivative (DTG) were used for characterisations, the heat flow was removed for clarity. As expected for a cement mortar the sample mass changes slowly up to 900 $^{\circ}\text{C}$ according to the dehydration of the cement paste. The extended mass loss is superimposed by the portlandite dehydration and by the calcite decomposition. The measurement in

air shows an additional mass change caused by the polymer decomposition. Obviously, the use of an inert argon atmosphere shifts the polymer decomposition in the range of the portlandite dehydration so that these two mass steps can not be distinguished.

Figure 3. Thermogravimetric measurements on PCC4-15 in different atmospheres

A quantitative analysis of the mass changes by the sole use of the TG curve is difficult since the decomposition reactions superimpose each other. Therefore, the limits for mass changes were consequently selected using the DTG curve maximums near the relevant mass changes. The mass changes were determined using a tangential baseline correction in contrast to the usual evaluation with horizontal baselines. In that way the superimposed cement stone dehydration was eliminated from the other mass steps. The tangential evaluation method was verified on synthetic mixtures of cement paste (CS) with CaCO_3 . According to [5] the tangential evaluation gave results close to the true CaCO_3 content in contrast to the horizontal evaluation [6] resulting in values much too high.

The DTG curves of the PCC's in air are depicted in Figure 4, the DTG peak top temperatures of the polymer decomposition of pure hardened polymers and of PCC's are summarized in Table 2. Although the peak temperatures of PCC's are shifted compared to the pure polymers possibly caused by the homogeneous distribution in PCC's, the polymer additives in PCC's can be clearly distinguished using the DTG peak top temperatures.

Table 2. DTG peak top temperatures of polymers and PCC samples in air

PCC	base peak		polymer	base peak further polymer peaks					Δm_{total} [w.-%]
	-5 ^a [°C]	-15 ^a [°C]		[°C]	[°C]	[°C]	[°C]	[°C]

^a last number in the sample mark, e.g. 15 in PCC1-15

Figure 5. Thermogravimetric measurements on mixtures of cement paste with SA-RP

The theoretical mass changes for the synthetic mixtures $\Delta m_{th, mi}$ can be calculated using the experimental mass changes of the pure cement paste $\Delta m_{exp, CS}$ and the polymer content w_{pol} according to Equation 2.

$$\Delta m_{th, mi} = \Delta m_{exp, CS} \cdot (1 - w_{pol}) \quad (2)$$

This equation is valid if no reactive interaction exists between the components of the mixture. For this case an increasing polymer content should only generate a slight decrease of the mass changes generated by the cement paste. In contrast to that, the observed distinct differences $\Delta \Delta m_{pol}$ between the theoretical $\Delta m_{th, mi}$ and the experimental mass changes $\Delta m_{exp, mi}$ of the $Ca(OH)_2$ and $CaCO_3$ decomposition should be assigned to the influence of reactive CO_2 coming from the polymer.

$$\Delta \Delta m_{pol} = \Delta m_{exp, mi} - \Delta m_{th, mi} \quad (3)$$

The values $\Delta \Delta m_{pol}$ were used to calculate the additional CO_2 amounts m_{pol-CO_2} which decreases the $Ca(OH)_2$ and increases the $CaCO_3$ mass change.

The simple stoichiometric calculation according Equation 4 shows that the CO_2 amount consumed by $Ca(OH)_2$ is significantly smaller than the polymer-generated CO_2 amount found by the $CaCO_3$ decomposition. Therefore it was concluded that free CaO existing above the portlandite decomposition temperature also consumes polymer-generated CO_2 . This conclusion is supported by the measurements in Figure 5 since the TG curves above the portlandite decomposition show more horizontal slopes for the mixtures compared to the cement paste. Surprisingly, a recently published work [7] even describes a distinct mass gain after or above the portlandite dehydration in a nitrogen atmosphere for a concrete modified by ethylene/vinyl acetate. This fact was explained by a reaction of an intermediate formed organic carboxylate with hydroxyl ions released by cement hydrate phases. However, a sample mass gain during thermoanalytic measurement requires absolutely the take up of a gaseous component. Therefore, the described mass increase has to be assigned to the

Figure 6. (a) Thermoanalytic mass changes of mixtures of cement stone with hardened polymers
(b) Mass changes of the polymer decomposition of synthetic mixtures and PCC's

oxidation of organic components caused by oxygen impurities of the atmosphere instantaneously followed by the take up by the sample. Besides, the content of hydroxyl groups is comparatively low at temperatures above the portlandite dehydration.

The relevant mass changes determined for all synthetic mixtures are shown in Figure 6a dependent on the polymer content. The opposite behaviour of the experimental and the theoretical mass changes demonstrates the strongly reactive interaction of the polymer-generated CO_2 with $\text{Ca}(\text{OH})_2$ and CaO . Unfortunately, a thermal analysis in an inert atmosphere is also not suited to fully suppress the reactions corresponding to the data of other works [7].

Fortunately, the mass change of the polymer decomposition in air shows a linear dependence on the polymer content and is obviously independent on the kind of polymer. This is supported by Figure 6b containing the mass changes of the polymer decomposition for PCC's and for the synthetic mixtures together. A linear regression using the whole data set results in a well-defined functional dependence with a satisfactory quadratic correlation coefficient.

4. CONCLUSIONS

It was shown that the polymer additives can be identified with IR spectroscopy and by thermal analysis. On principle, IR spectroscopy makes it possible to identify the basic polymer system of an additive without a reference sample. Nevertheless, a reliable identification of additives in concrete mortars requires the reflow extraction of the polymer component, since the vibrations of a typical mortar covers the majority of polymer peaks below 1700 cm^{-1} . A differentiation between some basic polymer systems can be made by some peaks within the wavenumber ranges from 1700 cm^{-1} to 2000 cm^{-1} and from 2840 to 3110 cm^{-1} , but a reliable assignment requires the measurement of reference samples to get "finger print" spectra. The main reason for this limitation is the unknown composition of commercial products consisting of a multitude of components. For example, small amounts of surfactants are able to change the properties of a polymer dispersion significantly, but these small amounts were normally not noticed in IR spectra.

The extraction of nearly 30 % of the polymer additives from hardened PCC's within 8 hours with an ordinary non-toxic solvent such as acetone was a real surprise, especially for the thermosetting epoxy resins. Because of the high molecular mass of the copolymers used it is understandable that an extraction of the whole polymer was not possible within such a short time, but the opinion that the extraction of polymers from hardened concrete is not possible [8] should be given up.

The IR spectra on the polymer films deposited from the extracts show no significant differences compared to those deposited from polymer solutions. In other words, no significant variations of the spectrum caused by the mortar hardening and no hints for a reactive conversion of the hardened polymer additives were observed in contrast to references [9, 10, 11].

The identification of polymer additives in PCC's with thermal analysis always requires the measurement of reference products, because the characteristic decomposition temperatures do not only depend on the measurement conditions as heating rate or atmosphere, but also on the special conditions of the thermal analyser used such as crucible shape and material, thermocouple, thermal contact, sample mass, gas flow etc. Nevertheless, the thermal analysis is well-suited for the quantification of the additives because of the high reproducibility of the mass changes. Although the experimental mass changes of the polymer decomposition amounted to only 40 % of the theoretical ones, the well-defined functional dependence on the real polymer content can be used for the quantitative determination of all polymers tested. In contrast to previous works [6, 7] the thermal analysis should be carried out in an oxidising atmosphere since, for some polymers, a shifting of the polymer decomposition step into the Ca(OH)_2 dehydration step was observed.

The most surprisingly result of this work is the evidence that a considerable part of the polymer-generated CO_2 reacts with Ca(OH)_2 and CaO during the thermoanalytic measurement. According to our previous comments, a quantitative thermal analysis of the portlandite and calcite content of a polymer containing concrete is accompanied by systematic errors at every time. Looked from this point of view, the opinions on the influence of the polymer content or more general of organic additives on the carbonation of concrete should be reconsidered if thermal analysis was used for the quantification [6, 7, 12, 13].

ABSTRACT

A better understanding of the evolution of cement hydration and of the development of microstructural formation of cementitious materials at early age is a very important requirement for developing a numerical simulation method. Experimental studies and numerical modelling become increasingly significant for understanding the microstructural properties during cement hydration. In this study, a multifunctional experiment combining ultrasonic pulse velocity measurements and dielectric conductivity measurements was performed both on cement paste and on concrete mixtures with water/cement ratio 0.4, 0.45, and 0.55 and with different amounts of aggregate. The samples were cured isothermally at 20°C, 30°C and 40°C. The measurements were conducted up to an age of 3 days for the cement paste and 7 days for concrete.

The initial setting of cement paste was found at the time when a sudden increase in the ultrasonic pulse velocity occurred and a notable drop in the electric conductivity was observed. These sudden changes were also detected with the cement hydration simulation model HYMOSTRUC, in which a percolation threshold of the solid phase corresponded with the initial setting time. As expected, the lower water/cement ratio and the higher curing temperature exhibited a quick increase in ultrasonic pulse velocity and a remarkable decrease in conductivity. At a certain point of hydration, the pulse velocity showed a slow increase whereas at the same moment a full connectivity of solid phases was found with the simulation model. From this study, the validity of the HYMOSTRUC model was proved by comparison with the ultrasonic pulse velocity measurements and dielectric measurements. This multifunctional experimental setup also shows the potential for monitoring the evolution of cement hydration and the development of microstructure in hardening cement-based materials in a non-destructive way.

1. INTRODUCTION

It is well known that cement hydration is a complicated process of physical and chemical reactions between cement particles and water, in which a wide variety of factors, such as water/cement ratio and curing temperature, are involved. In the engineering practices, the presence of aggregates, further aggravates this already complex process of microstructure evolution.

Enormous attempts were dedicated to a better and comprehensive understanding and quantitative description of the microstructure development of cement paste and concrete, with particular emphasis to the duration of cement setting. However, many techniques are suffering from all kinds of limitations and deficiencies. For example, the application of scanning electron microscopy image and small angle X-ray scattering is restricted due to the demanding process of sample preparation [1, 2]. The interpretation of mercury intrusion porosimetry experiments is very difficult because of

the so-called inkbottle effect and damages to the capillary pore structure [3]. Recently, non-destructive techniques have attracted increasing attention for monitoring the early-age behaviour of cementitious materials [4-8]. Among them, the ultrasonic technique seems to be a valuable tool for following the setting and hardening progress of cement and concrete because of its high sensitivity to the evolution of solid phases and especially to the solid phase percolation [4, 9]. In parallel, the electrical properties were found to be very useful in the investigation of properties and topology of aqueous phase [10]. It should be noted that ultrasonic pulse velocity (UPV) measurements and dielectric property measurements have the advantages of accuracy, simple test procedures, and applicability at early age of cement hydration.

A non-destructive multifunctional setup [11,12], consisting of a dielectric sensor and high-frequency ultrasonic transducers, was adopted in this research work to measure the electric conductivity and UPV of Portland cement pastes and concretes. Three important technical parameters, namely water/cement ratio, curing temperature and volume of aggregate, were taken into account. The experimental results were compared with the calculations performed with the cement hydration computer model HYMOSTRUC [13]. The detailed modelling concepts of this program will be given in section 2.

The purpose of this research work was to provide more accurate information about the microstructure development of cement and concrete and, on the other hand, to compare the numerical simulation of this evolution process with the experimental study in order to improve the reliability and applicability of HYMOSTRUC. Meanwhile, the technique employed in this study enables accurate monitoring of the setting and hardening process of concrete at the construction site, which is important for the time of removal of formwork and of applying the prestress.

2. MODELLING OF HYDRATION AND MICROSTRUCTURE DEVELOPMENT

For the simulation of reactions between water and cement and of the formation of microstructure in cement-based materials, a numerical simulation model called HYMOSTRUC was developed at Delft [13]. HYMOSTRUC stands for **HY**dration, **MO**rphology and **STRUC**tural development. A scheme of the model concepts and a simulated cement paste is shown in Figure 1.

Figure 1. Formation of a microstructure in hardening cement paste, simulated with HYMOSTRUC model [13, 18].

In this model, the rate of hydration is modelled as a function of the particle size distribution and the chemical composition of the cement, the water cement ratio and the reaction temperature. Moreover, the effect of physical interactions between hydrating cement particles on the rate of hydration of individual cement particles is modelled explicitly. The cement particles are modelled as digitised spheres randomly distributed in a three-dimensional cement-water system and the hydrating cement grains are simulated as growing spheres. As cement hydrates, the cement grains gradually dissolve and a porous shell of hydration products is formed around the grain in the porous space. This results in an outward growth or "expansion" of the particles. The hydrates around the cement grains first cause the formation of small isolated clusters. Big clusters are formed when small cement particles become embedded in the outer shell of other particles, which promotes the outward growth of these particles. As hydration progresses, the growing particles become more and more connected and the material changes from the state of a suspension to the state of porous elastic solid.

3. EXPERIMENTAL PROCEDURES

3.1 Theoretical background

As discussed before, cement hydration is an evolution process from a suspension state of cement in water to a solid heterogeneous network of hydration products and unhydrated cement particles. The theoretical background of UPV and dielectric measurements lies in the fact that the electric conductivity is mainly sensitive to changes in the liquid phase, whereas the ultrasonic pulse velocity corresponding to changes in the solid phase [5-7,9,14,15].

A basic principle of physics says that the motion of any wave will be affected by the medium through which it travels [16], because the wave velocity is determined by the stiffness and density of the material. In the process of cement hydration, cement matrix acquires and accumulates stiffness as a result of the microstructural evolution. This allows us to correlate the change of UPV through cement paste with the microstructural development of cement matrix at early age. In concrete mixtures, during the fluid period, the ultrasonic velocity is not sensitive to structure formation in the paste [7], while the water/air phase plays a dominant role in ultrasonic pulse propagation [7,17]. As cement particles gradually dissolve and nucleate, a percolating solid network will be developed as a result of increasing connection between small clusters of particles. At this moment, the ultrasonic pulse propagation path switches from the liquid phase to the solid phase.

The permittivity is correlated to the electrical polarization of a material and gives insight into the density of energy stored in the material that is subjected to an electric field. The electrical conductivity instead, is correlated to the amount of dissipated energy due to the ohmic flow of charge carriers or to the orientational movement of dipoles under the applied field. In cement paste, the pore space is partly filled with a conductive water solution that is the main path for the flow of current.

3.2 Experimental setup

A multifunctional experimental setup [11,12] was designed, incorporating an ultrasonic and a dielectric measurement device with a temperature controlling system. The ultrasonic transducers, dielectric sensor and temperature probe were integrated in a $150 \times 150 \times 200 \text{ mm}^3$ steel mould. Figure 2 provides a detailed description of the experimental setup.

A 20 MHz dielectric sensor called CONSENSOR was used to perform the permittivity and conductivity measurements. At this frequency, it was realistic to simulate the cementitious material as a capacitor and a resistor, where the capacitor was correlated to the permittivity and the resistor to the conductivity. The sensor is made of two stainless steel rods 3 cm long, 1 cm diameter and

spaced 2 cm, which are attached to a circular disc. The circular disc was fixed onto the inner surface of the mould so that the electrodes penetrated into the concrete.

Figure 2. Experimental setup for monitoring UPV and dielectric conductivity.

The ultrasonic measurement was conducted with a PUNDIT plus equipment with a 54 kHz transducer. In order to avoid the influence of the wall of the steel mould on the ultrasound propagation, two holes with a 54 mm diameter were made in the wall. The transducers were fixed by a PVC ring and coupled directly through a piece of plastic membrane glued on the inner wall of the mould; four springs were used to adjust the transducer's contact pressure to guarantee good contact with the specimen. In this way, the attenuation of ultrasound waves that may be caused by the wall of the steel mould was completely avoided.

The temperature of the whole system was controlled by a cooling system with an accuracy of $\Delta T = 0.1^\circ\text{C}$. One Pt 100 probe was used for the thermal control. All control units were connected with a industrial computer. The hydration time, permittivity, conductivity, ultrasonic pulse velocity, and temperature were automatically recorded every 10 minutes.

3.3 Materials

A series of tests is performed on two groups of cement and concrete with water/cement ratio of 0.40, 0.45, and 0.55, and isothermally cured at 20, 30, and 40 °C. For the concrete samples, the amount of aggregates is given in Table 1. Measurements started 15 minutes after mixing. The specimens were subjected to vibration in order to remove the extra air bubbles. The compressive strength tests on cubes, $150 \times 150 \times 150 \text{ mm}^3$ are performed at an age of 1, 3 and 7 days.

Table 1. Mixture proportions of concrete

Specimen No.	Cement type	Cement content [kg/m³]	Aggregate content [kg/m³]	w/c [-]	Temperature [°C]	Curing age [days]	
Concrete	PCA16350-40	CEM I/32.5	350	1942	0.40	20, 30,40	7
	PCA16350-45	CEM I/32.5	350	1884	0.45	20, 30,40	7
	PCA16350-55	CEM I/32.5	350	1792	0.55	20, 30,40	7
Cement paste	PCP-40	CEM I/32.5	350	0	0.40	20, 30,40	3
	PCP-45	CEM I/32.5	350	0	0.45	20, 30,40	3
	PCP-55	CEM I/32.5	350	0	0.55	20, 30,40	3

4. RESULTS AND DISCUSSIONS

4.1 Profile of UPV and conductivity with progressive hydration

UPV and conductivity were measured for all cement and concrete specimens with the evolution of cement hydration. The results were plotted versus hydration time. (see Figure 3). The profile of UPV indicated a very low value within the first few hours (corresponding to the fluid state) and then exhibited a sharp increase between 10 and 40 hours, which was followed by a plateau without significant changes. The quick and obvious increase in UPV revealed a concurrent increase in the connectivity of the solid phase. In fact, only connected solids are able to transmit high-velocity mechanical waves.

Figure 3. Correlation between UPV and microstructure development

Figure 4. Correlation between conductivity and microstructure development

The curve of conductivity evolution (see Figure 4) presented a different picture, with a slight increase in the very early stage just after mixing. This could be explained by the ion dissolution and correlated effects. However, a subsequent large decrease of conductivity could be attributed to the continuous reduction of the amount of water in the capillary pores. Similar to UPV profile, after 80 hours hydration of cement, the dielectric properties did not exhibit pronounced changes.

From the above discussion, the evolution of UPV and conductivity can be simplified to four typical characteristic stages, as shown in Figure 5. This profile of four stages was general for all test specimens. The duration of each stage depended on the technical parameters including water/cement ratio and curing temperature. The influence of these parameters will be discussed in the following section.

Figure 5. Simplification of the evolution of UPV/conductivity in four characteristic stages.

4.2 Correlation between UPV and dielectric properties with the microstructural evolution

With the progress of cement hydration, hydration products and unhydrated cement particles become interconnected, resulting in a porous network. The volume fraction of solid and pore phase will change and, as a consequence, the UPV and the dielectric properties will also change.

It was observed that the UPV value at the initial stage was lower than the UPV in water (1430m/s) and even lower than in air (340m/s). According to Keating and Sayers [6,7], this phenomenon was caused by air entrapped in the paste. Both the air bubbles in the mixing water and the tiny air bubbles that were entrapped into the paste during mixing contributed to the existence of air bubbles in fresh mixture. During this initial period, hydrates were formed in a very low amount and therefore, the entrapped air bubbles played a dominant role in the evolution of UPV [17]. The pronounced increase in the second stage could be accounted for by the following facts: (1) The entrapped air bubbles migrated to the surface of the concrete due to bleeding. Hence, the amount of entrapped air was reduced; (2) After the dormant period, the amount of solid phases became enough to interconnect the solid particles. At this moment, the material changed from a suspension system to the state of a porous elastic solid. Very slight increase in the pulse velocity was found when UPV had reached a plateau.

The HYMOSTRUC3D [18] model was utilized to study the quantitative relation between volume fraction of the solid/pore phase and the ultrasonic/dielectric properties. It was shown in Figure 3 that the percolation threshold of the solid phase (i.e. point A, when the solid phase became interconnected), calculated from HYMOSTRUC3D, was found to correspond exactly with the starting point of the sudden increase of the UPV. The percolation threshold of the solid phase is identified as the end of the dormant stage of cement hydration. When this threshold (about 3~4 hours of hydration in this research) was reached, a solid percolation path is formed in the hydrating paste. It was calculated from HYMOSTRUC3D that for a cement specimen with water/cement ratio of 0.45 and curing temperature at 20 °C, a percolation threshold was reached at a hydration degree of 2.7% [9]. At that moment, the volume fraction of the total solid was 52% and the volume fraction of connected solid was 30% of the cement paste. After this critical point, the UPV revealed a significant increase (A→B) because the stiffness of the cement paste largely depended on the connectivity of the solid phase. This period was accompanied by a similarly fast increase in volume fraction of connected solid from 30% to 60% (when degree of hydration is about 25%). However, after almost all the solid phases become connected (point C in Figure 5), the UPV showed a

plateau. The percolation threshold of the solid phase, point A in Figure 5, can be considered as the initial setting of the cement paste, whereas the point B, the end of the acceleration period, can be considered as the final setting of cement particles. Point C, in which most of the interparticle contacts are formed, is the significant moment for the removal of formwork and for applying the prestress.

While the UPV was sensitive to the connectivity of the solids, the electric properties were sensitive to the modifications of the aqueous phase. This could be proved by the good correspondence between the profile of conductivity and changes in the capillary pore phase. Therefore, the electric conductivity is a good parameter to monitor de-percolation of the capillary porosity [11, 12].

4.3 Influence of technical parameters

In this section, the influence of technical parameters on UPV and conductivity of cementitious material will be discussed.

4.3.1 Water/cement ratio

Results of UPV and conductivity measurements for cement and concrete of three different water/cement ratios revealed similar shapes and trends of the curves. A quicker increase in pulse velocity was observed in concrete than in cement paste with the same water/cement ratio. For example, the profile of UPV and conductivity for concrete cured at 20 °C is shown in Figure 6. Mixtures with a higher water/cement ratio showed lower values of the pulse velocity and higher conductivity. The pulse velocity was almost 8~10% higher in concrete with w/c ratio of 0.45 than in w/c ratio 0.55. This is expected because the higher the water/cement ratio, the lower the density of the microstructure of the cement paste.

Figure 6. Influence of water/cement ratio on UPV and conductivity of early age concrete

Figure 7. Influence of curing temperature on UPV and conductivity of early age concrete

4.3.2 Curing temperature

Due to the fact that the evolution of the UPV and conductivity were similar, results for a representative group of concrete with water/cement ratio 0.45 cured at different temperatures shown in Figure 7. It could be concluded that, the higher the isothermal curing temperature, the quicker the increase in pulse velocity during the second stage. In other words, the UPV reached a plateau within a shorter period if the specimen was cured at higher temperatures. As for the conductivity measurement, specimens with higher curing temperature also revealed a sharper decrease during the

second stage of profile evolution. After the plateau was reached, the temperature showed a less pronounced influence on both the pulse velocity and the conductivity.

4.3.3 Amount of aggregates

The influence of amount of aggregates was studied in the case of w/c ratio 0.37 and the aggregate volumetric fraction varied from zero (plain paste) up to 75% (concentrate concrete). The aggregate is composed of sand (lower than 4 mm) and crushed aggregate (between 4 and 16 mm). A constant weight ratio between the two components was kept. Additives were 5% silica fume on binder base (in slurry form), a lignosulphonate-based plasticizer and a naphthalene-sulphonate-based superplasticizer (see Table2). Tests were done till an age of 7 days. The temperature was kept at 10, 20 and 40°C. Figure 8 shows the effect of aggregate on the conductivity (left) and UPV (right). With increasing amount of aggregate, the UPV curve shifted upwards, this because the presence of aggregate contributed to the amount of connected solid phase in the concrete. It was well defined in [19], that the evolution of UPV in concrete is a function of the volume fraction of each phase (concrete was considered as a two phase system composed of paste and aggregate in this study). The calculation results of the evolution of UPV in concrete were proved to be in perfect agreement with the experimental results. In contrast, the number of charge carriers in the system decreased with increasing amount of aggregates so a gradual and continuous decrease was observed in the conductivity curves.

Figure 8. Evolution in time of conductivity (left) and UPV (right) of concretes having different aggregate concentrations at a temperature of 20°C [20].

5. CONCLUSIONS

A multifunctional experimental setup was designed and adopted in the measurements of dielectric and ultrasonic evolution versus hydration time for cement and concrete with different technical parameters. The validity of the computer based hydration model HYMOSTRUC was proved by the experimental results. The experimental results indicated that the profile of both dielectric and UPV evolution could be divided into four stages. At a certain hydration time, a threshold was found in the ultrasonic response, and at the same time a peak was observed in the conductivity curves. This critical point coincided exactly with the percolation threshold of solid phases calculated with the numerical simulation model HYMOSTRUC. Afterwards, in correspondence to the acceleration period simulated by the model, a sharp increase of UPV and a concurrent quick decrease of electric conductivity were recorded. This allows the determination of the setting and hardening process of cementitious materials at early-age hydration. On the other hand, non-destructive ultrasonic and dielectric measurements have the advantage of high accuracy and simple experimental procedures. They were demonstrated to be convenient and useful in monitoring the hydration

process of early-age cementitious materials. The comparison between experiments and numerical simulation revealed that the HYMOSTRUC model was able to provide an accurate and realistic quantitative description of the microstructural evolution of cementitious materials.

ACKNOWLEDGEMENTS

The authors wish to thank Mr. E.M. Horeweg for his expert assistance in conducting the experiments. Dielectric tests were performed in close cooperation with Dr. Princigallo from Pisa University. His fruitful cooperation and discussions were greatly acknowledged. The research was financially supported by the Dutch Technology Foundation (STW), which is gratefully acknowledged.

ABSTRACT

In this paper, the features of different computer-based cement hydration models are discussed. Simulations of cement paste hydration and formation of 3D microstructure were carried out on the basis of a simulation model, called HYMOSTRUC. The simulated pore structures were visualised and analysed explicitly by applying a serial algorithm associated with an overlapping criterion. The internal surface area, the hydraulic radius, the characteristic pore size distribution and the total capillary porosity were evaluated. The shape of the pore size distribution curve was similar to the experimental results obtained by BSEM image. The capillary pore connectivity in terms of connected pore fraction was calculated and the capillary pore network was derived. The influence of the digital resolution on the connectivity of the capillary channel was discussed and compared with previous work. The generated information on the pore structure was used in the prediction of the absolute permeability, in which the Carman-Kozeny model was utilized.

1. INTRODUCTION

The structure of the capillary pore system strongly influences transport properties of concrete. In particular, the ingress of water and aggressive agents into concrete (structures) is largely related to the microscopic properties of the pore network. To access the pore structure, the available experimental techniques are not completely adequate for describing the topological and geometrical properties of the pore network structure. For example, the application of 2D scanning electron microscopy image and small angle X-ray scattering microtomography only supply 2D information. Mercury intrusion porosimetry measurements, on the other hand, usually damage and change the pore structure [1]. However, with the rapid development of computer technology, a number of experimental complications can be circumvented by using computer-based simulation models. With these models it is possible to simulate the evolution of the microstructure, especially a pore structure, in hardening cementitious materials. This led to a new subject in the last 20 years, computational material science of concrete [2]. With the progress of this technology a better understanding of transport phenomena and associated degradation mechanisms is to be expected.

A computer-based model is required to numerically represent the amount and spatial distribution of the different phases of the materials being studied. To further qualify as a model, the computer-based model must have the power to predict, directly from the numerical representation of microstructure properties that can be checked against experimental measurements [3]. Based on this concept, during the last two decades a few fundamental pore structure models [4-7] have been developed that can be used successfully for predicting the transport properties of cement-based materials. These models are based on numerical simulation techniques and on a digital-image processing approach. Pioneering work in this field dates back to Jennings and Johnson [4], who first

proposed a cement hydration model. In their model, the cement particles were modelled as growing spheres. Another advanced model has been accomplished with the digital-image-based microstructure, which was developed by Bentz and Garboczi [5]. Their model allows the direct representation of multiphase and non-spherical cement particles. Based on the same principle of Jennings's model, van Breugel's model HYMOSTRUC [6], had the advantage of considering the individual particles interaction and reaction kinetics. These models vary widely in concept, accuracy, required computation time and "degree of reality". It is still very difficult for the present generation models to mimic the pore structure over the whole range of pore sizes satisfactorily.

In the present paper, the features of the cement hydration model HYMOSTRUC and reproduced microstructure are described. Four cement paste samples with different water/cement ratios, i.e. 0.3 to 0.6, have been simulated with HYMOSTRUC. The simulated microstructures are visualized. An integrated procedure for the characterization of the simulated microstructure structure (especially the pore structure) is presented and discussed. These include the extraction of the graph of the pore space, capillary network and the characterization of the pore size distribution curve. The geometrical characterizations of the pore structure will be used for the estimation of the absolute permeability of the cement paste, in which the Carman-Kozeny equation will be utilized.

2. 3D MICROSTRUCTURE SIMULATION AND ANALYSIS

2.1 Simulation of the degree of hydration of cementitious material

In the HYMOSTRUC model [6, 8], the degree of hydration is simulated as a function of the particle size distribution and the chemical composition of the cement grains, of the water/cement ratio and of the reaction temperature. The model starts from cement grains that are randomly distributed in a 3D body of cement paste. The cement particles are modelled as spheres. The three Cartesian coordinates of the centre and the radius of each particle are stored. The cement grains start to hydrate after mixing with water and the hydration processes are controlled by different mechanisms. Based on an expansion and interaction mechanism, the cement hydrates become part of gradually growing spheres. By taking into account the interaction kinetics, the growing particles become more and more connected; in this way, a simulated porous microstructure is formed (Figure 1a). In comparison to other models, HYMOSTRUC takes the embedded particles and overlap part into account explicitly.

Figure 1. The simulated cement paste and its pore structure ($w/c=0.3$, $\alpha=0.75$)

2.2 3D microstructure visualization

It is important to visualize the simulated microstructure, since this can help us to understand how the pore structure looks like and help us also to develop a better permeability model. In the HYMOSTRUC model, the characterization of the cement particles distributed in a box and presented by its three Cartesian coordinates of the centre and the particle radius enables us to use a constructive solid geometry algorithm [9], using union and difference operators, to visualise the pore structure. Figure 2 shows a simulated cement paste and its pore structure. The simulated cement paste has been visualised by applying the union operator between all cement particles and the box, whereas the pore structure was displayed by using the difference operator between a box and the merged result of the individual particle components. It was interesting to compare the simulated pore structure with a “realistic” pore structure. For example, a cylindrical pore shape is commonly assumed in order to quantify the pore size distribution of cement paste when a mercury intrusion porosimetry is interpreted. However, the simulated pore structure illustrated in Figure 2b will not obey this assumption as it shows a very irregular shape.

2.3 Pore topology

A quantitative description of geometrical and topological properties of the simulated pore microstructure plays an important role in predicting the transport properties. As shown in Figure 1, the simulated pore structure is very irregular. An important issue is describing this complex simulated pore structure. A program called HYMOSTRUC3D [10] was developed for this purpose. In this program, a serial section algorithm with overlap criteria was utilized. The serial sectioning method starts with scanning the simulated 3D microstructure layer by layer (Figure 2). The program first determines the features of all points in a 2D section by checking whether an arbitrary point belongs either to the subset of the solid phase or to the subset of the capillary pore phase. Secondly, checking around of this point to determine whether its neighbor point has the same feature, renumber each set with the same features points as an individual object (pore or solid). The information of each object including coordinate, area, and perimeter are stored.

Figure 2. Determination of pore topology by using serial sectioning method

The connectivity of the object between neighbor layers was determined by applying an "overlap criterion" (Figure 3). The overlap criterion checked each one of the objects on its up-layer and down-layer and examined whether this object was connected with its neighbors with the same feature. This procedure was repeated until the final layer of the body. A linked list network structure was built up to determine the interconnectedness of the structure. The hydraulic radius was calculated by taking the ratio of the total capillary pore volume to the total free surfaces of the hydration products. The volume fractions of the connected solid phase or capillary pore phase and the total internal surface area were derived. By applying these algorithms, the dead-end pores and isolated pores were distinguished. These pores will not be taken into account in the permeability prediction.

Figure 3. The pore network structure was determined by using an overlapping criterion. The effective pores, dead-end pores and isolated pores were distinguished. The pore size distribution was determined by calculating the pores which could be covered by fictitious spheres of radius r .

It is noticed that the connectivity of the pores is strongly influenced by the digital resolution and the layer depth in the image-based calculation. To accurately define the digital resolution, one has to consider the computational time needed and the reliability of the calculation result. If one applies this calculated pore structure to predict the transport properties, the validity of this calculated result will directly influence the reliability of capillary water permeability. For example, previous work [11] showed that the percolation threshold of capillary porosity changed from 30%, 12% to 0% when the digital resolution increased from $10\mu\text{m}/\text{pixel}$, $5\mu\text{m}/\text{pixel}$ to $2\mu\text{m}/\text{pixel}$ for a cement paste with water/cement ratio 0.4. In the NIST pixel-based simulation model [12], the percolation threshold of the capillary porosity changed from 24%, 18% and 12% while the digital resolution shifted from $1\mu\text{m}$ to $0.5\mu\text{m}$ and $0.25\mu\text{m}$ in a cement paste with 0.3 w/c. This can be explained because smaller pores can be resolved at the greater resolutions, and the pathway that would seem to be closed off at low resolution is seen to be narrowly open at higher resolutions. Further details of the effect of digital resolution were discussed in [10-12,].

2.4 Pore size distribution

The principle algorithms for the determination of the characteristic pore size distribution spectra of a simulated 3D binary image described by Bekri et. al [13], can be employed for our spherical-based 3D pore structure. In principle, the simulated pore structure is the inverse free space between the expanding cement grains. The characteristic pore size distribution curve can be determined in the following way. Consider the sub-volumes of the system that are accessible for spheres of different radii. Let $\rho_{(r)}$ be the volume fraction of the pore space “coverable” by spheres of radius r (Figure 3). We call these spheres pore spheres. $\rho_{(r)}$ is a monotonically decreasing function of r and can easily be compared with the “cumulative pore volume” curves measured by mercury intrusion porosimetry. The derivative $-d\rho_{(r)}/dr$ is the fraction of volume coverable by pore spheres of radius r but not by spheres of radius $r+dr$ and is a direct definition of the pore size distribution. The $\rho_{(r)}$ of the pore spheres with radius r can be computed by densely packing pore spheres in the free space.

3. CALCULATION OF PERMEABILITY

In general, permeability is a measure of the ease with which a fluid passes through a porous body [14]. Researches [15-16] have shown that the permeability of a porous medium is strongly influenced by the properties of liquids, by the hydraulic gradient and above all, by the geometrical properties. The most common expression used to describe the permeability, k , is Darcy's law:

$$k = -\nu \frac{Q}{A\delta g} \Delta P \quad (1)$$

where Q is the volume of fluid discharged per unit time through the cross sectional area A , ν is the viscosity of the fluid, δ is the density of the fluid, g is the acceleration of gravity, and Δp is the hydraulic gradient.

A frequently used absolute permeability model is the Carman-Kozeny model. This model considers some aspects of the geometrical properties of the porous medium. It relates the permeability to the total porosity and the specific surface area of the pores. The Carman-Kozeny model can be calculated as:

$$k = -\frac{\rho (V_p/S)^2}{2\beta} \quad (2)$$

where ρ , V_p and S denote respectively the porosity, the volume and the internal surface area of the pore space. β is the tortuosity of the conducting channels.

4. RESULTS AND DISCUSSIONS

4.1 Parameters for simulation

Four Portland cement pastes were simulated. The chemical compositions of the cement listed in Table 1, are the same for all samples. The curing temperature was 20°C.

Table 1. Chemical composition of cement particles

Max heat(KJ/g)	C ₃ S(%)	C ₂ S(%)	C ₃ A(%)	C ₄ AF(%)
530	63.0	13.0	8.43	9.0

Table 2 shows the physical parameters for the simulations. The main variable is the water/cement ratio, i.e. 0.3 to 0.6. The particle size distribution curves are shown in Figure 4. A continuous particle size distribution, between minimum size 2 µm and maximum size 45 µm was used for all samples; the Blaine fineness of the particles was 420 m²/kg. Figure 4 shows the consistency for all specimens. The physical size of the sample was a cube of 100µm side, while the resolution was 0.25 µm/pixel.

Table 2. Input parameter for the numerical experiments

w/c ratio [-]	Sample size [µm]	Particle size [µm]	Number of particles involved	Image size [Pixel]	Pixel resolution [µm/pixel]	Number of layers
0.3	100	2~50	8968	400	0.25	400
0.4	100	2~50	8168	400	0.25	400
0.5	100	2~50	6716	400	0.25	400
0.6	100	2~50	5898	400	0.25	400

Figure 4. Particle size distribution in the four simulated cement paste.

4.2 The geometry of the capillary porosity

The simulated pore structures are illustrated in Figure 5 for the sample with w/c ratio 0.3, 0.4 and 0.5, at a degree of hydration of 0.75. It is obvious that at the same degree of hydration, the sample with the lower water/cement ratio shows less porosity than the sample with a higher water/cement ratio. The calculated result revealed a capillary porosity of 6%, 19%, 28% for w/c 0.3, 0.4 and 0.5 respectively.

Figure 5. Simulated pore structure for the sample with a) w/c ratio 0.3, $\rho=6\%$, b) w/c ratio 0.4, $\rho=19\%$ and c) w/c ratio 0.5, $\rho=28\%$, at degree of hydration 0.75.

The degree of hydration simulated by HYMOSTRUC is shown in Figure 6. For each sample at a different hydration stage, the internal surface area, the hydraulic radius, the total porosity and the connectivity of the porosity were calculated and shown in Figure 7~Figure 9. Because of the huge computational time, the characteristic pore size distribution curves were computed only at the degree of hydration 0.64.

Figure 6. Degree of hydration of cement paste as function of hydration time.

Figure 7. Internal surface area of cement paste as function of degree of hydration

As shown in Figure 7, the samples with the lowest w/c ratio displayed the highest internal pore surface area at early age. However, after a certain degree of hydration, the surface area of the lower w/c ratio sample decreases more rapidly. If we look back to Table 2 and Figure 4, the samples with lower w/c ratio have a higher solid fraction, i.e. greater number of cement particles. This implies that per unit volume of paste more cement surface is contact with water. However, in the later stage, since there is less initial water in the lower w/c sample and most of it has reacted and converted into hydration products, only little capillary pores remain. This explains why both the hydraulic radius and capillary porosity decrease with a reduction in w/c ratio and with an increase in the degree of hydration, as shown in Figure 8 and Figure 9. This was also shown by the visualized pore structure illustrated in Figure 5.

Figure 8. Simulated hydraulic radius in cement paste as function of degree of hydration

Figure 9. Simulated porosity of cement paste as function of degree of hydration compared with Powers' model

The hydraulic radius obtained in the present simulation decreases from 0.75 μm to 0.60 μm for a cement paste with w/c 0.3 with a degree of hydration from 0.3 to 0.8. The present results are two orders higher than experimental results observed by Jiang et al [17]. The total porosity compared with Powers' model as a function of the degree of hydration for different w/c ratio is plotted in Figure 9. The simulation results are consistent with Powers' model.

Figure 10. Pore size distribution of simulated cement pastes with w/c ratio 0.3 and 0.6 at degree of hydration 0.64.

Figure 11. The connectivity of the porosity as function of degree of hydration.

The characteristic pore size distribution curve is plotted in the Figure 10 for the samples with w/c 0.3 and 0.6 at a degree of hydration 0.64. The sample with higher w/c ratio displays a wide range of pore sizes around 1~5 μm and the sample with lower w/c ratio exhibits a narrow range of pore size around 0.9 ~2 μm . The pore size is one order of magnitude above compared to experimental MIP data [18] and the total porosity is much higher. By applying Backscatter SEM or ESEM techniques, researches [1, 18] have proved that MIP measurements systematically underestimate the size of the capillary pores because of the so-called inkbottle effect. On the other hand, the numerical simulation agrees with SEM image reveals more realistic pore structures in cementitious materials.

4.3 Connectivity of the capillary porosity

The connectivity of capillary pores, in terms of connected porosity fraction is illustrated in Figure 11, as function of degree of hydration. It is noticed that, for all samples the capillary pores are almost always connected with each other even at ultimate hydration. No de-percolation of capillary porosity can be found. These results are quite different from the result of the NIST model [12], where a de-percolation threshold of the capillary porosity of 12% was found in cement paste with w/c ratio 0.4. On the other hand, the present results are quite similar to the results previously calculated by Navi [11]: when a resolution of 2 $\mu\text{m}/\text{pixel}$ was used, their results revealed that almost all pores were connected with each other. Why are so pronounced in different models? To answer this question, several aspects have to be considered. First, as discussed previously, the percolation threshold of the capillary porosity is largely dependent on the digital resolution. In the present simulation, the digital resolution was 0.25 $\mu\text{m}/\text{pixel}$; at this high digital resolution, even very small capillary pores pathways were detected, leading to a very low percolation threshold of the capillary porosity or no threshold at all. Another important factor, which influences the connectivity of the capillary porosity, is the fundamental principle of the different numerical models. As discussed earlier [12], the NIST model is a pixel-based model, where the different cement components are simulated as different sets of digital pixels and no shape constraint exist. In other models, such as HYMOSTRUC or Navi's model, the cement particles and hydration products are simulated as spheres. The growing spheres are overlapping when cement hydration take place. The pore space percolation threshold of the spherical based models has been numerically found always around a few percent porosity [19]. However, theoretically, in the cement pastes with w/c ratio from 0.3 to 0.6, even at the ultimate hydration stage, the capillary porosity will not be less than 5% (see Figure 9). This explains why no de-percolation of porosity can be found in a spherical based cement hydration model.

4.4 Transport properties

The simulated pore structure was used as bases for predicting the permeability. The absolute permeability of each system was computed using the Carman-Kozeny model. Figure 12 shows the computed water permeability curves as a function of degree of hydration, whereas Figure 13 shows its dependence on porosity.

Figure 12. Permeability as a function of degree of hydration for four different pastes.

Figure 13. The relationship between porosity and permeability for four different pastes.

The permeabilities calculated by the Carman-Kozeny model are one order of magnitude higher than the results proposed by the NIST model [12], where a lattice Boltzmann model was applied. Another advanced permeability model, based on a network model is under development. This network permeability model will consider the water penetration channel. The simulation result is expected to be more precise and close to the experimental results.

5. CONCLUSIONS

The simulation of cement paste hydration and of the formation of a 3D microstructure, especially the pore structure, were carried out with the HYMOSTRUC model. The simulated pore structures were visualised and analysed explicitly by applying a serial algorithm associated with an overlapping criterion. The internal surface area, the hydraulic radius and the total capillary porosity were calculated and evaluated. The characteristic pore size distribution was computed successfully by densely packing pore spheres in the free space. It was found that the pore size was one order of magnitude above compared to MIP results, while the shape of the pore size distribution curve was quite similar to obtained by SEM processing. The capillary pore connectivity was calculated as well. It was found that the connectivity is strongly influenced by the digital resolution used in the calculation. In the present study, no de-percolation threshold was found in all samples when a higher digital resolution of 0.25 $\mu\text{m}/\text{pixel}$ was used. This is in line if compared with the work presented by Elam et al. [19] and Navi et al. [11]. The simulated pore structures were used for the prediction of permeability. For that purpose the Carman-Kozeny model was used. In a further work, an improved network permeability model will be studied and validated by comparing the numerical results with mercury intrusion porosimetry measurements and permeability measurement.

ACKNOWLEDGEMENTS

The authors wish to thank Mr. F.P.J. Schilperoort for his advice in programming and Mr. P. Lura for the useful discussion. The research was financially supported by the Dutch Technology Foundation (STW), which is gratefully acknowledged.

ABSTRACT

This paper reports the results of the utilization of a silica waste from a geothermal power generation plant as replacement material of Portland cement. Pastes of OPC substituted with 0, 10, 15 and 20% of geothermal waste and water/solids ratio of 0.50 were cured at 20 and 40°C for up to six months. The pastes were characterised by thermogravimetry, compressive strength, non-evaporable water, and scanning electron microscopy. The results show that the presence of the silica enhances the compressive strength, which was also favoured by higher temperatures in the short term; however, at silica loads above 15% an anomalous strength reduction was noted; fracture microstructures under scanning electron microscopy showed the presence of Aft needle clusters. The geothermal silica shows pozzolanic character according to CH measurements and it also influenced the cement hydration in agreement with non-evaporable water results. The microstructures were more compact in the presence of geothermal silica.

Keywords: geothermal silica waste, pozzolanic reaction, blended cement, temperature, ettringite

1. INTRODUCTION

Using replacement materials for Portland cement is a practice that has increased considerably due to the advantages brought about not only in savings in natural resources and energy, but also in improvements in the properties of the cement. That is why it is important to search for new potential wastes or by products as replacements or additives to Portland cement. One potential waste is that obtained in the geothermal plants, as part of the process of energy production by means of steam extraction from the underground.

The geothermal waste is obtained from the mixture of geothermal brine and steam (naturally pressurized) that passes through the different stages of heat extraction. As the temperature is reduced (initially about 200°C) the silica precipitates from the mixture, which consists generally of amorphous silica and sodium and potassium chlorides. These precipitates produce serious problems, as they deposit in the ducts, forming a scale that grows several inches per month. In addition to these incrustations, a fraction of the remaining brine is reinjected to the underground and the rest is deposited in evaporation ponds that occupy large spaces containing thousands of tons of this geothermal sludge. The silica waste was obtained from the geothermal Cerro Prieto plant in Baja California, Mexico, which generates up to 50 thousand tons of it yearly. Preliminary characterisation of the geothermal silica has shown that it has properties that make it a good replacement material for Portland cement, such as: chemical composition rich in SiO₂; particle size of about 0.2 µm and highly amorphous [1].

Guttridge and Dalziel [2,3] reported the effect of replacement materials on the hydration of cement paste, they noted that the presence of a secondary component enhanced the hydration of Portland cement in the presence of PFA and slag, for which the finer the particle size the greater the improvement. The effect of temperature on the mechanical properties of mortars was reported by Verbeck and Helmuth [4], at short hydration times (14 days) the higher the curing temperature, the higher the compressive strength, but after 28 days, this effect was inverted in that at lower temperatures higher strengths were reached. They suggested that curing at higher temperatures resulted in a non uniform distribution of the hydration products building up around hydrating grains and retarding the posterior hydration, while at low temperatures, the products have sufficient time to diffuse and precipitate relatively more uniformly in the cement matrix.

Many reports about the effects of silica fume as a replacement of Portland cement in pastes, mortars and concretes pointed important effects of the silica fume, such as improved resistance to chemical attack [5] and improved strength [6] (especially on mortars and concretes) by means of its microfiller effect and its strong pozzolanic character [7,8]. There is very little information about investigation of the use of geothermal waste in Portland cement and in view of the similarities with silica fume, it was expected that the former would show pozzolanic behaviour and improve the properties of Portland cement pastes. As part of a more extensive study, this paper presents some results about the effects of silica waste on the chemistry of Portland cement hydration and the mechanical strength of Portland cement pastes under different hydration conditions.

2. EXPERIMENTAL PROCEDURE

2.1 Materials

One ordinary Portland cement (OPC) produced by Cementos Apasco (Planta Ramos Arizpe, Mexico) with calcite additions, a geothermal waste (GW) from Comision Federal de Electricidad (Planta Cerro Prieto, Mexico), and Rheobuild 1000 superplastizicer (SP) were used. The phase composition of OPC was (wt%): 66.9% alite, 7.3% belite, 2.4% C₃A, 7.2% C₄AF, 8.2% calcite, 2.7% gypsum and 4.8% quartz. The GW had to be treated in order to eliminate the chlorides present; washing with water at 80°C, as described by Diaz, resulted adequate for this purpose [9]. The chemical composition of the geothermal waste (GW) is shown in table 1, along with the phase and chemical composition of OPC. The average particle size of GW, by laser diffraction measurements, was of 7 µm; however further ultrasonic dispersion in HCl and methanol the particle size was of 100-200nm as noted by scanning electron microscopy.

Table 1. Chemical and phases composition of the silica waste and Portland cement

OXIDE	CaO	SiO₂	Al₂O₃	Fe₂O₃	MgO	Na₂O	K₂O	TiO₂	MnO	SO₃	Total
GW	1.72	94.67	1.04	--	0.53	0.66	0.53	0.84	--	--	100
OPC	67.53	18.16	3.5	2.52	1.89	0.89	0.57	--	0.14	4.05	99.23

2.2 Paste preparation and hydration

Cement pastes with water/solids ratios of 0.50 were prepared with replacement levels of 0, 10 and 15% GW, additional pastes with 20% were prepared for compression strength measurements only. The SP added was at 1, 1.25 and 1.5% for 10, 15 and 20% of GW, respectively. Cubes of 5 cm were cast and maintained for 24 hours at constant temperatures of 20 and 40°C and relative humidity of 90%. The cubes were then demolded and submerged in water, in plastic containers, at the same temperatures for curing for up to six months.

2.3 Characterisation

The pastes were characterised by means of: compressive strength (CS), non-evaporable water (NEW), thermogravimetric analysis (TGA) and scanning electron microscopy (SEM).

After the curing periods of 3, 7, 14, 28, 90 and 180 days the compressive strength was estimated from the average of four cubes. Fragments of the cubes were dried in a vacuum oven at 105°C during 24 hours. A fraction of these fragments were used for SEM, samples were cold mounted in resin, ground and polished down to $\frac{1}{4}$ μm using diamond pastes. The specimens were then carbon coated. The images in SEM were obtained by backscattered electrons (BEI) and secondary electrons (SEI), the accelerating voltage was of 20kV. Additional fragments were further ground in agate containers in a planetary ball mill to pass a 106 μm mesh. The powders were used for loss on ignition to estimate NEW and for TGA to estimate CH. The NEW was calculated by heating the hydrated samples at 130°C for one hour and then ignited at 950°C for one hour, the weight difference was referred to the ignited weight. The calcium hydroxide was graphically estimated by TGA from the weight loss step between 425-550°C, simultaneous decomposition of the C-S-H was considered by graphical correction.

3. RESULTS

3.1 Compressive strength

Figure 1 presents the results of compressive strength vs. time for all the studied mixes cured at both temperatures. The same colour and symbol codes were used for the subsequent figures. The effects of replacement level and temperature are analysed in all results.

3.1.1 Replacement level effect.

At 20°C, the addition of 10 and 15% GW resulted in progressively increased compressive strength; for 20% GW the compressive strengths were lower than those obtained for 15%; however, in all cases the addition of GW resulted favourable relative to the neat OPC. Nonetheless, while all specimens cured at 20°C continued gaining strength after 28 days those cured at 40°C with 15 and 20% GW registered strength reductions from 48 to 29 and from 40 to 23 MPa, respectively.

3.1.2 Temperature effect

For the neat cement pastes the compressive strength was slightly increased with the increment of the temperature; however, for all times considered the strength difference between the two temperatures was only about 10%. For the 10% of silica load the effect of temperature is noticeable in the first 14 days of hydration, however for the coming times the difference was as for the neat cement. In the presence of 15 and 20% GW the temperature effect was similar to that described for the 10% of silica; except for the strength loss mentioned.

The effect of the temperature on strength development in cements cured at relatively high temperatures is that the strength gain is reduced after a given time and ascribed to the phenomena described by Verbeck and Helmuth [4]. In this case a clear drop of strength was noted at 15 and 20% GW load when cured at 40°C; for such specimens extensive cracking was observed in the cubes. SEM characterisation was performed to search for a possible origin of this problem, the results presented are a microstructure of a fracture zone with EDS analysis from it and also EDS results from a polished sample, as shown in Figure 2. Localised zones rich in clusters of needles (pointed in the photo) were noted throughout the fracture surface, the chemical composition indicated the presence of ettringite in such hydration products.

Figure 2. (A) MEB SEI fracture surfaces of non dried samples (environmental mode) OPC-20%GW cured at 40°C, (B) EDS analysis of sample (A) in atomic ratios. Inner and outer products in (B) from polished samples

3.2 Thermogravimetric analysis

Figure 3A shows the results of % calcium hydroxide vs. time for all cements. The data were normalised for an equivalent of 85% of cement. For the neat cement the CH values increased as time advanced and with the higher temperature. For both blended cements the CH amounts were lower compared to the neat cement; the values increased for the first 7 to 14 days and then the CH concentration was depleted. This provided evidence of the pozzolanic behaviour of the silica waste since the first days of hydration. The CH consumption was greater as the silica load and the hydration temperature increased. The trend towards lower CH concentrations indicates that the pozzolanic reaction is still in progress. The behaviour of the dependence of the pozzolanic reaction (with the temperature and the replacement level) is similar to that found in cement pastes with silica fume [7,8] and other replacement materials [10].

Figure 3. (A) % Calcium hydroxide vs. time for the neat and blended cements. (B) % Non-Evaporable Water vs. time for the neat and blended cements

3.3 Non-evaporable water (NEW)

Figure 3B shows the results of non-evaporable water vs. time for neat and blended cements cured at both temperatures. The NEW results for the first three days with silica load of 10 and 15%, were higher than those of the neat cement, which suggest an actual increase of the cement hydration. After 14 days onwards the NEW values of the blended cements were lower. After 90 days curing, the NEW values were lower, for higher silica contents for a given temperature.

Several authors [7,8,11,12] have described the silica fume effect on the non-evaporable water produced by Portland cement with replacement levels from 5 to 30%, and various w/s ratios. They found that the amounts of NEW for neat cements were higher than those in blended cements for a given w/s ratio, especially at long periods of hydration. Moreover, the greater the silica load, the lower the NEW relative to the neat cement values. This phenomenon was reported with evidence of pozzolanic behaviour of the silica fume.

The reduced NEW values noted were explained in the literature in several ways. One is that described by Zhang and Gjorv [12], due to the increased average chain length of polysilicates in the C-S-H gel, with both silica fume content and time, which was believed to result in water release, hence lower NEW values. Attlasi [11] concluded that the water from CH involved in the pozzolanic reaction is released as evaporable water, lowering the total amount of NEW per hydrated cement content in silica fume blends. Yogendran et. al. [8], pointed that since the pozzolanic reaction reduces the CH amounts in OPC blended with silica fume, and the cement fraction is lower, the NEW values are reduced and it is not possible to directly compare NEW values of a neat and the blended cement; they suggested a direct comparison between NEW values that excluded CH water losses. In this way the latter authors found that the NEW values from the pozzolanic reaction and the accelerating effect on the cement hydration were greater than the NEW reduction due to a lower neat cement fraction.

Figure 4A presents modified NEW values (NEWH), in which the CH water losses were extracted. In the presence of the geothermal waste the NEWH higher values than those of the neat cement for the first 28 days hydration. This suggests that the silica accelerated the cement hydration, probably acting as nucleation sites [2,3] for deposition of the hydration products and also promoting the formation of calcium silicates hydrates by the removal of CH by the pozzolanic reaction, which favour further progress of the calcium silicates hydration. After 90 days, it can be noted that the

NEWH values for the neat and blended pastes at 20°C were similar; however, at 40°C the NEWH values were higher in both blended cements, indicating that the cement hydration and the pozzolanic reaction are favoured by increased temperatures. Figure 4B presents a plot of NEW vs NEWH, it can be noted that for a fixed NEW value, the corresponding NEWH are higher for the blended cements; the latter are higher for increased silica waste content and higher temperature (which corresponds to the CH depletion trends plotted in figure 2). This could suggest that the pozzolanic reaction consumes water, although it is not clear whether it is only that present in the CH, and the excess of NEWH relative to NEW is due to a mixed effect of the additional C-S-H formed by the pozzolanic reaction and the cement hydration acceleration.

Figure 4. A) Non-evaporable water in hydrates vs. time, B) Non-evaporable water in hydrates vs. total non-evaporable water

These results indicate that the consumption of CH has a strong influence in the values of NEW obtained from blends of cement with pozzolanic materials. From the above comparison it seems that to analyse the effect of silica in the hydration of the cement is preferable compare the data of NEWH, however, the effect of the NEW reduction could be associated to the pozzolanic behaviour of the silica but the effect of a real cement fraction reduction must be taken into account.

3.4 Scanning electron microscopy

Figures 5 A and B show the microstructures of neat cements hydrated for 180 days at 20°C and 40°C respectively. The main features are those commonly observed in cement pastes with water/solids ratio of 0.50. In both cases a fraction of the cement was still unreacted, with calcium hydroxide crystals and porosity dispersed throughout the microstructure. There were no marked differences between the microstructures at both temperatures.

Figure 5. SEM-BEI of the microstructure of OPC after 180 days of hydration a)20°C and B)40°C.

Figure 6. SEM-BEI of the microstructure of OPC-10%GW after 180 days of hydration a)20°C and B)40°C.

Figure 7. SEM-BEI of the microstructure of OPC-15%GW after 180 days of hydration a)20°C and B)40°C.

Figures 6 and 7 present the microstructures, after 180 days for both temperatures, of blended cements with 10 and 15% GW, respectively. For the two replacement levels was observed that the amount of calcium hydroxide crystals was drastically reduced. Also the silica waste was relatively well dispersed in the matrix, and occasionally some silica agglomerates were noted (Figure 7). Moreover, the apparent porosity was reduced in both replacement levels in comparison with the neat cement.

4. DISCUSSION

From the general analysis of the results it was observed that the presence of silica waste increased the compressive strength, this can be associated to several factors, which were evidenced by the results here presented. Increased reactivity of the cement was indicated by NEWH results. The formation of additional C-S-H was pointed by the CH consumption in the presence of the silica waste. These two factors led to an enhanced C-S-H formation which, together with a microfiller effect that was observed from the microstructures, resulted in a more compact matrix of hydration products.

Figure 8. Microstructure of OPC-15%GW after 180 days of hydration at: A) 20°C and B) 40°C. Backscattered electron images

Evidence of the pozzolanic activity was indirectly obtained from thermal analysis. Careful observation of some relatively large silica particles, by backscattered electron images in Figure 8, allowed to note that the edges of such particles showed a lighter gray shade than the centre. Considering that the differences in chemical composition are reflected in the gray shades, lighter gray shades are expected from areas of higher average atomic number. On this basis, EDS analyses of various zones around and within some of the silica particles were taken. As the spot was moved from the edge towards the centre of some of the particles, it was noted that the SiO_2/CaO ratio increased from about 1 (lighter gray zones) to very high values (darker zones). This would provide an indication that there is a surface chemical interaction between the silica and the CH, with the absorption of Ca locally increasing the average atomic number. In figures 8 A and B small areas of CH crystals, what could be relics of larger crystals, were noted around the silica particles.

The circumstances under which ettringite appears are not yet fully explained. Collepardi [13] determined the preconditions of delayed ettringite formation (DEF): microcracks, release of sulfate in later period and sufficient water supply; DEF damage would result provided all factors are present. Nevertheless, Yang et.al.[14] pointed out that the microcracks are induced by DEF. Taylor [15] established that there is no supporting evidence from laboratory studies of the existence of DEF without steam curing conditions; however, Diamond [16] found that DEF is to be expected in both steam and not steam cured concrete and that the microstructural features appear to be identical. Stark et. al.[17], presented a hypothesis on the possible causes of accumulation of ettringite in hardened concrete: additional formation of ettringite by internal sulfate release and mobilization of existing ettringite, their transport and recrystallization; could be attributed to factors such as: heat treatment (above mentioned), freeze thaw attack, carbonation, chemical composition of the clinker, alternating moisture conditions and marginal conditions which promote damage like ASR and chemical shrinkage or self desiccation.

Localized zones rich in ettringite clusters were noted in fracture surfaces for 20% GW cured at 40°C in the long term. Microanalysis (EDS) suggested that the extensive cracking observed was due to the formation of ettringite. The cracked samples were not submitted to any of the above mentioned conditions for DEF. The potential effect of the OPC composition for DEF could be disregarded since the cracking occurred only with 15 and 20% and not with 0 and 10% GW. The absence of sulphur in the GW composition brings additional questions as to whether the GW favours DEF with sulphur supply. In spite that some authors have been found that agglomerates of silica fume can cause ASR problems as pre-conditions for DEF, for the pastes analysed here no ASR evidence was observed. There is uncertainty whether the GW can participate in creating some kind of predamage that could favour DEF in the cement paste, which was clear is that the relatively higher temperature favoured DEF, nonetheless 40°C is much lower than the temperature of about 70°C reported for thermal treatment by some authors. Additional work is required to elucidate the causes DEF in the presence of GW.

5. CONCLUSIONS

- The silica presence in cement pastes increased the compressive strength, which was associated with the reduction of porosity in the microstructures.
- The cement hydration was accelerated by the presence of silica waste, in agreement with the results of non-evaporable water.
- The silica waste presented pozzolanic activity, depleting the CH concentration, which was strongly influenced by the curing temperature and the replacement level.
- Overall, the pozzolanic activity and the cement hydration enhancement increased the amounts of C-S-H, which together with the microfiller effect resulted in more compact hydration product matrix.
- The pastes with 15 and 20% of silica waste at 40°C presented extensive cracking, attributed to the formation of ettringite.

INTERNAL AND SURFACE DAMAGE OF CONCRETE DURING FREEZING AND THAWING LOADS

ABSTRACT

The internal and surface damages during freezing and thawing tests of 45 different concretes were assessed by slab test and CIF-test procedures. Tests were performed with deionized water as the freezing liquid in which no additional salts were dissolved. The test concretes were produced so that a large range of compressive strengths, air contents, curing measures, and binder amounts were covered. In the slab and CIF-tests surface deterioration was measured by weighing the deterioration of the surface layer after 56 freezing and thawing cycles in which temperature varied between +20 and -20 °C. The internal damage in the test slabs was studied by measuring the change in ultrasonic pulse velocity of the test slabs.

The most significant variables affecting the freezing and thawing durability of concrete were calculated statistically and contours of estimated response surface were produced. Water-cement ratio and air content of the concretes were the most dominant variables affecting the internal and surface damage caused by the freezing and thawing loads. Water curing improved the R-squared values of the test population in the surface damage tests. In the internal damage tests the curing measures did not improve the statistical relevancy of the estimated response surfaces.

1. INTRODUCTION

Almost one third of the concrete volume cast in the Nordic countries must possess adequate freezing and thawing durability. Majority of concrete durability research and test methods concentrate on the degradation of concrete surface due to the freezing and thawing loads while only during the last decennium the internal damage of the frost action has gained increasing attention. It has been noticed that internal damage has been the dimensioning criterium in concretes produced by a low water-binder ratio.

2. LITERATURE REVIEW

The two classical freezing and thawing theories of concrete are based on the research work by T. C. Powers and his coworkers [1]-[5]. The theory of hydraulic pressure is not considered valid nowadays and even Powers replaced it by the theory of osmotic pressure. In these theories the direction of the pore water movements are opposite. In the theory of hydraulic pressure the pore water is considered to move from those parts of the capillary space in which ice is first generated towards other parts of the concrete matrix. However, test results and also theoretical considerations have shown that the direction of water movement during freezing is opposite. The unfrozen pore water in the nearby smaller pore spaces is drawn to those parts of the pore system in which ice is first induced. In the theory of osmotic pressure Powers deduced that the pore water is moving in this direction due to the osmotic pressure caused by the dissolved salts (mainly K₂O and Na₂O) which

are not incorporated to the formed ice structure. This increases the salt concentration so that the surrounding unfrozen pore water moves towards the frozen pore in the pursuit to dilute the larger salt concentration. In normal pore water into which no additional salts are introduced there are only few millimols of dissolved substances and, therefore, the osmotic pressures induced into the concrete matrix do not seem to be large enough to cause the large contraction noticed in concrete during the freezing phase.

In the 1970's G. Fagerlund [6] developed the concept of critical degree of saturation in freezing concrete. According to his findings there is in porous materials a critical degree of saturation which causes deterioration or cracks into the material if the material is frozen even once. The theory was first developed according to the theory of hydraulic pressure but because of the universal nature of the concept it is applicable also to other freezing theories. However, in order to give reasonable results the freezing and thawing cycles by which the critical degree of saturation is achieved ought to take place according to the freezing and thawing loads in real structures.

According to G. G. Litvan [7]-[10] water in the capillary pores cannot freeze in situ but the freezing takes place in the vicinity of the outer surface of the structure. The supercooled water causes water movements and drying in the porous body which can cause freezing and thawing deterioration. M. Setzer [11] took in his freezing theory into account the surface forces of the pores and revised Litvan's theory. He was also the first to propose the micro-ice lens theory [12] which explained the water suction from the environment during freezing and thawing cycles. V. Penttala [13],[14] derived a theory based on thermodynamics by which the pressures in pore water can be derived from temperature and relative humidity data measured in concrete during the freezing and thawing cycle. If the pore water amount is known the pressures in the concrete structures can be calculated. In the theory, the pore size distribution data is not needed. According to the theory based on thermodynamics the main reason for the pore water movements towards the ice bodies that are first induced is the difference in chemical potential between ice and the unfrozen pore water in the smaller pores surrounding ice and the osmotic pressures play only a minor role.

In the previously mentioned theories the need for air-entrainment, adequate pore size distribution or spacing cannot be calculated with the exception of the theory of hydraulic pressure. However, this theory is not considered valid in the modeling of freezing and thawing durability of concrete.

There exists a large number of test methods by which the internal damage and surface scaling of concrete can be evaluated. The critical dilation test ASTM C 671 [15] and rapid freezing and thawing test ASTM C 666 [16] are typical tests by which the internal damage of the concrete specimen can be assessed. Salt scaling test ASTM C 672 [17] measures the scaling of the specimen surface in the presence of de-icer salts. There are numerous national freezing and thawing tests that resemble these three which are so called direct tests performed by using actual freezing and thawing loads. In this paper two recently developed freezing and thawing tests will be applied. In the CIF test [18] and the slab test [19] both internal damage and surface scaling can be determined by the same specimen and test simultaneously.

3. MATERIALS AND TEST ARRANGEMENTS

All test specimens were cast by using the same cement type CEM IIA 42,5R of local origin produced by Finnsementti Oy. No other additional binders were used. The petrographic composition of the aggregates was mainly granite and the maximum aggregate diameter was 16 mm except for 4 batches in which it was 10 mm or 32 mm. The total amount of the different test concretes was 45.

The water cement ratio of the test concretes was varied so that the test population comprised of concretes having water cement ratios of 0.30, 0.40, 0.54, 0.65, 0.76, 0.94, and 1.12. The cement content of the test concretes varied from 170 to 634 kg/m³. The air content of the test concretes varied from 0.6 to 10.5%. The water curing times ranged from 0 to 13 days after the stripping of the moulds at the concrete age of 24 hours. Thereafter, the test specimens were stored in a climate cabin in the temperature of 20±2 °C and relative humidity of 65±5%. The amount of the fine aggregates (<0.6 mm) varied from 34 to 384 kg/m³.

The CIF test specimens had dimensions of 150x110x75 mm and at the age of 25 days a bituminous aluminium sheet was glued on the edge faces of the specimens according to the RILEM recommendation [18]. The dimensions of the test specimens of the slab test were 150x150x50 mm. As an exception to the Swedish standard [19] the freezing surface of the test specimens was the mould surface and not the sawn surface inside the the test cube so that the freezing surfaces of both tests were comparable to each other. At the age of 25 days a rubber sheet was glued on the other faces of the test specimens except the freezing surface of the slab test specimens according to the standard [19]. The tests of these two freezing and thawing test methods were performed otherwise according to the respective references [18], [19]. Both freezing and thawing tests started at the concrete age of 35 days. The freezing liquid was deionized water having electrical conductivity less than 3 µS/cm. Figure 1 shows the test layout for the CIF test and Figure 2 shows the layout for the slab test.

The test specimens of the CIF tests were weighed for scaling deterioration and the ultrasound measurements were performed after 6, 14, 20, 28, 34, 42, 48, and 56 cycles. Similar tests for the slab test specimens were done after 7, 14, 28, 42, and 56 freezing and thawing cycles. Both tests ended after 56 cycles. The test concretes were also tested by 100-mm³ cubes in a salt freezing test according to Finnish standard SFS 5449 [20] but the results are not presented in this paper. The compression strength of the concretes was measured by loading six 100-mm cubes at the age of 28 days.

Figure 1. The test arrangement of the CIF test [18].

4. TEST RESULTS

The internal damage and surface scaling test results of the concretes have been analyzed statistically in two parts. Using the Statgraphics computer program the validity of the most relevant variables was first calculated by simple linear regression. Thereafter, the models for these variables were construed by nonlinear regression.

According to the results obtained from the linear regression calculations the most relevant variables to model the scaling results were cement content, water content, water cement ratio, air content, and curing time. In the internal damage modelling the same variables were the most relevant with the exception of curing time which did not increase the R-squared statistics of the test population. The best nonlinear regression model of the scaling results was formulated as

$$D = a + b \cdot \left[(W / C)^c / A^d / B^e \right] \quad (1)$$

in which W is water content [kg/m³]
 C is cement content [kg/m³]
 A is air content [%]
 B is curing time [d]
 D is deterioration, if surface scaling [g/m²] or if internal damage [decrease of ultra sound penetration time in %]
 a, b, c, d, e are coefficients

The most suitable model of the internal damage is

$$D = a + b \cdot \left[(W / C)^c / A^d \right] \quad (2)$$

The coefficients of the models and the respective R-squared values are presented in Tables 1 and 2.

Figure 2. The test arrangement of the slab test [19]. In the picture A denotes a thermo-element, B is a evaporation protection, C is the freezing liquid, D is the concrete test specimen, E denotes a rubber cover, and F is thermal insulation.

Table 1. The model coefficients of Equation (1) and the R-squared values of the 45 test concretes.

Test/damage type	a	b	c	d	e	R ² [%]
CIF/scaling	175.229	7574.63	6.96392	1.18921	0.637267	82.8
Slab test/scaling	-70.2615	8656.28	3.32138	0.48781	0.210174	89.1
CIF/internal damage	198.374	-121.202	-0.385581	-0.130708	0.0059914	71.7
Slab test/internal damage	-128.69	227.804	0.452682	0.142734	-0.004007	79.9

Table 2. The model coefficients of Equation (2) and the R-squared values of the 45 test concretes.

Test/damage type	a	b	c	d	R ² [%]
CIF/scaling	173.998	2321.26	6.46967	1.0597	80.4
Slab test/scaling	-78.9908	5760.49	3.20856	0.475537	87.6
CIF/internal damage	-149.021	232.705	0.329404	0.121914	74.9
Slab test/internal damage	-130.691	231.776	0.450739	0.140754	79.9

The R-squared statistics indicates that the model explains the percentage of the variability in the test in question. The Durbin-Watson statistics of the residuals indicated that there may be some serial correlation in several of the different models. The contours of the estimated response surface of the different tests are presented in Figures 3 to 10 by using Equation (2). Two examples of the surface scaling of a CIF and slab test specimen are presented in Figures 11 and 12.

5. DISCUSSION

The R-squared results presented in Tables 1 and 2 show that if the curing measures are included in the model this increases the R^2 -values of surface scaling damage and decreases the internal damage validity of the model. Similarly, as the exponent e of curing time B in Table 1 is a very small number in the internal damage situation, curing measures have very little effect on the internal damage of concrete. This seems quite obvious because curing enhances the quality of the surface layer of concrete, and hence improves the freezing and thawing durability of the surface. Curing increases the hydration degree inside the test slab only marginally especially in concretes which are produced by using a low water cement ratio, and therefore, curing does not effect the internal damage caused by freeze-thaw loads very much. The proposed deterioration models give to the slab test a somewhat higher R-squared values compared to the CIF test. The difference is over 6 percent-units in the scaling mode and from 5 to 8 percent-units in the internal damage mode.

Comparing the slab and CIF test results in Figures 3 to 10 one can notice that the slab test is a more severe test than the CIF test. This seems to be reasonable because in the slab test the freezing solution is situated on the top surface of the test slab, and therefore, gravity draws it towards the inside of the specimen. In the CIF test water is in contact to the lower surface of the test slab and it is drawn inside the test specimen only by capillary suction and due to the thermodynamic pumping action caused by the cyclic freezing and thawing load. This difference in the severity of the frost action is apparent both in the surface scaling results and also in the internal damage results. These

two freezing and thawing durability tests will be presumably approved as the official frost durability tests in the European concrete standardization, and therefore, the approval criteria must be different for these tests as can be seen in comparing the results of Figures 13 and 14.

When the contours of the estimated response surfaces of the CIF and the slab tests are compared with each other in Figures 7 and 9 it can be noticed that the scaling values in the CIF surface seem to level off to a constant value of 160 g/m^2 when water/cement ratio is diminishing. In Figure 9 the surface in the slab test cuts the plane where the scaling damage is zero. This gives a possibility to select the water/cement ratio and the air content so that no scaling takes place in the slab test. The internal damage surfaces of Figures 8 and 10 are quite similar for both test types even though the slab test surface is somewhat higher.

Figure 11. Surface scaling of 200 g/m^2 of a CIF test specimen after 56 freeze-thaw cycles.

Figure 12. Surface scaling of 550 g/m^2 of a slab test specimen after 56 freeze-thaw cycles.

Figure 13. Two curves of the estimated response surfaces of the surface scaling and the internal damage results in the CIF test.

Figure 14. Two curves of the estimated response surfaces of the surface scaling and the internal damage results in the slab test.

In Figures 13 and 14 it can be seen that when the water/cement ratio of concrete increases the need of air entrainment increases due to surface scaling damage much faster compared to the need of air entrainment in the internal damage failure mode. On the other hand, in concretes possessing low water/cement ratios the dimensioning criteria for the air content comes from the internal damage curves in these figures. Comparing the curves of 200 and 500 g/m² surface scaling in these figures it becomes apparent how much more severe the slab test is compared to the CIF test. Similarly, also the internal damage loading is more severe in the slab test compared to the CIF test. However, the difference is not as pronounced as in the scaling deterioration.

The effect of water curing is compared in Figures 15 and 16 in the CIF-test and the slab test. The curing time has an remarkable effect on the required air content or water/cement ratio. In the internal damage situation the effect of curing is negligible taking into consideration the accuracy of the statistical method.

Figure 15. Comparison of the effect of water curing on the surface scaling of 200 g/m^2 in the CIF-test by using Equation (1).

Figure 16. Comparison of the effect of water curing on the surface scaling of 500 g/m^2 in the slab test by using Equation (1).

6. CONCLUSIONS

One of the biggest merits of the CIF and slab tests is that both the surface scaling and the internal damage can be assessed from the same test specimen in a single test so that the two deterioration mechanisms do not interfere with each others test result in the same extent as in the other contemporary freezing and thawing tests. Similarly, the thermodynamic pumping effect is taken into consideration in these tests and the freezing action is taking place only in one direction. The test results give a good basis to estimate the serviceability life prediction of concrete structures.

ABSTRACT

To understand the effects of alkalis on the rheology, set and strength of superplasticized concrete, tests were carried out on four selected cements which did or did not present an incompatibility phenomenon and having high and low levels of C₃A and alkalis. The results obtained on cement pastes with addition of different salts of sodium and potassium show a great improvement in the slump loss for the cements presenting initially a problem of incompatibility. It has been shown the existence of an optimal amount of soluble alkalis varying as a function of the superplasticizer dosage. In contrast, the normal cements having a relatively high alkali content show a similar or even slightly deteriorated rheological behavior when the chemical additives are used. The results obtained on concrete confirm the improvement of rheological behavior by addition of the chemical additives. Moreover, they show the impact of added alkalis on the setting time and the improvement of the one day strength by up to 30% for the slump-improved concrete. The same effects were also observed when the lithium salts were used instead of the salts of sodium and potassium.

1. INTRODUCTION

The phenomenon of cement-superplasticizer incompatibility, increasing drastically in high performance concretes having a low W/C ratio and using superplasticizers, has been giving rise to the strong desire of researchers and attracting the attention of cement, concrete and admixture industries.

The phenomenon of cement-superplasticizer incompatibility, characterized generally by the rapid slump loss, is usually attributed to the lack of SO₄²⁻ ions in solution and the reaction of the SO₃²⁻ sites of the polysulfonated superplasticizer with C₃A [1, 2, 3, 4, 5, 6]. In this case, there is no longer enough polysulfonated superplasticizer molecules remaining in solution to plasticize the concrete. Therefore the compatibility of a particular cement and a particular superplasticizer depends on the balance between the amount and the reactivity of C₃A and the amount of SO₄²⁻ ions present in the mixing water as hydration is developing. The parameters controlling this balance in the presence of polysulfonated superplasticizer are first related to the characteristics of cement: finesse, content of the interstitial phase, crystalline form of C₃A, nature and amount of calcium sulfate added in the cement etc. It is also known that the characteristics of the superplasticizer should be optimized to produce a maximum of efficiency: sulfonation degree, percentage of beta sulfonated sites, chain length, nature of the counter-ion etc.

The two practical solutions used to solve the problem of incompatibility based on this approach are the double introduction method and the use of a small amount of retarder [7, 8]. The first one consists of adding the superplasticizer in two steps: at the beginning of the mixing to neutralize the reactive sites of C_3A and then at the end of the mixing or just before placing the concrete to produce the fluidification effect. This solution presents often some technical complications and has a limited efficiency. The later one consists in using a retarder with the superplasticizer to slow down the reactivity of C_3A , but causes often, as a consequence, the early strength loss.

Within the framework of the research and development project on the phenomenon of cement-superplasticizer incompatibility conducted in the university of Sherbrooke in Canada between 1996 and 1998, one of the topics based on the chemical approach consists of studying some chemical factors inclined to affect at the same time the reactivity of the cement phases and the cement-superplasticizer interactions. This work aims the influence of the nature and the amount of the alkalis on the rheology, the set and the strength of superplasticized concretes.

2. MATERIALS AND METHODS

Four North-American commercial cements, named H, C, L and Q were selected according to their C_3A and alkali content. Their chemical composition and Bogue composition are indicated in Table 1. The cement H is characterized by its relatively low content of C_3A and low content of alkali. The cement C is characterized by its high content of C_3A but low content of alkali. The cements L and Q have a high content of alkali, but do not have the same C_3A content. It is to be noted the high $SO_3\%$ in the clinkers corresponding to the cements L and Q.

The superplasticizer used in this study is a pure sodium salt of polynaphthalene sulfonate (PNS) enhanced in an aqueous solution at 41% solids with the pH near 8 and specific gravity of 1.21.

The additives used are sodium, potassium and lithium salts.

Table 1. Chemical and phase composition of the cements

% by mass	L – type 10*	Q – type 10*	H – type I	C – type I
CaO	62.80	62.00	65.45	64.60
SiO ₂	20.50	19.60	20.66	21.00

C ₄ AF	9	7	11	6

* According to Canadian CSA standard. It's basically an ASTM type I with a maximum of 5% filler

The tests conducted on grout are the two simplified methods: the mini-slump and the Marsh cone methods. The mini-slump method consists of using the slump cone $\phi 19 \times \phi 38 \times h 57$ mm described by Kanto [9], allowing a quick comparison of the fluidity of various cement-superplasticizer mixtures on a small amount of grout. The paste was prepared with 200 g of cement, adequate amount of water, superplasticizer and chemical additive if necessary. The mixing was done by hand with a spatula for the first one minute and then with an electronic mixer at high speed for two

minutes. The paste was remixed by hand with a spatula for 30 sec just before measuring the spreading diameter at a given time.

The Marsh cone method consists of measuring the time required for 1 liter of grout contained in the Marsh cone to flow through a funnel having a diameter of 5 mm [10], allowing the characterization of the rheological behavior of the grout in more "dynamic" condition. The mixture was prepared in a mixer for mortar with appropriate amounts of cement, water and PNS to prepare 1.2 l of grout. Usually the test was done at a water/cement of 0.35 and around 1.8kg of cement is needed. The mixing time was generally 1 min 30 sec for introducing progressively the cement and 60 sec for final mixing. After introducing the grout (1.2 liter) in the Marsh cone, it was measured the time necessary to fill the 1 liter graduate placed under the cone. To keep the homogeneity of the grout and to simulate concrete transportation, the grout was put in a plastic bottle and then placed on two rollers.

The optimized cement-superplasticizer couples by using the mini-slump and Marsh cone methods were then tested on concrete with typical composition indicated in Table 2. The slump, the setting time and the compressive strength were measured according ASTM C143-90a, C403-95 and C39-94. The mixing procedure is described as follows:

- Introducing the sand in the mixer,
- Introducing the aggregate and then a half of the mixing water.
- Adding the chemical additives and then the superplasticizer in the remaining mixing water
- Introducing the total cement, starting the chronometer and mixing for 1 minute 30 seconds.
- Introducing the remaining water with superplasticizer and continuing the mixing for 1 minute 30 seconds.
- Stopping the mixing for 2 minutes.
- Restarting the mixing for 3 minutes and then stopping the mixing.
- One minute before a given time, mixing the concrete for 1 minute. After the measure, the used concrete used is then removed in the mixer and mixed for 30 seconds.

Table 2. Concrete composition at saturated surface state

	kg/m ³	Type and characteristics
Water	151	W/C=0.33
Cement	462	cements L, Q, H and C
Sand	733	natural siliceous, fineness modulus of 2.70, absorption of 1.2%
Coarse aggregate	1112	dolimitic limestone, 14 mm, absorption of 0.4%
Superplasticizer		PNS, generally at 0.6%, except indication
Alkali additives		Na ₂ SO ₄ , Na ₂ SiO ₃ .9H ₂ O and Li ₂ SO ₄ , expressed as Na ₂ Oeq%

3. RESULTS AND DISCUSSION

3.1 Saturation point of superplasticizer – Marsh cone test

The saturation point of a superplasticizer for a given cement is defined as the optimal dosage after which any supplementary addition of superplasticizer does not significantly improve the rheology of the grout. According to the study [10], the flow time at 5 and 60 min. of a superplasticized grout with a Marsh cone may give reliable indications of the degree of cement-superplasticizer compatibility. Typically, four cases may be produced for a given cement-superplasticizer. The first case corresponds to a compatible combination for which the slump at 5 min and the loss of slump 5-60 min can be fully controlled. The second case corresponds to a poor compatibility for which a high dosage of superplasticizer is required to obtain a given slump at 5 min and the slump loss

increases rapidly with the time despite this high dosage. The two others cases correspond to intermediate situations: the initial slump can be easily obtained but the slump loss is high, or the initial slump is always difficult to obtain but the slump loss stays at a low level.

For four selected cements and the PNS used in this study, the flow times with Marsh cone are shown in Figure 1. The cement L presents a full compatibility with PNS with a saturation point situated between 0.6 and 0.8%. Even at a lower dosage, the grout still presents a reasonable fluidity at 60 min. A preliminary study shows that cement Q behaves in the same way as cement L despite the high C_3A content. With cement H, the saturation point is higher, between 1.0 and 1.2%, but when a lower dosage was used, the slump loss was so high that the flow time could not be recorded. Therefore cement H presents a partial compatibility with PNS. Concerning cement C, the saturation point is very high ($>1.8\%$). The initial fluidity was more difficult and decreases rapidly when the dosage of PNS is lower than this saturation point. Therefore cement C presents a poor compatibility with PNS.

In a preliminary study, the use of a gluconate based retarder (0.1%) allows to improve the compatibility in the case of cement H when the superplasticizer is lower than the saturation point. In the case of cement C, the use of the retarder at a dosage as high as 0.2% can improve the initial fluidity, but not at all the slump loss. Moreover, the tests on concrete made with these cements showed that the early strength was strongly affected even with a dosage of retarder as low as 0.1%, for cement C as well as for cement H.

3.2 Effect of soluble alkalis on the rheology – Mini-slump test

To observe the effect of alkalis on the rheology, the mini-slump test was carried out on pastes with PNS dosage lower than the saturation point previously determined by Marsh cone. Figure 2 shows the spreading area change vs time of pastes prepared with cement H. The different salts, with a

equivalent amount of 0.2% Na_2O , were added in the mixing water. The results indicate that the slump retention is greatly improved by adding sodium, potassium or lithium salts, except Na_2CO_3 , NaHCO_3 and NaF . Among the tested salts, the highest improvement of the slump retention is given by Li_2SO_4 , then followed by $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$. The potassium salts show a similar effect than the sodium salts. The same results were also observed with cement C presenting a poor compatibility.

With high-alkali cement, the added soluble alkalis have no effect or even a small negative effect on the initial slump as well as the slump retention, as shown in Figure 3.

To understand the influence of the amount of soluble alkalis in the case of cements H and C, different quantities of Na_2SO_4 , expressed as Na_2Oeq were added. The results are shown in Figure 4. For cement H, the initial slump at 5 min is high and it is not affected by the added alkali content, but the slump loss at 60 or 90 min is reduced with the increased alkali content until an optimum of 0.2% Na_2Oeq is reached.

For cement C, the initial slump is very low, but the slump loss is small. The addition of soluble alkalis improves efficiently the initial slump, but the slump loss remains unaffected. The optimum content of soluble alkalis, determined from the initial slump for this cement, is around 0.12% Na_2Oeq when 1.0% PNS is used. This optimum content increases to around 0.25% when PNS dosage is cut to 0.8% PNS, to around 0.4% when PNS is cut to 0.6% PNS. The slump loss seems to increase with the decrease of PNS dosage, particularly in the case of an added alkali content lower than the optimum value.

Figure 3. Effect of added Na_2SO_4 expressed as Na_2Oeq . Cement L with $E/C=0.35$, 0.6%PNS

Figure 4. Rheology change as function of the amount of Na_2O . Cement H (a), cement C (b, c, d)

3.3 Effect of soluble alkalis on the hydration kinetics of the cement H in presence of PNS

The effect of added alkalis was also investigated using adiabatic calorimetry. The alkalis were introduced by Na_2SO_4 , NaOH and $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ added in mixing water. The calorimetric curves are shown in Figure 5. It can be observed that the alkalis brought by Na_2SO_4 or NaOH accelerate hydration. The sodium metasilicate presents a retarding effect on the initial hydration, but after this initial stage the hydration rate is accelerated. These results indicate that the addition of alkalis does not seem to have a negative effect on the one day strength.

Figure 5. Effect of Na_2O on the heat evolution of hydration. Cement H with $\text{E/C}=0.35$, 0.6%PNS

3.4 Effect of soluble alkalis on the properties of concrete

The slump evolution is presented in Figure 6. For high alkali cements L and Q without a particular compatibility problem, the slump of the concrete without additive presents a normal evolution with time. Any addition of alkalis causes a lower initial slump and/or rapid slump loss. The more difficult rheology of cement Q may be attributed to its high C_3A content.

For low alkali cements H and C that present a partial or poor compatibility with PNS, the slump of the concrete without additive dropped quickly with time, from 24 cm at 10 min to only 5 cm at 30 min. The addition of alkalis in the form of Na_2SO_4 , $Na_2SiO_3 \cdot 9H_2O$ and Li_2SO_4 allowed to reduce greatly or even inhibit totally the slump loss. It is to be noted that when the alkalis were added at 0.2% Na_2O_{eq} , the concrete made of cements H and C presented systematically a pronounced bleeding phenomenon, therefore it was necessary to cut the PNS dosage from 0.6% to 0.5% or 0.4%. Even with a lower PNS dosage, the addition of alkalis still allowed the achievement of the same initial slump and the reduction of the slump loss as compared to the one found in the reference concrete with a higher PNS dosage.

Figure 6. Effect of Na_2O on the slump of concrete with 0.6%PNS (except indication)

The setting time is presented in Figure 7. For high alkali cements L and Q, the setting time decreased with addition of alkalis, higher the added amount, shorter is the setting time. $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ seems to have a more pronounced effect.

For low alkali cement H that presents a partial compatibility with PNS, the setting time increased significantly with added alkalis, the difference may reach as high as 2 hours for $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ or Li_2SO_4 added at 0.1% Na_2Oeq . It can be hoped that this difference should be bigger for $\text{Na}_2\text{SiO}_3 \cdot 9\text{H}_2\text{O}$ or Li_2SO_4 added at 0.2% Na_2Oeq if the PNS dosage was not cut to a lower level.

For low alkali cement C that presents a poor compatibility with PNS, the setting time increased or decreased slightly as function of the nature of alkali salts used and the added alkali amount. The difference does not exceed 0.5 hour.

It is interesting to point out that the alkalis are generally considered as accelerators for OPC as can be observed on cements L and Q. However, in the case of cements H and C that present a incompatibility phenomenon, the effect of alkalis is completely different.

3b – 0.2% Na_2Oeq (Li_2SO_4) (*0.15%)

Figure 7. Effect of Na_2O on the setting time of concrete with 0.6%PNS (except indication)

The compressive strength measured at 1, 3 and 28 days is presented in Figure 8. For high alkali cements L and Q, the one day strength is not affected. The initial strength is high, but the later strength development is relatively slow, from about 40 MPa at 1 day to about 60 MPa at 28 days.

The concretes made with low alkali cements H and C showed a big difference if soluble alkali salts were added or not. Generally, the addition of soluble alkali salts in these cements increased the one day strength. The increasing rates, varying from 6% to up to 30%, depend on the nature of the salts, but especially on the amount of soluble alkalis. Li_2SO_4 shows an interesting performance for two cements H and C. It is to be noted that the initial strength is relatively low for these two cements, even with addition of alkalis, but the later strength development is high.

The impact of added alkalis on the 28 day strength is neglected. Anyway, a tendency of slight drop of 28 day strength could be observed on the concretes made with cements L, Q and C, compared to the reference concrete without any addition of alkalis.

3.5 Discussions

The previous results show the different behavior of cements L (low C_3A , high alkali), Q (high C_3A , high alkali), H (low C_3A , low alkali) and C (high C_3A , low alkali), in the presence of PNS. The cements L and Q are totally compatible with PNS, the cement H is partially compatible with PNS and the cement C is poorly compatible with PNS. It can be concluded that the cement – superplasticizer compatibility depends not only on the C_3A content, but also on the availability of soluble alkalis. In fact, the alkali content, as well as $SO_3\%$, is high in the clinkers corresponding to cements L and Q. These alkalis are most probably combined with SO_3 to form soluble alkali sulfates. In contrast, no soluble alkali sulfates are expected to present in cement H and C because of the very low alkali content and very low $SO_3\%$ in the original clinkers.

The problem of compatibility can be readily solved by adding an adequate amount of soluble alkalis. The working mechanisms [11, 12] are related to the rapid increase of the pH in the interstitial solution which controls the adsorption of the PNS on the cement particle, especially C_3A . Another possibility is the increase of the solubility of calcium sulfates in the presence of alkalis. The higher SO_4^{2-} reduces the amount of PNS adsorbed on the positive surface, such as C_3A and C_4AF .

However, adding sodium and potassium salts in concrete made a potentially reactive aggregate is not an acceptable solution due to the risk of AAR, even when the total Na_2O_{eq} is lower than 0.6%, accepted as a maximum limit. The previous results show that lithium salts perform in the same way or even better in improving the cement-PNS compatibility. Moreover, lithium salts do not cause any AAR or even can be used to fight AAR [13, 14]. It seems that lithium ions react preferentially and rapidly with reactive silica without forming an expanding gel.

4. CONCLUSIONS

The problem of cement-superplasticizer incompatibility is not only related to the C_3A content, but also to the availability of soluble alkalis in cements.

In the cements that have low alkali content and present a problem of incompatibility, soluble alkali salts can be used to reduce greatly or inhibit totally the slump loss. Meantime, the use of soluble alkalis in these cements improves significantly the one day strength and the 28 days is not affected. Among the chosen soluble alkali salts, metasilicate and sulfates are the most efficient additive to improve the cement-superplasticizer compatibility. It has been shown the existence of an optimum content of alkalis as a function of the superplasticizer dosage for a given W/C.

Lithium salts have shown the same or better performance than sodium or potassium salts. If the addition of sodium or potassium salts can be perceived as detrimental from AAR point of view, the addition of lithium salts as alternative is totally safe and even beneficial.

On the contrary, normal cements having a relatively high alkalis content show a similar or even slightly deteriorated rheological behavior when soluble alkalis are used. The setting time is systematically reduced by addition of alkalis, but the strength is not affected.

ABSTRACT

In High Performance Concrete (HPC) mixtures, a low water/binder ratio and addition of silica fume cause a significant drop of the relative humidity in the cement paste during hydration. As a consequence of self-desiccation, the cement paste undergoes shrinkage. In the case where shrinkage is restrained, micro- or macrocracking may occur, which impairs the concrete quality.

In research on autogenous shrinkage, emphasis has been on Portland cement mixtures cured isothermally at 20°C. In this paper, the results are presented of an experimental study on the influence of the curing temperature and the type of cement on the autogenous deformations of concrete mixtures. Three mixtures were tested with w/b ratio 0.35 and 5% silica fume, differing for the kind of cement, i.e. Portland cement, Blast-Furnace Slag cement and a blend of the two. The development of compressive strength, modulus of elasticity and linear free deformations in the first six days after casting for curing temperatures 10, 20, 30 and 40°C were measured. The evolution of the hydration process and the changes of the relative humidity at early ages were measured as well. It was found that higher temperatures do not lead to higher final deformations, but generally cause a higher shrinkage rate in the first hours. The mixtures with Blast Furnace Slag cement showed higher shrinkage in the first days than mixtures made with Portland cement. The potential of numerical simulation models for quantifying autogenous deformations is also addressed.

1. INTRODUCTION

In High Performance Concrete (HPC) mixtures, a low water/binder ratio and addition of silica fume cause a significant drop of the relative humidity during hydration. As a consequence of self-desiccation, the cement paste undergoes shrinkage. The shrinkage of the cement paste is restrained by the aggregates: this results in tensile stresses within the cement paste and in bulk deformation of the concrete itself. Both these phenomena should be limited since they could induce micro- or macrocracking and jeopardize the quality and durability of the concrete [1].

In the last two decades much experimental research on autogenous deformations has been performed. In most of this research the focus was on mixtures made with Portland cement cured at 20°C. Since autogenous shrinkage is related to the self-desiccation process and self-desiccation is strongly related to the hydration process, autogenous shrinkage should be a function of the degree of hydration. According to Koenders [2] and Hedlund [3] autogenous shrinkage strongly correlate to the degree of hydration. Hedlund [4] successfully used the maturity concept for quantification of the effect of temperature on the autogenous shrinkage. In a number of other studies, however, a very unsystematic effect of temperature on the autogenous deformations has been found [5,6]. Moreover, besides autogenous shrinkage also autogenous swelling of some concretes, i.e. some cement types,

has been observed [7]. Since in practice non-isothermal curing regimes are more likely than isothermal temperatures and cement types other than Portland cement are often used, an extensive study was conducted in which both the type of cement and the curing temperature were varied.

2. EXPERIMENTAL STUDIES

2.1 Description of experiments

The experimental program on autogenous deformations included the determination of the compressive strength, the modulus of elasticity and the autogenous deformations of 3 different types of concrete, made with 2 different types of cement and cured isothermally at 4 different temperatures. The reaction kinetics and the evolution of the relative humidity in cement pastes were measured as well.

2.1.1 *Isothermal heat evolution*

Cement pastes made with Portland cement and blast furnace slag cement were examined using the isothermal calorimeter TAM Air from Thermometric AB, Sweden. The cement paste specimens weighed about 10 grams. The paste composition was identical to the pastes used in the concrete mixtures used for studying the autogenous deformations (see paragraphs 2.2).

2.1.2 *Relative humidity*

Measurements of the relative humidity were carried out in cooperation with Aalborg University in Denmark [8]. The measurements were performed on fresh cement paste, about 10 grams per sample. The samples were cast in the measuring chamber of two Rotronic hygroscopic DT stations equipped with WA-14TH and WA-40TH measuring cells. The RH stations were placed in a thermostatically controlled room at $20 \pm 0.1^\circ\text{C}$. The development of the RH in the samples and the temperature were measured every 15 minutes for a period of about one week after water addition. Before and after the measurements, calibration of the stations was carried out with four saturated salt solutions in the range of 75-100% RH. In this way a measuring accuracy of $\pm 1\%$ RH could be achieved.

2.1.3 *Autogenous deformation*

Measurements of the free deformations were performed with an Autogenous Deformation Testing Machine (ADTM) (Figure 1). The concrete was cast in a prismatic mould, $150 \times 150 \times 1000$ mm, made with thin steel plates provided with an external insulating material. The mould could be cooled or heated by a system of tubes located between the plates and the insulating material. Temperature differences inside the concrete could be kept as low as 1.5°K . Length changes of the hardening concrete were measured with two external quartz rods provided with linear variable differential transducers at both ends. The quartz rods were connected to steel bars cast in the concrete and measured displacements over a length of 750 mm. The rods could be fixed to the cast-in bars when the concrete had reached sufficient strength to support them (see Figure 1, right). After casting, the top surface of the concrete was covered with a tight cover in order to avoid moisture loss to the environment. The autogenous deformation up to six days after casting was recorded.

2.1.4 *Strength and modulus of elasticity*

Compressive strength was measured on cubes, $150 \times 150 \times 150$ mm, whereas the modulus of elasticity was determined on prisms, $100 \times 100 \times 400$ mm. The concrete was cast in temperature-controlled steel moulds. During the first six days after casting the concrete was kept in the moulds. In this period curing took place under sealed conditions at temperatures exactly the same as that of the specimens used for determination of the autogenous deformation. In this way the curing regime of the concrete for the different types of tests was always the same at the moment of testing. The specimens tested at later ages were removed from the moulds after six days, sealed and stored at constant temperature until the moment of testing.

Figure 1. Mould (left) and details (right) of measurement device for determination of autogenous deformation of concrete.

2.2 Materials

Cements used were a Portland cement, CEM I 52.5 R, and a blast furnace slag cement, CEM III/B 42.5 LH HS. The Portland cement had Blaine fineness of $530 \text{ m}^2/\text{kg}$ and calculated Bogue composition of C_3S 53.6%, C_2S 20.1%, C_3A 8.2%, and C_4AF 9.1%. The BFS cement contained 76% slag and had Blaine fineness of $390 \text{ m}^2/\text{kg}$.

For the measurement of the changes of the relative humidity with progress of the hydration process two cement pastes were studied, one with Portland cement and one with BFS cement. The w/b ratio of the pastes was 0.35. Silica fume with a BET surface area of $19 \text{ m}^2/\text{g}$ was added in slurry form, 5% by cement weight. A lignosulphonate-based plasticizer (0.2%) and a naphthalene-sulphonate-based superplasticizer (1.7%) were also added to the mix.

The measurements for the strength, modulus of elasticity and autogenous deformations were performed on three concrete mixtures. Portland cement (CEM I 52.5 R) was used in mixture A, BFS cement (CEM III/B 42.5 LH HS) in mixture B and a blend of the two in mixture C. In all the mixtures a water/binder ratio 0.35 and 5% silica fume were used (see Table 1). Data about the performance of mixture C at 20°C were obtained in a previous research study [9]. For that particular mix and curing conditions, the Young's modulus was not measured.

Table 1. Mixture compositions of concrete with w/b 0.35.

Mixture composition	Unit	A	B	C
CEM I 52.5 R (Portland cement)	kg/m^3	475.0	---	238.0
CEM III/B 42.5 LH HS (BFS cement)	kg/m^3	---	475.0	237.0
Water (including water in admixtures)	kg/m^3	175.8	175.8	175.8
Crushed aggregate (4-16 mm)	kg/m^3	944.2	944.2	944.2
Sand 0-4 mm	kg/m^3	772.5	772.5	772.5
Lignosulphonate	kg/m^3	0.9	0.9	0.9
Naphtalene sulphonate	kg/m^3	8.1	7.1	7.6
Silica fume slurry (50% powder, 50% water)	kg/m^3	50.0	50.0	50.0

2.3 Experimental series – Curing regimes

For the determination of the strength, modulus of elasticity and autogenous deformation tests were carried out at isothermal temperatures, viz. 10, 20, 30 and 40°C . In all these tests curing took place under sealed conditions.

3. RESULTS

3.1 Isothermal heat evolution and relative humidity

Figure 2 shows the rate of heat liberation at 20°C of the two cement pastes in the first two days of hydration. The cement pastes were placed into the calorimeter after mixing; therefore, only a part of the first reaction peak, happening immediately after water addition, was recorded. Hydration of the Portland cement paste took place in the first hours at a very fast rate, also due to its very high fineness, 530 m²/kg. In the case of the BFS cement paste, hydration of the Portland cement fraction, 24% by weight, was postponed. This is possibly due to a higher w/c ratio if related only to the Portland cement clinker in the mixture. The peak was correspondingly lower than in the Portland cement paste, about 1/4. Just after the first peak, the pozzolanic reaction of the slag with calcium hydroxide, formed by the Portland cement hydration, started [10]. This reaction peaked at about 30 hours after water addition.

Figure 2. Rate of heat evolution in cement pastes, w/b = 0.35.

The evolution of the relative humidity in the cement pastes was measured in twofold over a period of at least 6 days. Results are shown in Figure 3. After casting and before starting the RH measurements, the BFS paste was rotated in order to avoid bleeding. Rotation started about 50 min after water addition and lasted for 4 hours. After an initial equilibrium of the sensors was achieved, the RH decreased with hydration time. The start of the RH drop coincided with the decrease in the rate of the reaction shown in Fig. 2.

It is emphasized that the RH measurements are very sensitive to the temperature [11]. It has been calculated that near saturation at 20°C a temperature difference of 1°C may lead to an error of about 6% RH [12]. The BFS cement paste develops less and slower heat of hydration than the Portland cement paste; therefore the temperature, also due to the small dimensions of the sample, is closer to isothermal and the measured RH should be more reliable. In fact, the temperature measured inside the Rotronic stations was always less than 21°C in the case of the Portland cement paste, while for the BFS cement paste the temperature remained practically constant.

Figure 3. Internal relative humidity vs. time for the two cement pastes.

3.2 Compressive strength

The evolution of the cube compressive strength of the concrete is presented in Table 2. It is noticed that at later ages the strength achieved by the specimens cured at elevated temperatures is lower than the strength at lower temperatures. Similar effects were found for the modulus of elasticity.

Table 2. Cube compressive strength of concretes A, B and C (Table 1). Sealed curing at different isothermal temperatures.

Mixture	Temperature	Mean cube compressive strength [MPa]						
		1 day	2 days	3 days	7 days	14 days	28 days	56 days
A	10°C	---	57.2	65.8	81.7	91.7	97.7	---
	20°C	53.2	65.1	---	85.9	94.0	99.5	---
	30°C	55.4	68.5	78.6	92.3	100.1	---	---
	40°C	66.5	74.2	86.6	92.5 ¹⁾	97.0	---	---
B	10°C	---	5.2 ²⁾	13.1 ³⁾	34.5	51.8	58.9	---
	20°C	4.9	20.4	32.7	53.8	---	65.9	---
	30°C	23.6	44.6	50.6	59.6	64.8	---	---
	40°C	31.8	47.7	53.6	59.4 ¹⁾	---	---	69.7
C	10°C	---	31.1 ²⁾	38.1 ³⁾	57.4	72.2	82.8	---
	20°C	42	52	58	70	---	82	---
	30°C	40.7	54.5	63.9	---	84.8	---	---
	40°C	44.9	65.1	71.4	78.8 ¹⁾	79.2	---	---

¹⁾ Tested 8 days after casting; ²⁾ Tested 1.5 days after casting; ³⁾ Tested 2.5 days after casting

3.3 Autogenous deformation

In Figures 4 to 6 the autogenous deformations of the mixtures A, B and C are plotted. The autogenous deformations were zeroed at the time when the deformations became stress inducing. This moment was determined in a Temperature Stress Testing Machine (TSTM), a test rig in which the concrete was cured under the same conditions as the concrete in the ADTM and in which the autogenous deformations were completely restrained [13]. Thus, only the stress-inducing deformations are shown. For mixtures A and C this means only shrinkage, since only tensile stresses were measured in the stress-rig. For mixture B, at some curing temperatures, swelling preceded shrinkage, resulting in a low compressive stress in the TSTM (<0.3 MPa). The stress-inducing deformations were preceded by a phase, lasting for some hours, where the concrete deformed plastically without generating any stress in the TSTM. In this plastic phase, all the concrete mixtures expanded shortly after the beginning of the measurements, with swelling up to $50 \cdot 10^{-6}$.

The autogenous deformations of mixture A are shown in Figure 4. The stress-inducing shrinkage developed rather unsystematically with temperature. Specimen cured at 40°C showed a faster shrinkage in the first hours, but then slowed down. After one day the total shrinkage was less than for 20°C curing. Shrinkage after six days varied between $130 \cdot 10^{-6}$ and $170 \cdot 10^{-6}$ for the four curing temperatures.

In Figure 5 the autogenous deformation of mixture B, made with BFS cement, is shown. Also in this case, the influence of the curing temperature on the autogenous deformation seems unsystematic.

Figure 4. Autogenous deformation of mixture A (see Table 1). Isothermal sealed curing at 10, 20, 30 and 40°C. Shrinkage is plotted as negative.

Figure 5. Autogenous deformation of mixture B (see Table 1). Isothermal sealed curing at different 10, 20, 30 and 40°C. Shrinkage is plotted as negative.

Figure 6. Autogenous deformation of mixture C (see Table 1). Isothermal sealed curing at 10, 20, 30 and 40°C. Shrinkage is plotted as negative.

The initial swelling was followed by shrinkage, which occurred earlier for the specimen cured at 40°C. However, 30 hours after casting the shrinkage of the specimen cured at 30°C became higher. Shrinkage of the specimen cured at 10°C developed slowly, but at the end of the test it was about the same as in the case of 40°C curing. Shrinkage values after six days were about $170\text{--}180 \cdot 10^{-6}$ for curing at 10, 20 or 40°C, and about $230 \cdot 10^{-6}$ for curing at 30°C. These values are noticeably higher than those found for Portland cement mixtures (see Figure 4).

Results of tests on mixture C, made with blended cement, are shown in Figure 6. Shrinkage was lowest for 10°C and highest for 40°C curing. The specimen cured at 20°C showed a faster rate of shrinkage than the one cured at 30°C. It should be recalled, however, that the data at 20°C curing had been obtained in a previous research [9]. The materials used might have been slightly different. Shrinkage values after 6 days were $120 \cdot 10^{-6}$ for 10°C curing, $140 \cdot 10^{-6}$ for 30°C and $210 \cdot 10^{-6}$ for 20 or 40°C. These values lay between the ones found for mixtures A and B.

4. DISCUSSION AND CONCLUSIONS

From the figures 4 to 6 it is clear that the effect of temperature on the autogenous deformation of concrete is unsystematic. The fact that also the type of cement gives rise to different autogenous deformation curves is clearly illustrated in Figure 7, showing the autogenous strain in the first 48 hours obtained at 40°C for the mixtures A, B and C.

The unsystematic effect of temperature on the autogenous deformations makes it difficult to apply the Arrhenius function to the curves obtained at different temperatures. On the other hand, it is noticed that for the mixtures A, B and C the Arrhenius function turned out to be applicable indeed for quantifying the effect of temperature on the strength. Figures 8 and 9, left, show the compressive strength at 5 days of age as a function of the degree of hydration (α) at the moment of testing. In the figures 8 and 9, right, the corresponding stress-inducing autogenous deformations are shown. The degree of hydration after 5 days for the different curing temperatures was calculated with the numerical simulation program HYMOSTRUC [14]. In this program the effect of temperature on the rate of hydration is accounted for with the Arrhenius function, here with a constant value of the apparent activation energy. The figures clearly demonstrate an almost linear relationship between compressive strength and degree of hydration.

Figure 7. Autogenous deformations of mixtures A, B and C in the first 48 hours after casting, cured at 40°. The measurements include the non stress-inducing strains in the early stage of hydration.

Figure 8. Compressive strength and stress-inducing autogenous shrinkage of a Portland cement based mixture (A) at $t = 5$ days.

Figure 9. Compressive strength and stress-inducing autogenous shrinkage of mixture B, based on blast furnace slag cement at $t = 5$ days.

Such a linear relationship, however, did not hold for the autogenous deformations. This illustrates that the dependence of the autogenous deformations on the degree of hydration at different curing temperature is more complex. In this case, a simple Arrhenius function cannot be used for quantifying the effect of temperature.

It is widely accepted that autogenous shrinkage originates from the changes in the relative humidity in the pore systems and the associated changes in the capillary pressure in the pore water. In fact the degree of hydration is too crude a parameter to inform us about these microstructural phenomena in detail. From the figures 2 and 3 it can be deduced that both the rate of hydration and the evolution of the relative humidity in the paste develop quite differently for the Portland cement paste and the BFSC paste. The rapid heat evolution of the PC pastes is accompanied with a steep decrease of the RH between 16 and 28 hours. The slower reacting BFSC exhibits a RH-plateau until about 48 hours after casting. From that moment on the RH gradually decreases and reaches values substantially lower than in the PC pastes (see Fig. 3).

It is well known that pastes made with slag cement are very dense and have a fine capillary pore structure. Portland cement pastes have a coarser pore structure. The coarseness of the pore system also depends on the curing temperature: at elevated temperatures the capillary pore structures is coarser than in case of hydration at room temperature [15]. The characteristics of the pore structure, the water distribution and the relative humidity in the pore system are related to each other on a thermodynamic basis. This relationship can be described with the Kelvin's equation, which can be written like:

$$r = - \frac{2\gamma \cdot M}{\ln RH \cdot \rho \cdot RT} \quad (1)$$

where γ is the surface tension of water (0.073 N/m in pure water), M the molar weight of water (0.01802 kg/mol), ρ the density of water (approx. 1000 kg/m³), r the radius of the meniscus, R the ideal gas constant (8.314 J/mol K), T the absolute temperature and RH the relative humidity. From equation (1) it can be seen that a low relative humidity means small values of the meniscus r . Small radii of the meniscus are accompanied with high values of the pore fluid pressure:

$$\sigma_{cap} = \frac{2\gamma}{r} \quad (2)$$

in which with σ_{cap} is the pore fluid pressure. These capillary forces put the solid skeleton of hydrated paste under compression, resulting in shrinkage. The fact that both the type of cement and temperature affect the capillary pore structure explains why a simple maturity law does not apply for evaluating the effect of temperature on autogenous deformations comprehensively. Autogenous deformations of hydrating pastes should be considered as the response of a complex and continuously changing system on changes in the pore fluid pressure. A quantitative evaluation of autogenous phenomena requires a description of the relevant phenomena active on a microstructural level, including the effects of temperature and type of cement. Against the background of the equations (1) and (2) it is conceivable that specimens made with blast furnace slag cement, because the slag results in a finer pore structure, exhibit a higher autogenous deformation, and the curing at elevated temperatures, because of a coarser pore structure of the paste, results in relatively low autogeneous shrinkage. This was in fact confirmed by the experimental data presented in this paper.

From the qualitative explanation of the effect of temperature and type of cement on autogeneous deformation it can be concluded that further quantitative modeling of autogenous should focus on the modeling of the pore structure. Meanwhile promising results have been achieved in this field [16,17]. It believed that advanced microstructural models can support the design of modified and new cement-based materials with reduced hydration-induced volume changes and hence a lower susceptibility to micro- and macrocracking of hardening concrete and enhanced durability.

Klaas van Breugel

Klaas van Breugel, (1952) is full professor at Delft University of Technology in the Division of Concrete Structures. He graduated at this university in 1979. After his graduation he became employed at the faculty of Civil Engineering of Delft University of Technology. His main research and lecturing topics are structural design of concrete protective structures, structural response under extreme load conditions, design of reservoirs and tightness and self-healing of cracks. In 1991 he got his PhD at TU Delft on numerical modeling of hydration and microstructural development in hardening cement-based systems. Since that time young concrete and durability issues are among his main research topics.

ALKALI-ACTIVATED BINDERS AND POZZOLAN CEMENT BINDERS – COMPETE BINDER REACTION OR TWO SIDES OF THE SAME STORY?

ABSTRACT

Increasingly attention has been paid in recent years to alkali-activated binders such as alkali-activated fly ash and slag. Related binders are known as geopolymers which are at least alkali-activated metakaolin binders. In all cases the activation of the solid is made with different alkaline solutions containing alkali hydroxides, alkali silicates and/or alkali carbonates. It has been shown by other authors [1, 2] and the author's own investigations [3, 4] that other aluminosilicate minerals and thermal activated clays also react into stable solids after alkali-activation. All these materials – fly ash, slag, metakaolin, thermal activated clays – are also well known as pozzolanic or latent-hydraulic components in cements.

Are these different binder reactions or not? It will be discussed the common and the different aspects of both binder systems based on literature and our own investigation. Results are presented for solubility tests and strength performance of different alkali-activated binders made from fly ash, slag, metakaolin, thermal activated clay and brick powder.

1. BINDER REACTION STEPS

1.1 Alkali-activated binder systems

A reactable material in the light of alkali-activated binders has to consist of a certain amount of highly active phases like a glassy phase (fly ash, slag). Clays can be transformed into a reactive material by a thermal activation process in which the dehydroxylation of the clay mineral leads to a highly active, unstable and nearly amorphous state of the solid. The reaction mechanism of alkali-activated materials can be described in two steps,

1) The generation of reactable species (alkaline activation)

Alkali hydroxide disintegrates the solid network to produce small reactable silicate and aluminate species.

2) The real setting reaction

Pure aluminosilicate materials like metakaolin and some types of fly ash set under a condensation reaction which leads to the formation of aluminosilicate polymers [5]. As could be shown by several authors, the setting of alkali-activated slag and calcium containing materials can be characterised by both a condensation reaction and a more or less hydration reaction forming CSH- (or Al-substituted CSH-) and CAH-phases depending on the calcium content and the alkalinity [6-9].

A detailed characterisation of the reaction products seems to be quite difficult because of the low crystallinity of the reaction products. Depending on curing temperature and alkalinity, the aluminosilicate polymer changes into a zeolitic phase detectable by XRD.

1.2 Pozzolan cements and slag cements

The reaction of pozzolans and slag with OPC is usually described by the following two definitions. The pozzolan forms additional CSH-phases with the Ca(OH)_2 from cement hydration. The latent-hydraulic material needs an activation to form CSH-phases.

The different performance of pozzolanic cements has been shown in many reports, especially the loss of strength if the pozzolan content reaches high values or if using slag cements in combination with fly ash. A high pH-value in the pore solution is undoubtedly necessary to get a good pozzolanic performance of the cement [10, 11]. Obviously the alkali hydroxide is necessary to disintegrate the glassy or amorphous phases to produce reactable silicate and aluminate units. This units react with calcium hydroxide to CSH- and CAH-phases [12].

1.3 Similarity of the binder reactions

As one can see the two binder systems are more similar than different. The pozzolan cement looks like a special case of alkaline activated systems. The alkaline activation is guaranteed by the OPC pore solution. Therefore a certain amount of OPC is necessary for a good performance. But the first reaction step is the alkaline activation of the reactive solid to produce reactable monomers which can afterwards react with calcium ions.

2. EXPERIMENTAL INVESTIGATIONS

2.1 Solubility of SiO_4 - and AlO_4 -monomers by alkaline solutions

How alkali hydroxide disintegrates the reactive phases of the solid material can be seen directly in the solubility tests. The usefulness of such tests to determine the reactivity of different raw materials has been described by several authors [2, 13, 14] and has been widely used in our own investigations.

Several test regimes have been used to determine the release of silicate and aluminate monomers in alkaline solution:

- Regime 1: The solubility of the solid in 10% NaOH-solution has been measured for a long-term period investigation up to 90 days. The mass ratio solution to solid of 400 was used.
- Regime 2: The same conditions as in regime 1 (40g of 10% NaOH-solution) with a contact time of 20 h but under variation of the mass of the solid (mass ratio solution to solid between 8 and 400, resp. between 2 and 139 mg solid per ml solution).
- Regime 3: The influence of concentration and kind of alkaline solution has been investigated with the following test parameters:
 - alkaline solution: KOH, NaOH, LiOH
 - concentration of the solutions: 0.01, 0.03, 0.06, 0.1, 0.3, 0.6, 1 and 2.8 mol/l
 - solid-to-solution of 2,5 mg/ml
 - duration of test: 20 h

The concentration of silicate and aluminate monomers are determined by measuring the element concentration of Si and Al using Optical Emission Spectroscopy. It has been proven that the silicate species are really monomeric units under these conditions. Therefore the small reactive species will be designated as monomers henceforth.

2.2 Binder preparation and strength measurements

Pure binder specimens were prepared by mixing the solid material with the defined amount of solution containing water and solved sodium hydroxide. The amount of water has been levelled on the same workability of the paste. No aggregates are added.

The flexural strength (centre point loading) has been measured on specimen with an geometry of $10 \times 10 \times 60 \text{ mm}^3$, the compressive strength on the broken samples with an compression area of $10 \times 20 \text{ mm}^2$. Before testing all samples were cured for one day at 35°C without drying and the following days at room temperature under 60% relative humidity.

3. CHARACTERIZATION OF THE RAW MATERIALS

Five different materials were used in our investigation: a commercial metakaolin, a slag, a fly ash, the brick powder and the thermal activated clay base on the raw material which contained the main phases of quartz, illite and kaolinite beside some feldspar and carbonate. Both are heated up to 850°C , the brick under reduced oxygen, water enriched atmosphere and the clay in a normal laboratory oven under normal air. The chemical composition of these materials are shown in Figure 1.

Figure 1. Chemical composition of the investigated materials

4. RESULTS AND DISCUSSION

4.1 Influence of the contact time of the reactive solid with NaOH solution on the release of silicate and aluminate monomers and strength performance of the binder

Figure 2 presents the results obtained by measuring the release of silicate and aluminate monomers in a 10% sodium hydroxide solution after different contact time with the solid material (test regime 1). As one can see the metakaolin shows the highest release per weight of both silicate and aluminate even after few hours. It is followed by the fly ash, but this material needs some time before a certain amount of monomers are detectable in the solution. This is clear because of the smaller surface of the particles and the higher stability of the glassy phase compared to the metakaolinite phase. The amount of released aluminate monomers is lower according to the lower amount of aluminate in the material.

The thermal activated clay and the brick powder reach almost the same amount of silicate and aluminate in the solution which is understandable because of the almost identical chemical and phase composition. The differences in the light of the release kinetics are due to the different surfaces of the materials.

The results of the slag material depart from those of the other materials. The measured amount of silicate and aluminate are quite low and do not change over the contact time. The available calcium ions seem to react with the released silicate and aluminate monomers to insoluble CSH- and CAH-phases as precipitate. CAH-phases and partly carbonated CAH-phases could be detected in the elution residue by XRD. The amount of crystalline C_2S and C_3S -Phases were decreasing as well.

Figure 2. Influence of contact time on the release of silicate (left side) and aluminate (right side) monomers, measured after regime 1

Will the release behaviour be found again in the strength performance? The results of the compressive strength measured after the same curing time steps are presented in Figure 3. Looking only at the progress of the compressive strength one is forced to correlate the results of both investigations. But the trends are not significant and the distribution of the strength values is quite high. Apart from this it is noticeable that the only “latent hydraulic material” – the slag – performs at best as was to be expected. The different strength levels can not be compared directly as will be discussed later.

Should one expect to find the same progress of both the release of monomers in the solubility test and the strength performance? If looking at the parameters used in the solubility test of regime 1, there has been set ideal conditions for analysis and discussion of the reactivity. In contrast to the solubility test, the solid-to-solution-ratio of real binder systems easily reaches values over 1 g/ml pore solution. That’s why we used test regime 2 to measure the influence of solid-to-solution-ratio on the silicate and aluminate monomer concentration released from metakaolin by keeping the NaOH concentration constantly. The results are presented at Figure 4.

It can be seen that the concentration of silicate and aluminate monomers reaches a maximum around a ratio of 20 mg/ml. Either the solution process arrives an equilibrium or released monomers condensate already to insoluble aluminosilicate which will remain in the elution residue.

Figure 3. Influence of curing time on the strength development of some alkali-activated binders (compositions of the same ratio NaOH to solid material are compared)

Figure 4. Influence of the ratio solid to solution on the release of silicate and aluminate monomers from metakaolin (test regime 2)

4.2 Influence of the concentration of sodium hydroxide on the release of silicate and aluminate monomers and strength performance of the binders

The concentration of the alkaline solution plays an important role for the reaction step 1 (disintegration of the solid material). The silicate and aluminate monomers released from metakaolin using different concentrations of sodium hydroxide are presented in Figure 5. The lower the pH-value of the solution, the lower the monomer concentration will be. There is no selectivity between silicate and aluminate.

Figure 5. Influence of the NaOH concentration on the release of silicate and aluminate monomers from metakaolin (test regime 3)

The strength performance of binders prepared with different NaOH amounts per solid material are presented in Figure 6. In general the strength increases by an increasing content of sodium hydroxide.

Figure 6. Influence of the NaOH content on the compressive strength of the alkali-activated binders after 28 days (*14 days)

Because of the different water contents used to obtain a certain workability, the concentration of the pore solution will be different for two binders even with the same NaOH amount per solid material. Therefore the strength values are presented again in dependence of the NaOH concentration in the initial pore solution (Figure 7). The compressive strength shows almost the same dependence from the NaOH concentration for all materials apart from the slag. However in every binder the pore volume which has to be filled by the reaction products is very different. Metakaolin needs many more reactable monomers than fly ash because of its higher surface area. On the other hand the reactivity of the materials by means of releasable amounts of monomers is also quite different (see results in 4.1). A different setting behaviour shows again for the slag material. The building of CSH- and CAH-phases leads to good strength performance even at low alkalinity.

Figure 7. Influence of the NaOH concentration in the pore solution on the compressive strength of the alkali-activated binders after 28 days (*14 days)

4.3 Influence of the kind of alkaline hydroxide on the release of silicate and aluminate monomers from metakaolin

The pH-values of the single alkaline solutions varying in concentration and kind of alkali ion are shown in Figure 8. If one replaces the sodium ions by other alkaline ions in the solubility test one would expect an order of released monomers correlated to the hydroxide activity. That means we would expect a higher solubility performed by KOH than by NaOH because of the higher alkalinity.

Figure 8. Influence of the concentration and kind of the alkaline solution on the pH-value (an electrode with a low alkaline error was used for measurements)

The results using test regime 3 to determine the influence on the kind of alkaline solution are shown in Figure 9. The diagram shows only the release of silicate from metakaolin. Similar to Figure 5 there is no selectivity between silicate and aluminate. The order of monomer releasing followed our expectations only as regards NaOH and LiOH. The KOH which has a much higher hydroxide activity doesn't show a higher monomer releasing. FRAAY [13] got similar results if eluting fly ash with KOH and NaOH solution. Obviously this effect can't be described thermodynamically alone. Maybe there are kinetic effects due to the different ion sizes (diffusion rate in the reaction zone) playing an important role by the disintegration of glassy and dehydroxylated solid phases.

Figure 9. Influence of the concentration and kind of alkaline-solution on the on the release of silicate monomers from metakaolin (test regime 3)

5. CONCLUSIONS

The disintegration of glassy and dehydroxylated phases could be shown by the presented results of the solubility tests. The chosen test parameters were optimised for ideal measurement conditions and therefore they are not identical with those in the real process in the pore solution. Nevertheless one can extract the following conclusions:

- 1) Glassy and dehydroxylated aluminosilicate phases will be disintegrated by alkaline solutions into silicate and aluminate monomers.
- 2) The amount of released silicate and aluminate monomers depends on the content of the reactive phase and the kind and concentration of the alkaline solution.
- 3) The kinetics of disintegration depend on the contact surface and the kind of the reactive phase and also on the degree of disorder.
- 4) The maximum of released monomers will not be reached in real binder systems because of the lower amount of alkaline solution. The layer which has been precipitated during alkaline activation can limit the process of further disintegration. The remaining solid grains will then work as aggregates.
- 5) If calcium ions are present in the solution as well the building of insoluble CSH- and CAH-phases will be preferred.

These points confirm the assertion that alkali-activated binders and pozzolanic cement binders are two sides of the same story. In pozzolanic cement binders two connected reaction types exist, ordinary cement hydration and alkali-activation of the pozzolanic material by the alkaline pore solution. As reaction products one can find primary CSH and CAH-phases (from the OPC), secondary CSH- and CAH-phases (from the reaction of $\text{Ca}(\text{OH})_2$ with the released silicate and aluminate monomers) and maybe aluminosilicate polymers. Alkali-activated binders which will be activated by alkali hydroxide lead to aluminosilicate polymers partly detectable as crystalline zeolitic phases or to CSH and CAH-phases if calcium ions are present in the solution [9].

INFLUENCE OF THE MOLECULAR WEIGHT OF POLYCARBOXYLATE ETHER SUPERPLASTICIZERS ON THE RHEOLOGICAL PROPERTIES OF FRESH CEMENT PASTES, MORTAR AND CONCRETE

R. Magarotto, I. Torresan and N. Zeminian

MAC S.P.A. – Degussa, Treviso, Italy; E-mail: mactv@mac-mbt.com

ABSTRACT

This paper highlights the influence of the molecular weight on the performances of polycarboxylate ether (CE) superplasticizers.

A polymer was separated into different fractions on a laboratory scale by means of ultrafiltration membranes. The weight average molecular weight (\bar{M}_w) and the molecular weight distribution of such fractions were determined through gel permeation chromatography and their performances were investigated in fresh cement pastes and in mortar mixes and compared to those of the original unfractionated polymer. The data collected indicate that the performances of the polymer are considerably affected by its molecular weight, the best effect being obtained with the highest molecular weight fractions (>30K and >50K Dalton). The lowest fraction (< 30K) performs far less well than the original unfractionated polymer.

The higher molecular weight fractions are adsorbed in a greater amount and more increasingly over time, while the smaller are adsorbed weakly and more constantly over the time.

It can be concluded that there is an ideal molecular weight for the best performance of the superplasticizer investigated. This could be taken into account for optimisation of the product.

1. INTRODUCTION

In the last decades, the technology of concrete has evolved and nowadays the market increasingly demands concrete with properties such as higher flowability, higher early mechanical strengths and increased durability. The use of high range water reducing admixtures (HRWRA) has represented a fundamental step in this direction. Since the introduction of salts of sulfonated naphthalene formaldehyde condensate (NS) invented in Japan, and salts of sulfonated melamine formaldehyde condensate (MS), which appeared on the German market in the '60s, a new generation of admixtures, based on polycarboxylate ether polymers (CE) has been recently developed. The widespread diffusion of such compounds has stimulated research aimed at understanding the mechanism of action and to find out if a correlation exists between their structure and their performances, in order to optimise them.

Among the most important parameters of a polymer are its molecular weight and polydispersion (1,2). The weight average molecular weight \overline{M}_w is expressed by formula i):

$$\overline{M}_w = \frac{\sum_i w_i \cdot M_i}{\sum_i w_i} = \frac{\sum_i n_i \cdot M_i^2}{\sum_i n_i M_i} \quad \text{i)}$$

and the numerical average molecular weight \overline{M}_n , expressed by formula ii):

$$\overline{M}_n = \frac{\text{weight of polymer}}{\text{moles of macromolecules}} = \frac{\sum_i n_i \cdot M_i}{\sum_i n_i} \quad \text{ii)}$$

where M_i = molecular weight of the i-species

w_i = weight of the i-species

n_i = moles of the i-species,

The polydispersion, defined as the ratio between \overline{M}_w and \overline{M}_n , represents the width of the curve of the molecular weight distribution.

Previous studies were carried out on the effect of molecular weight on the performances of traditional superplasticizers, based on ligninsulfonate and β -naphthalenesulfonate polymers (3-8) but similar studies on polycarboxylate ether admixtures have not yet been reported in the literature.

The present study is therefore aimed at investigating of the effect of molecular weight on the performances of sodium salts of a polycarboxylate ether based superplasticizer (CE).

2. EXPERIMENTAL

2.1 Materials employed

Table 1 shows the chemical composition, determined according to the methods reported in UNI ENV 196/2, of the two cements (A and B) employed in the present work. The polymer fractioned was a polycarboxylate ether with total solid content 40.0%, density 1.05 g/cm³ and pH 7.

The gel permeation chromatography analyses were performed using a GPC system from Shimadzu, with UV detector SPD10A (Shimadzu) and RI detector 10A (Shimadzu).

The instrument calibration was performed by means of narrow MWD standards of polyethylene oxides. They represent the closest commercially available approximation to CE polymers but their molecular structure is still distinct from that of polycarboxylate ethers; therefore the \overline{M}_w values given by GPC are meant as relative molecular weights.

Table 1. Chemical analyses of cements employed

	Cement A (type II A/L 42.5)	Cement B (type I 52.5)
free CaO	1.0	0.84
R.I.	3.0	0.04
LOI	3.9	1.1
SiO ₂	21.1	20.1
Al ₂ O ₃	6.2	4.8
Fe ₂ O ₃	2.7	5.5
CaO	61.0	63.8
MgO	1.4	1.4
SO ₃	2.9	2.7
Na ₂ O	0.4	0.3
K ₂ O	0.7	0.9
Blaine (cm ² /g)	3327	3940

2.2 Ultrafiltration

Prior to ultrafiltration the polymer, diluted with tap water to a 10% concentration, was submitted to dialysis through cellulose dialysis tubes by SIGMA CHEMICAL. The tubings employed have a 49 mm diameter and retain, according to SIGMA specifications, molecules with molecular weights 12,000 or greater. They are designed more specifically for protein dialysis.

The polymer was put into closed tubes made with the cellulose membranes and left for 72h under running water. The dialyzed product was concentrated through evaporation at the roto-evaporator. After dialysis, the polymer was submitted to ultrafiltration through stirred cell devices with a membrane of polyethersulfone (low release), encapsulated within the cell, with a filtering area of 23.2 cm² and a capacity of 150 ml. The polymer sample, diluted again to a 10% dry concentration, was placed within the cell; nitrogen gas at 50 psi pressure was used as the driving force for filtration, together with a magnetic stir plate which, moving the stir bar, created a gentle turbulence at the membrane surface. This caused macromolecules to be swept off the membrane surface, minimising the phenomenon called “concentration polymerization”; the build-up of a dense macromolecular layer at the membrane surface precluding filtration. Two molecular weight cut-off (MWCO) membranes were used: 30K and 50K Dalton.

After completing the filtration through one membrane, the filtrate was reprocessed in the same membrane for two more times in order to obtain a cleaner fraction. Previous GPC investigations have in fact shown the usefulness of this procedure.

Figure 1 shows the molecular weight distribution, as obtained by GPC, of the starting polymer and of all the fractions gained from it.

Figure 1. Molecular weight distribution of the polymer fractions from GPC analyses

Figure 2. Superimposition of GPC analyses from <30K Dalton, 30-50K Dalton and > 50K Dalton fractions of the GPC analyses.

Table 2 shows some data regarding the initial polymer and its fractions. The percentage of the initial polymer represented by each fraction was determined as the ratio between the dry matter of the two. Besides the other data (\overline{M}_w , polydispersion, retention time), Table 2 reports the molar ratio between carboxylate groups and ether chains in the polymer molecule of each fraction as determined through TCAV (Total Carboxylic Acid Value) analysis, with respect to that of the whole polymer.

Table 2. Polymer fractions features

	Whole polymer	<30K Dalton	30-50K Dalton	>50K Dalton
% in the unfractionated polymer	100	18	28	54
WAMw as determined by GPC analyses	22 900	5 400	11 400	31 100
r.t. (mins)	17.7	20.2	18.8	17.1
Polydispersion (D)	3.37	2.11	1.65	1.8
Molar Ratio variations (from TCAV determinations)		no variation	no variation	no variation

2.3 Rheological evaluations on cement pastes - minislump tests

The rheology of cement pastes treated with the different fractions of superplasticizer or with the whole polymer at the dosage of 0.25% dry material by weight of cement (bwc), was investigated by means of the minislump test: the cement/water paste was poured, after mixing, into a metallic truncated cone mould standing on a flat Plexiglas surface; the cone was then lifted and the diameter of the collapsed paste measured. Both cements A and B were employed for these tests. Results are reported in Figures 3 and 4.

2.4 Rheological evaluations on mortars

Mortars were prepared according to the norm EN 196/1 with normalized sand and the two cements. The unfractionated CE polymer and all the fractions obtained from it were used as admixtures. The flow was evaluated for each mortar according to the norm EN 413-2.

The dosage of admixtures was 0.20% active by weight of cement (act. bwc.) in the case of cement A (type II A/L 42,5) and 0.28% act. bwc. for cement B (type I 52,5). These dosage rates have been chosen in order to represent the two situations found in the Italian ready-mix concrete and precast concrete industries.

Since ultrafiltration was carried out on a laboratory scale, the amounts of each fraction obtained were insufficient to test them directly in concrete. In order to better simulate concrete practice, where the performances of a superplasticizer are expressed in terms of slump according to EN 12350-2, one more parameter was considered and evaluated in the mortar tests, which will be referred to as “static” flow: it is the flow measured on the drop table after lifting the truncated cone (EN 413-2). The flow measured according to the Norm EN 413-2 after the 15 drops will be called “dynamic” flow in order to distinguish it from the previous one.

Two series of mortar tests were carried out with cement A, the first keeping constant the W/C ratio and the other at constant initial flow. Specimens for compressive strength evaluation were also prepared (EN 196/1); results are reported in Tables 3a and 3b. In this case each fraction was formulated with a little antifoam agent, in order to bring the air entrained to what is considered an upper limit for a superplasticizer (about 5% in mortar).

Two series of mortars, both at the same initial flow, were made with cement B: in the first the samples were previously formulated with antifoam while in the second they were used as obtained, in order to evaluate their natural air entrainment; furthermore the “static” flow was measured over time in order to predict the flowability maintenance of concrete. All the results regarding mortar tests on cement B are reported in Tables 4a, 4b.1 and 4b.2.

2.5 Adsorption analyses

T.O.C. (Total Organic Carbon) analyses were carried out with a Shimadzu 5000A T.O.C. analyser in order to evaluate the adsorption of the different polymer fractions by cement/water pastes.

Both Cement A and B were used, and the superplasticizer fractions were dosed at 0.25% dry content bwc. The water/cement ratio was kept constantly at 0.50.

The samples were prepared according to the following procedure: cement and water, the latter containing the superplasticizer, were stirred for the defined time and then filtered in a büchner with a vacuum pump. The amount of polymer adsorbed was determined by difference between the organic carbon originally contained in the polymer solution and the amount left in the solution filtered from the paste. The results are expressed as percentage of polymer adsorbed (Tables 5, 6 and Figures 8 and 9).

3. RESULTS

3.1 Polymer fractionation

As Figures 1 and 2 show, dialysis and ultrafiltration were quite effective in fractionating the polymer. Figure 2 is a superimposition of the main fractions obtained from ultrafiltration, namely <30K, 30-50K and >50K Dalton. It can be observed from Table 2 that the >50K fraction represents more than 50% by weight of the total polymer, while the lowest molecular weight, <30K, represents only 18%. The fraction taken out by dialysis is therefore less than 18%, but a more precise determination was not possible.

Figure 1 shows the differences between the two fractions with \overline{M}_w lower than 30K Dalton, in the dialysed and the non-dialysed sample. Basically, the effect of dialysis consists of removing monomers and residues from the polymerization process. The dialysed sample is therefore “cleaner”, in terms of polymer, than the non dialysed one.

3.2 Minislump rheological tests

As shown in Figures 3 and 4, the minislump diameter and therefore the flowability of cement pastes after 1 minute mixing increases with increasing polymer molecular weight.

Figure 3. Minislump results – cem. A (II A/L 42.5)

Figure 4. Minislump results – cem. B (I 52.5)

The fraction <30K does not perform well in both cases; with cement B (type I 52.5) the paste was so stiff that it was not even possible to lift the cone. With both cements, the >50K Dalton fraction has a much greater flow than the >30K.

Considering the minislump values obtained after 5 minutes (abbreviated) mixing, it may be noted that:

- in the case of cement A, there are no significant difference between 1' and 5' mixing; there is a good workability retention;
- in the case of cement B, there are greater differences between 1' and 5' mixing; the flowability is higher at 5' for each fraction, >30K and 30-50K fractions being those with the highest increment: >30K, at 5' becomes even more flowable than >50K.

It is possible to conclude from the minislump evaluations that the higher \overline{M}_w fractions perform better; at 1' >50K gives the greatest diameter, but >30K seems better at 5', at least with cement B.

3.3 Mortar tests

Table 3a. Mortar tests with cement A (II A/L 42.5) – W/C ratio constant – admixture dosage: 0.20% active by weight of cement.

Sample	W/C	Initial “static flow” (%)	Flow (%)				Compressive Strength 20°C (MPa)		
			0'	15'	30'	60'	24h	7 days	28 days
Unfractionated Polymer	0.49	28	121	109	95	88	17.7	40.4	46.4
Fraction <30K	0.49	12	89	85	82	76	17.8	41.6	49.2
30-50K	0.49	46	118*	115	110	99	15.5	42.6	50.3
> 30K	0.49	75	146*	134	132	130	17.7 ⁺⁺	38.0 ⁺⁺	41.9 ⁺⁺
> 50K	0.49	47	126*	124	124	110	13.9 ⁺⁺	32.6 ⁺⁺	35.6 ⁺⁺

*= bleeding

++= values not reliable because of bleeding

Figure 5a. Mortar tests – cement A – W/C constant (0.49)

Figure 5b. Mortar tests – cement A – comparison between “static” and “dynamic” flow

Considering cement A first, the following observations can be made:

- in the mortars at the same W/C ratio (Table 3a, Figures 5a and 5b), the fractions giving the highest initial flow are >30K and >50K Dalton; the first works better than the second.
- The <30K fraction gives very low fluidifying effect.
- The 30-50K fraction gives intermediate performance, only slightly better than the unfractionated polymer.
- Concerning the flow retention over the time, as shown by the slope of curves in Figure 5a, the fractions 30-50K and >50K perform better than the unfractionated polymer and the >30K Dalton fraction;
- The initial “static” flow values confirm that >30K has the best performance.
- There is a good correspondence between “static” and “dynamic” flow for the three heaviest fractions, while their differences with respect to the unfractionated polymer and the <30K fraction are more accentuated in the “static” flow than the “dynamic” one. We can therefore expect that the differences in performances among the fractions will eventually be more evident in concrete than they appear in the mortar.
- The compressive strength values from the mortar tests of the first series are not so reliable because of bleeding.

Table 3b. Mortar tests - cement A (II A/L 42.5) – different W/C ratio
admixture dosage: 0.20% active by weight of cement.

Sample	W/C	Initial “static” flow (%)	Flow (%)				Compressive Strength (MPa) 20°C		
			0'	15'	30'	60'	24 h	7 days	28 days
Unfractioned polymer	0.49	20	108	90	76	-	16.5	30.0	44.6
> 50K	0.44	25	118	110	104	96	17.3	36.3	43.2
30-50K	0.48	30	104	94	83	-	17.8	33.4	46.6
>30K	0.42	46	122	90	80	-	21.2	44.2	46.2

Figure 6a. Mortar tests – cement A – “dynamic” flow

Figure 6b. Mortar tests – cement A comparison between “static” and “dynamic” flow

- Mortars, at the same initial flow: >30K reduces the water demand, with respect to the unfractionated polymer, by a 14%, and >50K fraction by a 10%. The medium fraction, 30-50K Dalton, does not give any improvement (Table 3b and Figures 6a and 6b).
- Again the >50K fraction offers a better flow retention than >30K.
- The “static” flow values are more differentiated than the “dynamic” flow values. The greatest difference is shown by the >30K fraction, which has a static flow much higher than all the others, even at the lowest W/C ratio.
- Looking at compressive strengths values, >30K fraction seems to give the highest early strengths, but the results are similar at 28 days.

Considering cement B, the following results are found (see Tabs. 4a, 4b.1 and 4b.2):

Table 4a. Mortar tests - cement B (I 52.5) – different W/C ratio
Admixture dosage: 0.28% active by weight of cement.

Sample	W/C	Initial “static” flow (%)	Air entrainment (%)*	Compressive strength (MPa) 20°C				
				0'	15'	24h	7days	28days
Unfractionated Polymer	0.43	39	5.4%	122	70	40.9	74.5	88.2
Fraction >50K	0.41	32	5.4%	117	75	42.5	78.2	94.8
30-50K	0.44	15	5.2%	104	75	36.1	68.5	84.8
<30K	0.46	-	4.8%	63	-	34.3	60.8	74.8
>30K	0.41	25	5.2%	114	65	40.4	74.8	87.7

Table 4b.1. Mortar tests - cement B (I 52.5) – different W/C ratio – “dynamic flow”

Sample	Dosage	W/C	Air entrainment (%)		Flow (%)			
			0'	30'	0'	15'	30'	60'
Unfractionated Polymer	0.28% act.	0.42	23%	22%	120	110	110	-
Fraction >50K	0.28% act.	0.41	20%	20%	127	115	113	110
30-50K	0.28% act.	0.44	19%	21%	119	101	101	97
<30K	0.28% act.	0.47	13%		96	85	-	-
<50K	0.28% act.	0.47	18%	17%	121	108	105	101

Table 4b.2. Mortar test – cement B (I 52.5) – different W/C ratio – “static” flow

Sample	Dosage	W/C	Static Flow (%)			
			0'	15'	30'	60'
Unfractionated polymer	0.28% act.	0.42	62	55	55	-
>50K	0.28% act.	0.41	85	75	65	60
30-50K	0.28% act.	0.44	62	45	45	42
<30K	0.28% act.	0.47	10	-	-	-
<50K	0.28% act.	0.47	60	33	30	30

- the >50K and >30K fractions are the best performing. They both bring about a reduction of 5% in the water/cement ratio.
- The >50K fraction, gives better flow retention;
- the <30K fraction requires more water than the unfractionated polymer (ca 7%.);
- both early and long term strengths are much higher for the >50K fraction compared to others.
- As regards the air-entrainment, there are no substantial differences among the samples: the <30K Dalton fraction entrains a smaller amount of air both with and without antifoam (Tables 4 and 4b.1), and the >50K one entrains a little bit less than the unfractionated polymer (20% versus 23%) in the absence of antifoam.
- Comparing the values of “static” and “dynamic” flow for cement B, (Figs. 7a and 7b) it is confirmed that the “static” exalts the differences among the fractions.

Figure 7a. Mortar tests – cement B – “dynamic” flow

Figure 7b. Mortar tests – cement B – “static” flow

3.4 Adsorption analyses

As shown in Table 5 and Figure 8, in the case of cement A (type II A/L 42,5) the percentage of polymer adsorbed by cement pastes varies from 40 to 63%. The highest molecular weight fraction, >50K Dalton, is adsorbed in higher amount, in the range 55,4-63% within 30 minutes. The fraction lower than 30K Dalton is far less adsorbed (40-42% within the 30 minutes). The adsorption of the unfractionated polymer is exactly in the middle between those of the high and low molecular weight fractions.

For cement B (type I 52,5), adsorption values of the polymer are generally much lower than the previous ones, about half the amount. The lowest molecular weight fractions, which is <30K dialysed and not dialysed, in particular, are only 15% adsorbed, reaching 20% within 30 minutes.

Table 5. Adsorption tests - cement A

Time (mins.)	<i>Polymer adsorpted (%)</i>				
	all polymer	>30K	>50K	<30K	<50K
1	52.4	54	55.4	39.7	44.1
5	52.9	54.3	57.6	41.2	46.8
10	54.6	57.3	60.8	43.2	46.6
30	56.2	60	63	42.3	47.3

Figure 8. Adsorption values of the different polymer fractions onto cement A (type II A/L 42.5)

Table 6. Adsorption tests - cement B

Time (min.)	<i>Polymer adsorpted (%)</i>				
	all polymer	<30K n.d.	<30K D.	30-50K	>50K
1	26.7	15.3	14.7	19.6	28.2
5	29.2	19.4	19	26.1	30.9
10	33	19.3	17	27.8	34
30	34.7	19.5	18.9	29.4	41.5

Figure 9. Adsorption values of the different polymer fractions onto cement B (type I 52.5)

In the case of cement B, the differences among the fractions are bigger than for cement A: both initial and final adsorption of the highest fraction are double the amount of the lowest molecular weight fraction. There seems to be a good correspondence, in the sense that the fractions that are adsorbed more, also perform better.

The reason for the much higher adsorption of polymer shown by cement A is not associated with higher surface area: as Table 1 shows, the Blaine value is higher for cement B. The explanation presumably lies in the nature of limestone present in the type II A/L 42,5 cement. Previous studies, performed by our research group (9), revealed how some kinds of limestone, because of their porosity, can bring about a high adsorption of admixture, which is entrapped inside these pores and in this way subtracted from the clinker phases.

4. CONCLUDING REMARKS

The data obtained can be used for an optimisation of polycarboxylate ether admixtures. A displacement towards higher molecular weights and a reduction of low-molecular weight material could, for instance, improve the performances of investigated admixtures. Also elimination of the residue of the polymerization process and of the monomers seems to have a positive effect.

The “static flow” measurement can presumably be applied while conducting mortar tests, to predict admixture behaviour in concrete.

EFFECT OF ALKALINE SULPHATES ON THE PERFORMANCE OF SUPERPLASTICIZERS

R. Magarotto, I. Torresan and N. Zeminian

MAC s.p.a. - Degussa, Treviso; E-mail: mactv@mac-mbt.com

ABSTRACT

Polycarboxylate-based superplasticizers (CE) are acquiring increasing importance in the production of concrete since they allow the production of high workability concrete with lower water/cement and reduced slump loss as compared to the old generation superplasticizers like β -naphthalene sulphonate formaldehyde condensate (NS) and melamine formaldehyde condensate. Extensive study is therefore necessary to better understand the mechanism of action of these new types of admixtures and how the composition of cement affects their performance.

In the present study, the effect of alkali sulphates on the interaction between cement and superplasticizer is investigated by means of minislump tests, mortars and adsorption tests, with special reference to an admixture of this new generation.

The data collected reveal that the CE superplasticizer performs in any case better than NS. An increased amount of sodium sulphate leads altogether to a lower adsorption of the CE superplasticizer, together with a reduced performance in terms of water reduction. When it is employed in the presence of added sodium sulphate, the performances of a CE superplasticizer become closer to those of NS.

No effect is observed on the maintenance of workability.

The performance of an NS type admixture is almost independent from the alkali sulphate addition, at least up to 1% sodium sulphate.

Keywords: superplasticizer, high performance concrete, alkali sulphates, mortar, adsorption

1. INTRODUCTION

The performance of superplasticizers depends to a great extent on the cement they act on. It is important to identify which variables in a cement composition affect more the interaction with the admixture (1). Previous investigations pointed to the C_3A content, calcium sulphate amount and its nature (anhydrite, emihydrate, bihydrate). Each of these factors contributes presumably to the performance of the superplasticizer. Among the others, soluble sulphates, i.e. alkaline sulphates contained in cement have been found to be very important and will be investigated in this paper.

Alkali sulphates, which form during Portland cement production in the clinkerization phase, are the most soluble of the sulphates contained in cement; together with calcium sulphate, added as a set regulator, they provide the sulphate ions necessary for the reaction with C_3A in the early stages of cement hydration.

The standard specification for cement EN 197/1, states that total sulphates, expressed as SO_3 , must not exceed 3,5% for a type II A/L cement and 4.0% for a type I; however, no explicit mention is made of the acceptable amount of soluble alkali.

ASTM C 150-94, on the other hand, suggests, among additional requirements for cement, an equivalent alkali content not exceeding 0.6% but such indication has no mandatory value.

Analyses undertaken in the present study show that a wide range of variability exists among different cements regarding the content of sodium and potassium sulphates.

The nature and concentration of soluble species in cement, which dissolve soon after coming into contact with water containing the superplasticizer, is particularly important because they determine the environment in which the first stages of cement hydration occur (3a, 3b). They influence the rate of reaction and the morphology of the products formed and thus the properties of concrete.

Soluble sulphates can react with C_3A to form different products. According to Aïtcin (2), it is not the total amount of SO_3 in cement that is important, but rather the availability, or the rate of dissolution of SO_4^{2-} ions.

Some previous studies have focused on the effect of alkali sulphates on the interaction between cement and an NS admixture. Nawa (4) states that the viscosity reduction performed by the NS superplasticizer is due to its adsorption on C_2S and C_3S phases, although it tends to be easily adsorbed on C_3A and C_4AF . An increase in alkali sulphates reduces viscosity of cement pastes because they reduce the adsorption on C_3A and C_4AF and increase the one on C_2S and C_3S phases. A too high increase in soluble sulphates produces a negative result, since it brings about a compression in the electrical double layer, increasing viscosity. There is, therefore, an optimum amount of such compounds in cement.

Jiang (5), while investigating incompatibility between sodium β -naphthalene sulfonate polymers and cement, states that the ideal amount of soluble alkali is 0,4-0,5% (expressed as equivalent sodium), both for initial flowability and for slump retention.

The effect of alkali sulphates is presumably associated with polymer adsorption and desorption phenomena: an increase of alkali, simulated by means of KOH additions as in Diamond's work (6) produces as effect the partial desorption of NS polymer, associated with a total dissolution of anhydrite.

Most of the previous works have focused on β -naphthalene sulfonate based polymers. A work has recently been published (7), regarding the effect of sulphates on the fluidity of cement pastes added with polycarboxylic acid type superplasticizer: the authors have found that the viscosity of paste is increased and the amount of adsorbed admixture is decreased by addition of sodium sulphate.

In the present study, the effect produced by sodium sulphate additions on the rheological properties of mortars, in the presence of a superplasticizer, is investigated.

The aim of the work on the new superplasticizers, based on polycarboxylate polymers, is to undertake an investigation similar to that previously conducted on NS polymers, in order to clarify whether the alkali sulphate contents are responsible for the unexpected behaviour that is sometimes experienced with certain cement-plasticizer combinations, despite the fact that both components satisfy their respective acceptable requirements.

Two superplasticizers were examined: a traditional one, i.e. a β -naphthalene sulfonate formaldehyde condensed (NS) and a new generation one (CE), based on a polycarboxylate ether polymers.

2. EXPERIMENTAL

2.1 Materials employed

Nine different Italian commercial cements were investigated (A to I); five type II A/L 42.5 (A to E) and four type I 52.5 (F to I) cements (EN 197/1).

The cements were chemically analysed with respect to their total sulphate and total alkali content, by means of a flame photometer, according to EN 196/2. Soluble sulphates and soluble alkalis were also determined, by means of ionic chromatography.

The results are reported in Tables 1 and 2.

Four of the previous cements, the one with the highest and the one with the lowest alkali sulphate contents, both among the type I 52.5 and among the type II A/L 42.5 cements, have been intensively investigated. Their complete chemical analysis has been carried out according to the methods reported in EN 196/2 and is reported in Table 3.

Table 1. Alkali and sulphates (total and soluble) content of the cements employed

Cement H	0.20	0.73	0.05	0.59
Cement I	0.47	0.81	0.19	0.70

2.2 Test procedures

Mortars were prepared with all the nine cements studied, according to EN 196/1, in the presence either of NS or of CE superplasticizers. CE was dosed at 0.25% active bwc., NS 0.40% active bwc., which are the dosages usually applied in practice in concrete production.

These mortar tests were made in the attempt to see if a correlation exists between the alkali sulphate content of these cements and their interaction with the admixtures. Results are reported in Figs.1a, 1b for the CE admixture and Figures.2a and 2b for NS.

Four cements mentioned before, namely cement A, D, F and H, were selected for rheological evaluation in cement pastes. Samples A and F represent cements that are very rich in alkali sulphates, type II A/L 42.5 and I 52.5 respectively, while D and H have the lowest amount of such components.

The rheological evaluations of cement pastes were undertaken through the empirical minislump test: the paste was poured, after mixing, into a metallic truncated cone mould standing on a flat plexiglass surface. The cone was then lifted and the diameter of the collapsed paste measured.

Both with CE and with NS superplasticizer (0.25% and 0.40% active dosage bwc. respectively), the minislump tests were made first without addition and then adding sodium sulphate in amounts varying from 0.5 to 2.0% bwc.

Results of the minislump tests are reported in Figures 3a, 3b, 3c and 3d.

The four cements selected were later used for the preparation of mortars with NS and CE admixtures, in which a percentage of cement of 0.5 % was substituted with an equal amount of sodium sulphate of pure reagent degree. Flow values of such mortars, determined in accordance with UNI 7044/72, are reported in Figures 4a and 4b.

The degree of adsorption onto cement of the polycarbolylate-based (CE) admixture and of the β -naphthalensulphonate-based (NS) one was determined in cement pastes by T.O.C. analyses performed with a Shimadzu 5000-A. Both the superplasticizers were dosed at 0.25% dry content by cement weight. The water/cement ratio was kept constant at 0.50.

The samples were prepared according to the following procedure: the cement and the water containing the superplasticizer were stirred for the defined time and then filtered in a büchner with a vacuum pump. The amount of polymer adsorbed was determined by the difference between the organic carbon originally contained in the polymer solution and the amount left in the solution filtered from the paste.

Such evaluations were undertaken on cement pastes with and without the addition of sodium sulphate (0,5% bwc.). Cements A, D, F and H were employed also for T.O.C. analyses.

The results of such evaluations, expressed as percentage of polymer adsorbed, are reported in Tables 4a and 4b.

Table 3. Chemical analysis of cements

	Cement A	Cement D	Cement F	Cement H

K₂O	1.0	0.46	1.1	0.73

3. RESULTS

3.1 Analysis

The values reported in Tables 1 and 2 show that the nine cements examined, contain different amounts of soluble alkali sulphates. Actually, all the cements exceed the 0.6% content of alkali suggested by ASTM C 150-94. Among the type II A/L 42.5 cements (A to E), cement D contains the lowest percentage and A and E the highest amount of alkali sulphates; a comparison between the last two deserves a note: E contains more total sulphates, but A has more soluble sulphates, i.e. alkali sulphates.

Among type I 52.5 cements, the differences between the four samples considered are even higher: cement H has very low alkali sulphates content and cement F a very high content.

3.2 Mortar tests of all the nine cements

Figures 1a and 1b show the flow values of mortars made with 9 cements and CE superplasticizers at 30-minutes intervals. Comparison of data reported in Tables 1a, 1b, 2a and 2b suggests that a kind of correlation exists between the rheological behaviour and the alkali sulphate contents. The initial flow seems lower in cements with higher alkali sulphate (i.e. soluble sulphates and soluble alkali). This trend is shown both by the type II A/L 42.5 cements (Figure 1a) and by the I 52.5 cements (Figure 1b).

Variations in alkali sulphates, which are more soluble, are presumably more important than total sulphates in determining the flowability. This is suggested by the better performance of cement E with respect to cement A.

The results reported in Figures 2a and 2b with NS superplasticizer don't show any correspondence between alkali sulphate contents and flowability.

In order to confirm that a reduction of the performance of a CE admixture can be brought about by an excess of alkali sulphates, further investigations were performed on the cements A, D, F and H, both in cement pastes (minislump tests) and in mortar.

Figure 1a. Mortar flow results- cements type II A/L 42.5 – CE admixture (W/C=0.43)

Figure 1b. Mortar flow results – cements type I 52.5 – CE admixture (W/C=0.40)

Figure 2a. Mortar flow results – cements type II A/L 42.5 – NS admixture (W/C=0.47)

Figure 2b. Mortar flow results – type I 52.5 cements – NS admixture (W/C=0.47)

3.3 Minislump tests

Figures. 3a, 3b, 3c and 3d show the results of the minislump tests carried out on cements A, D, F, and H. Cement A, which is very rich in soluble sulphates shows a considerable reduction of the minislump with CE superplasticizers as a consequence of addition of sodium sulphate, 14% reduction by 0.5% addition and 33% reduction by 2% Na_2SO_4 addition. When NS is employed, no variation of minislump diameter is detected up to 1% addition, and 14% reduction is observed with a 2% addition. Since the W/C ratio was a little different with the two admixtures, a trial was made for cement A and F to change the dosage of NS or CE in order to get the same W/C ratio for the two. No change was detected in the result.

3.4 Mortar tests on cements A, D, F and H with sodium sulphate addition

Mortar tests give a lot of information on the rheological effect of alkali sulphates, and the situation they depict is practically closer to the real one in concrete with a plasticizer.

Figures 4a and 4b confirm that a reduction of the performance of a CE admixture can be brought about by an excess of alkali sulphates. The addition of sodium sulphates in percentage of 0.5 % causes little or no variation in the initial flow when a NS admixture is used while in the case of a CE admixture the negative effect is particularly high.

It's worth noting that the addition of 0.5% sodium sulphate corresponds to a variation of alkali sulphates in the cement of 0.21%, if expressed as sodium equivalent content (Table 1), which is well the difference between some of the cements, for example G and I.

The negative influence of an increase in soluble alkali sulphates is not observed in the workability retention: the loss of workability is basically the same in all the tests undertaken.

*= presence of some bleeding

Figure 4b. Mortar flow results (%) – NS admixture

3.5 Adsorption measures

Adsorption tests (Figure 3) illustrate how the addition of sodium sulphate brings about a reduction in the sorption capability of cement towards CE admixture. The lower adsorption of plasticizer evidently reflects a reduced interaction between the cement particles and the admixture, and, therefore, a diminished plasticizing effectiveness.

It may be concluded that sodium and potassium sulphate contents can have a strong negative effect on the performance of a superplasticizer, specially a CE type, with reference to water reduction.

Such values should therefore be checked, whenever incompatibility phenomena between cement and the plasticizer occur.

4. CONCLUDING REMARKS

From the above experimental results, the following conclusions can be drawn:

1. Commercial cements available on the Italian market, both for type I and for Type II A/L cements, show a wide range of variability in the amount of alkali sulphates.
2. A traditional β -naphtalene sulfonate admixture does not seem to be significantly influenced by an increase in the alkali sulphate content up to a 1.0% addition. A CE admixture is strongly affected by the increase of alkali sulphates dissolved. Reduced performances in terms of water demand are shown both in cement pastes and in mortars.
3. No effect of the sodium sulphate amount on workability retention is observed with NS or with CE admixture.
4. There seems to be an ideal alkali sulphate content of cements for their interaction with this new, high performance, generation of superplasticizers.
5. In the case of cements rich in alkali sulphates, the early stages of hydration occur in a solution that is, presumably, not balanced for what concerns dissolved sulphates when a CE superplasticizer is used. The amount of alkali sulphates in a cement seems to be a potential source of incompatibility between cement and polycarboxylate-based superplasticizers.

1. INTRODUCTION

In this study five different types of Pulverized Fuel Ash (PFA) from the same source were assessed and their influence on concrete properties investigated. The properties of the PFA-types were first determined to quantify their differences. Thereafter they were incorporated into concrete mixtures and their effects tested in terms of workability and compressive strength. To study the effect of PFA-type on mortar properties, tests were also conducted on pastes containing only PFA and cement. The effect of the PFA was enhanced by replacing up to 67% of the cement with PFA.

2. BACKGROUND

PFA is a byproduct of coal combustion and has been used as a cement-replacement material for a number of years. Partial replacement of cement in concrete by PFA is believed to influence the properties of the wet slurry as well as the hardened concrete mortar. Researchers have shown that the workability as well as later strength and durability of concrete can be improved by this partial replacement [1].

Figure 1 shows a schematic diagram of five different fractions of PFA marketed by Ash Resources and produced at the Lethabo power station, which is situated near Sasolburg, South Africa and produces around 5.3 million tons of PFA annually [2]. For the purpose of this paper, the different PFA-types are numbered A to E as indicated in Figure 1.

Figure 1. Five different types of PFA from Lethabo power station.

3. MATERIAL PROPERTIES

The PFA fractions were obtained from the Lethabo power station and were collected from different stages in the classification process. Particle size distribution curves are shown in Figure 2 as determined using a Malvern apparatus. Chemical analyses were performed by means of X-ray fluorescence. Results are shown in table 1 and indicate no major differences in chemical composition between PFA-types. The effect of variation in chemical composition was thus minimized in this investigation.

Figure 2. Particle size distribution curves of cement and PFA.

Table 1. Chemical analyses of cement and PFA samples.

%	CEM I 42.5R	PFA-A	PFA-B	PFA-C	PFA-D	PFA-E

TOTAL	98.1	98.8	98.1	98.5	98.4	99.0

Relative densities of the PFA-types were determined [3] and it was found that values differed significantly and that these differences may be related to particle size as shown in Figure 3.

Figure 3. Density as a function of mean particle diameter for the different PFA-types.

In this investigation the PFA was blended with a CEM I 42.5R with a particle size distribution and chemical composition as indicated in Figure 2 and table 1 respectively. Oven dried crushed dolomite was used as aggregate in concrete tests.

4. CONCRETE TESTS

Three sets of mixtures with compositions as indicated in table 2 were cast. The first mixture was a standard containing cement, sand, stone and water. In the second mixture 30% cement was replaced with PFA and in the third 15% of cement was replaced and the cementitious content was further extended by 15%. By replacing and extending it was assumed that 50% of the PFA would act as binder and the other 50% as inert filler. The water content was kept constant for all mixtures. The mixtures containing PFA were cast using each of the five different types of PFA (A to E).

Table 2. Mix proportions (kg/m³).

Mix no.	Cement (kg)	Pfa (kg)	Sand (kg)	Stone (kg)	Water (L)	Water/binder ratio	Water/cement ratio
1	300	0	1080	790	225	0.75	0.75
2	210	90	1047	790	225	0.75	1.07
3	256	90	1033	790	225	0.75	0.88

Workability was measured by means of the slump test [4]. Compressive strength measurements [5] were performed on sets of three 150mm cubes at 28 days after curing samples in water at 25°C. The test results obtained from these mixtures can be seen in Figure 4.

Figure 4. Test results for concrete mixtures.

Although the water content of all mixtures was kept constant the workability of the mixtures (as measured by slump) varied from 125mm for the reference mixture containing no PFA to 180mm for mixture 3 with type A-PFA (replacement and extending). It can thus be concluded that the PFA has a significant influence on workability.

As expected, mixtures containing no PFA had the highest 28-day strength. At later ages the strength difference should reduce or even disappear. It is a well-documented fact that high PFA contents reduce early age strengths, for up to 3 months [1]. Mixtures where 30% of cement was replaced showed slightly lower strengths than mixtures where 15% was replaced. The type of PFA used did not significantly influence the compressive strength of the concrete. It can thus be concluded that the type of PFA used does not affect the strength of the concrete significantly. The strength of the concrete will however be affected if constant workability is required.

5. PASTE TESTS

To establish why the workability of the concrete is affected by the type of PFA used it was decided to concentrate on the properties of the paste used in the concrete. For the rest of the project slurries containing only cement and PFA were compared. To emphasize the effect of the PFA up to 67% of cement was replaced.

Slurries were made containing cement and PFA on their own as well and in blends of 33% cement and 67% PFA. This time the water content was varied for each mix to obtain constant workability. Various researchers have concluded that one-point tests like the slump test are not suitable for measuring workability of mixtures with high PFA contents [6; 7]. Two-point workability tests considered include shear mixers [6], modified slump tests [7] and j-tube tests [8]. The workability test used was the j-tube test, which is used in Japan as a standard test for prestressed concrete grouts [9].

When gravity forces concrete to flow in a vertical tube, the velocity of the concrete in the center of the tube is higher than that for the concrete on the sides. The concrete can be seen as cylinders sliding over one another with radii ranging from $r=0$ at the center to $r=R_{\text{tube}}$ at the inside surface of the tube. The velocity of these cylinders increases quadratically from zero at the sides of the tube to maximum in the center, thus creating intra laminar shear stress between these cylinders. The magnitude of the difference in velocity between the center and the sides of the tube will thus be governed by the intra laminar shear resistance of these cylinders, and this relates back to the viscosity of the concrete.

The test set-up is shown in Figure 5. A tube was mounted onto a load cell connected to a signal amplifier and computer. By using software, it was possible to log the mass loss of the slurry-filled j-tube at time-intervals of 0.1 seconds as the flow proceeded. A shallow bin was put under the lower mouth of the tube to catch the out-flowing slurry. The mouth of the j-tube was cut at an angle of 30° to prevent accumulation of slurry (drag-before-drip effect) before it falls over into the bin as this would result in a step-like flow curve.

Figure 5. The j-tube apparatus set-up.

A typical flow curve is shown in Figure 6. The results in this graph are for mixtures that differed only in water/binder ratio. As the water/binder ratio of the mixtures is increased, their flow rate also increases resulting in a steeper slope for the mass/time-graph. This relates to a decrease in viscosity. The end height of the slurry in the tube when flow ceases relates to the yield stress of the slurry. The higher the end height the higher the yield stress.

Figure 6. Typical flow curves for the j-tube test.

Shear stress and shear rate values for each time interval were calculated as for capillary viscometers [8; 10]. The average fluid velocity (V) was calculated using the following equation:

$$V = \frac{4Q}{\pi D^2} \quad (1)$$

Where: V = Average fluid velocity (cm/s)
 Q = Volumetric flow rate (cm³/s)
 D = Inside diameter of tube (cm)

The shear stress at the tube wall was calculated using the following equation:

$$\tau_w = \frac{D\Delta P}{4L} \quad (2)$$

Where: τ_w = Shear stress (g/cm.s²)

L = Effective length of tube (cm)

ΔP = Pressure drop due to elevation (g/cm.s²)

The rate of shear at the tube wall was calculated from the following equations:

$$S = \frac{1+3n}{4n} \times \frac{8V}{D} \quad (3)$$

Where S = Rate of shear (1/s) and;

$$n = \frac{\partial \ln \frac{D\Delta P}{4L}}{\partial \ln \frac{8V}{D}} \quad (4)$$

Concrete is believed to be a Bingham fluid, thus the τ_w versus S plot should be linear with the τ_w -axes intercept value being the yield stress and the slope of the plot the viscosity. Shear stress and shear rate values were calculated and plotted. Figure 7 shows the shear stress versus shear rate plot for the same mixtures shown in Figure 6.

Figure 7. Shear stress versus rate of shear graph.

The workability range for which the test can be used is relatively small. The lower range limit is set by initiation of flow and the upper by maximum shear velocity for transition from laminar to turbulent flow, as the test is only valid for laminar shear flow. The water demand required for each PFA-blend to fall within this workability range differed, thus different water contents were used. For comparative purposes, flow table tests were also performed. Workability results and 28-day compressive strength values are shown in table 3.

Table 3. Results of binder tests.

* The viscosity of this slurry was too high to determine

In Figure 8 compressive strength results for all mixtures are plotted as a function of water/binder ratio. These results confirm our earlier finding that the strength of mixtures containing high volumes of PFA is influenced by the water/binder ratio and not by the PFA type. If the workability of the mortar is kept constant the water/binder ratio and thus the strength will be influenced.

Figure 8. Compressive strength values of cement/pfa mortars.

The effect of water/binder ratio on the flow (as tested by the flow table test) of different types of PFA can be seen in Figure 9. The measured flow radius values for all the mortars varied between 88mm and 110mm. From this graph it can be seen that the water/binder ratio to produce a flow radius of between 100 and 110mm can vary from 0.28 to 0.38 depending on the type of PFA used. The flow characteristics for PFA-types A, C and E are similar, while B has a higher water demand and PFA-D has the highest water demand for a given flow.

Figure 9. Flow table test results.

The effect of water/binder ratio on viscosity and yield stress of cement/PFA-blend slurries can be seen in Figure 10.

Figure 10. Viscosity and yield stress values for cement/PFA slurries

Figure 10 indicates that the viscosity and yield stress is not only a function of the water/binder ratio but also of the PFA-type used. For a given water/binder ratio the viscosities of PFA-A and E are similar as are the viscosities of PFA-B and C at a higher water/binder ratio. PFA-D requires significantly more water than any of the other PFA-types to produce the same viscosity and yield stress. As there are no significant differences in chemical composition of the five PFA samples the workability must be affected by physical differences.

To establish the effect of particle size on workability, the water/binder ratio needed to produce a viscosity of approximately 50cp was calculated for each of the PFA-types. The effect of PFA-particle size on this calculated water/binder ratio can be seen in Figure 11. The particle size distribution of the PFA-types as shown in Figure 2 was used to determine D50 and D90 values. These values are the particle sizes where 50% and 90% respectively of the particles (per mass) are smaller than the given value.

Figure 11. Effect of D50 and D90 on water demand

From Figure 11 it can be seen that there is an optimum water/binder ratio for a D90 value in the region of 150 μ m. For this cement-type and PFA replacement level the highest compressive strength (for constant workability) will be obtained for PFA where 90% of the particles are smaller than 150 μ m. These results indicate that for a specific mixture an optimal PFA particle size exists.

6. CONCLUSIONS

The properties of five different PFA-types from the same source were found to differ significantly in terms of particle size and distribution. It was found that their relative densities varied with average particle size from 1.94 for the coarsest fraction to 2.33 for the finest.

Concrete mixtures were made at constant water content. It was found that concrete strength did not differ significantly for PFA-types with only expected variations due to cement replacement and extension. However, a significant variation in workability for different PFA-types was observed.

Further tests on slurries containing high volumes of PFA were also performed. The j-tube test proved to be rather sensitive and differences in workability at very small water/binder ratio increments could be observed. Different water contents had to be used for different PFA-types to fit into the workability range of the test method. It was again found that water/binder ratio was the main contributing parameter to compressive strength.

The physical properties of PFA have an influence on concrete workability. This influence will also reflect on strength when constant workability is desired due to water demand. For a given cement and PFA-replacement an optimal particle size distribution could exist, which would result in maximum workability and therefore minimum water/binder ratio and optimum strength. For each type of cement and PFA an optimum percentage cement replacement should exist which should result in an optimum combined particle size distribution and thus optimum workability and strength.

Currently tests are under way on all physical aspects of the different PFA-types including effects on particle packing. Attempts are made to quantify particle size distribution parameters. Success will hopefully explain the influence of PFA on concrete workability conclusively.

ABSTRACT

In this paper the production and use – as a cement and concrete constituent - of metakaolin, originated from poor Greek kaolins, is investigated. The kaolin was thermally treated at optimized conditions and the produced metakaolin was ground superfine. In addition, a commercial metakaolin of high purity was used. Four mixture proportions were used to produce blended cements and high performance concrete. The mechanical and physical properties of the blended cements were measured. Furthermore, the properties of the fresh concrete, the strength development and some properties concerning the concrete durability - chloride permeability, air permeability, sorptivity and porosity – were studied. It is concluded that kaolinite is completely converted to metakaolinite after 3 hours at 650°C and at these conditions the metakaolin exhibits higher pozzolanic reactivity. The produced metakaolin as well as the commercial one indicate a similar behavior concerning cement strength development and concrete strength development and durability and lead to the production of cement and concrete with an excellent performance. Metakaolin has a very positive effect on concrete strength after 2 days and particularly at 28 days and 90 days. Metakaolin concrete exhibits significantly lower chloride permeability, gas permeability, sorptivity and pore size compared with OPC concrete. Metakaolin, originated from poor Greek kaolins, can be efficiently used as a cement and concrete constituent.

1. INTRODUCTION

The most common cementitious materials that are used as concrete constituents are fly ash, ggbs and silica fume. They save energy, conserve resources and have many technical benefits [1]. Metakaolin, produced by controlled thermal treatment of kaolin, can also be used as a concrete constituent, since it has pozzolanic properties [2-3].

According to the literature, the research work on metakaolin is focused on two main areas. The first one is the effect of the kaolin structure on the kaolinite to metakaolinite conversion and the use of thermoanalytical methods for the investigation of kaolin thermal treatment [4-12], while the second one concerns the pozzolanic behaviour of metakaolin and its effect on concrete properties [2-3, 13-26]. Although there is a disagreement on specific issues, the knowledge level is satisfactory and continuously extended.

Concrete performance depends mainly on the environmental conditions, the microstructure and the chemistry of the concrete. The two latter factors are strongly affected by the concrete components. It is obvious that the metakaolin addition affects the concrete performance. The present work deals with the study of the kaolin to metakaolin conversion as well as the investigation on the effect of metakaolin on cement and concrete properties and behaviour. This work belongs to a research project aimed at the exploitation of Greek kaolins in concrete technology.

2. EXPERIMENTAL

2.1 Materials

A poor Greek kaolin (K), originated from Milos Island, was used. In addition, a commercial metakaolin (MKC) of high purity was also used as a reference material. The chemical analysis of the materials is given in Table 1 and their mineralogical analysis in Table 2. Concerning the commercial metakaolin, for comparison reasons, the characteristics of the commercial kaolin (KC), instead of MKC, are given.

Table 1. Chemical analysis of kaolins (%)

	SiO ₂	Al ₂ O ₃	CaO	MgO	Fe ₂ O ₃	L.O.I.	SO ₃
KC	47.85	38.20	0.03	0.04	1.29	12.30	-
K	65.92	22.56	0.36	0.02	0.90	8.60	2.00

Table 2. Mineralogical analysis of kaolins (%)

	Kaolinite	Alunite	Quartz*	Illite
KC	96	-	-	3
K	52	5	41	-

*: Quartz (mainly) + cristobalite

Ordinary Portland Cement (OPC: I/55) of industrial origin was used for the production of the mixtures. The chemical analysis of OPC and the characteristics of clinker are given in Table 3.

Table 3. Chemical analysis of OPC and characteristics of clinker

Cement		Clinker	
Chemical analysis (%)		Mineralogical composition (%)	
SiO ₂	21.54	C ₃ S	57.8
Al ₂ O ₃	4.83	C ₂ S	18.1
Fe ₂ O ₃	3.89	C ₃ A	6.2
CaO	65.67	C ₄ AF	11.8
MgO	1.71	Moduli	
K ₂ O	0.60	LSF	0.949
Na ₂ O	0.07	SR	2.47
SO ₃	2.74	AR	1.24
Cl ⁻	0.00	HM	2.17

2.2 Thermal treatment of kaolin

The thermal treatment of the kaolins was carried out in a laboratory programmable furnace under controlled conditions and the optimum conditions of thermal treatment were determined. Thermogravimetric analysis (TGA) was applied in order to measure the weight loss during the thermal treatment of the samples. Mineralogical analyses in the raw and thermally treated samples were carried out by means of X-ray diffraction (XRD). The pozzolanic activity of thermally treated samples was measured according to the Chapelle test [12, 27-28].

In order to define the optimum temperature, the sample K was thermally treated ($m=140\text{g}$) at varying temperature ($T: 550^{\circ}\text{C}-950^{\circ}\text{C}$) for constant time $t=3\text{h}$. The temperature was raised at a constant rate ($10^{\circ}\text{C}\cdot\text{min}^{-1}$) from ambient to the desired temperature. In order to define the optimum heating time, the sample K was thermally treated at the previously defined temperature for varying time ($t:1-8\text{h}$).

The definition of the optimum thermal treatment conditions was based on the determination of the unconverted kaolinite in the burnt samples. Each sample of calcined kaolin is subjected to thermogravimetric analysis (TGA) using a Mettler Toledo TGA/SDTA 851 instrument. The samples ($\sim 50\text{mg}$) were heated over the range 20°C to 950°C at a constant rate of $20^{\circ}\text{C}/\text{min}$ in an atmosphere of air. The weight loss of the calcined samples indicate mainly the amount of kaolinite that has not been converted to metakaolinite during the thermal treatment. Mineralogical analysis in the thermally treated samples was carried out by X-ray diffraction (Siemens D5000 diffractometer - Cu $K\alpha$ radiation - Ni Filter), in order to certify the disappearance of kaolinite peaks.

The pozzolanic activity of the samples MK and MKC was measured according to Chapelle test. 1g of metakaolinite is mixed with 1 g of $\text{Ca}(\text{OH})_2$ and 100 ml of water. The suspension is boiled for 16 hours and the free $\text{Ca}(\text{OH})_2$ is determined by means of sucrose extraction and titration with a HCl solution.

2.3 Metakaolin production

The Greek kaolin was thermally treated in a pro-pilot plant furnace at the experimentally defined conditions ($T=650^{\circ}\text{C}$, $t=3\text{h}$) and the produced metakaolin (MK) was ground superfine, using the AJ100 Aerojet Mill Minisplit Classifier of British Rema. The fineness characteristics of the ground metakaolin (MK) as well as the MKC are given in Table 4.

Table 4. Metakolin fineness characteristics

	$d_{20}(\mu\text{m})$	$d_{50}(\mu\text{m})$	$d_{80}(\mu\text{m})$
MKC	10.3	5.1	1.9
MK	13.6	7.5	3.4

2.4 Cement properties

Blended cements were produced by replacing OPC with 10% w/w MK, 20% w/w MK, 10% w/w MKC and 20% w/w MKC. The compressive strength of the samples (EN 196-1) as well as the setting time (EN 196-3) was determined.

2.5 Concrete properties

The concrete production was carried out in a mixer of 50 l capacity. The mixture proportions of all concrete specimens are summarized in Table 5. Normal graded calcareous aggregates with maximum size 31.5 mm were used. A common superplasticizer was used at appropriate percentages in order to retain the slump of the fresh concrete between 50-90 mm (class S2 of EN 206). The dry materials were mixed for 2 min. Then the water, containing the plasticizer was added, and the mixing was continued for 2 min.

The slump (ASTM C 143-90a), the density (BS 1881-103/1993) and the air content (ASTM C 138-92) of the fresh concrete were tested. Concerning the hardened concrete, the compressive strength after 2, 7, 28 and 90 days (ASTM C 39) was measured.

The specimens for the durability tests were cast in steel cylinders of 100 mm diameter and 200 mm height. The molds were stripped after 24 h and the specimens placed under lime-saturated water at 20°C for 90 days. This long-term curing period under water ensures an advanced degree of both Portland cement hydration and pozzolanic activity.

Table 5. Concrete mix proportions

Sample	Content (Kg/m ³)					Superpl. (%)	W/C	W/B
	C	MKC	MK	Aggregates	W			
OPC	350	-	-			0.057	0.50	
MKC-10	315	35	-	Fine: 720		0.140	0.56	
MKC-20	280	70	-	Medium: 400	175	0.170	0.63	0.50
MK-10	315	-	35	Coarse: 800		0.181	0.56	
MK-20	280	-	70			0.400	0.63	

The AASHTO T277 rapid test method was followed to rank the chloride penetration resistance of concrete by applying a potential of 60 V DC and measuring the charge passed through the specimen. The tested concrete cores were slices 51 mm thick, cut from the middle of the initially 200 mm specimens and coated with watertight tape on the cylindrical surface.

The air permeability tests were applied to a concrete cylinder of 100mm diameter and height varied between 45mm and 50mm. The samples were oven-dried at 105°C, until a weight change of less than 0.1% over 24h was observed [29]. The drying period of these specimens was 4-6 days. A modified commercial triaxial cell for 100mm diameter samples, operating to maximum cell pressure of 1.7 N/mm², was used for the determination of the gas (N₂) permeability of the specimens. The equipment used as well as the detailed procedure is described in a previous work [30].

The sorptivity test was applied to a concrete cylinder of 100mm diameter and 125mm height, oven-dried at 105°C for 24h. The equipment used as well as the detailed procedure is described in a previous work [30].

The concrete pore structure was studied using mercury intrusion porosimetry. More specifically, the porosity of the specimen as well as its pore size distribution were measured with a Carlo Erba 2000 Hg porosimeter.

3. RESULTS AND DISCUSSION

3.1 Thermal treatment of kaolin

Kaolin K was thermally treated at 550, 650, 750, 850 and 950°C for 3 hours. Table 6 shows the weight loss (TGA) of calcined samples. The untreated kaolin loses 8.60% weight in the range 20-950°C, which is mostly due to removal of the water combined in the structure of the kaolinite mineral. The weight loss of calcined samples indicates that the kaolinite to metakaolinite conversion is almost completed at 650°C. The XRD patterns of K, treated at various temperatures for 3 hours, showed that the characteristic peaks of kaolinite disappear in samples calcined over 650°C. Incomplete metakaolinization was found only in the sample burnt at 550°C.

Table 6. Weight loss of calcined kaolin K, treated at different temperatures for 3h

Temperature (°C)	Untreated	550	650	750	850	950
Weight loss (%)	8.60	1.35	0.71	0.35	0.23	0.00

In order to define the optimum duration of the thermal treatment, kaolin K was calcined at 650°C for 1-8h. The weight loss (TGA) of the calcined samples is given in Table 7. As is shown, the samples, treated for 2, 3, 4, 6 and 8h, have negligible differences. The XRD patterns of K, treated at 650°C for 1-8h, showed that the characteristic peaks of kaolinite disappear in samples calcined over 3h.

Table 7. Weight loss of calcined kaolin K, treated at 650°C for 1-8h

Time (h)	1	2	3	4	6	8
Weight loss (%)	1.49	0.77	0.75	0.78	0.61	0.75

Table 8 presents the results of the Chapelle test for the commercial metakaolin MKC and the MK, after thermal treatment at 550, 650 and 750°C. The pozzolanic reactivity is evaluated on the basis of the amount of $\text{Ca}(\text{OH})_2$ consumed per gram of metakaolin during the pozzolanic reaction. The higher reactivity of the sample treated at 650°C, confirms the previous results. The lower reactivity of metakaolin at higher temperatures is attributed to the re-crystallization of amorphous minerals. As was expected, the commercial product MKC is the most reactive sample, since it has a considerably higher kaolinite content, compared with the MK. However, the reactivity of MK is higher than was expected, based on the metakaolinite content (MKC: 95% w/w, MK: 49% w/w). As is established elsewhere, kaolinite in kaolin K is less-ordered than kaolinite in KC and this has a positive effect on MK reactivity [12].

Table 8. Chapelle test - Reacted $\text{Ca}(\text{OH})_2$ per gram of metakaolin

Sample	$\text{Ca}(\text{OH})_2$ (g/g of metakaolin)			
	550 °C	650 °C	750 °C	-
MK	0.741	0.815	0.741	
MKC				0.926

3.2 Cement properties

Table 9 presents the compressive strength of the tested samples. It is observed that the addition of metakaolin does not significantly alter the 1-day strength, but it has a very positive effect on the strength after 2 days and specifically at 28 days. As far as the metakaolin type is concerned, it is concluded that MK and MKC have a similar contribution to strength development. OPC with 10% MK showed the best results.

The main factors that affect the contribution of a pozzolanic material to strength are: a) the filler effect, b) the (clinker) dilution effect and c) the pozzolanic reaction with CH. Due to metakaolin high reactivity and high fineness, the pozzolanic reaction of metakaolin is completed between 7 and 28 days [31, 32]. Thus, after 28 days the strength development of metakaolin cements is retarded, due to the dilution effect.

Table 9 presents the water demand of cement paste and the setting time of the tested samples. The “water demand” is the quantity of water that is required to prepare a cement paste of standard consistency as specified in EN 196-3. The blended cements demand significantly more water than the relatively pure cement and this phenomenon is mainly attributed to the high fineness of metakaolin. The increase of the metakaolin content causes a significant increase in the water demand. OPC with 10% MKC showed the lowest water demand, compared with the other blended cements. The initial and final setting time of metakaolin cements is higher than the setting time of pure cement.

Table 9. Mechanical and physical properties of blended cements with metakaolin

Sample	Composition (%)			Compressive strength (N/mm^2)					Water demand (%)	Setting time (min)	
	OPC	MKC	MK	1 d	2 d	7 d	28 d	180 d		Initial	Final
OPC	100	-	-	17.6	29.4	44.5	57.5	70.3	27.5	105	140
MKC-10	90	10	-	20.2	32.4	52.7	71.3	75.0	31.0	95	130
MKC-20	80	20	-	18.8	29.1	50.4	69.7	75.8	37.5	140	170
MK-10	90	-	10	20.0	32.0	50.7	68.1	79.6	32.5	155	180
MK-20	80	-	20	18.0	28.5	50.0	65.3	77.1	41.0	205	230

3.3 Concrete properties

Table 10 presents the properties of the fresh concrete. The slump of the mixes was in the range 50-95 mm (class S2 of EN 206) with the appropriate use of superplasticizers (Table 5). The density of the fresh concrete varies from 2427 to 2453 kg/m³. The concrete is well compacted as is shown from the air content values.

Table 10. Properties of fresh concrete

Sample	Slump (mm)	Unit weight (Kg/m ³)	Air content (%)
OPC	70	2453	1.4
MKC-10	95	2434	1.5
MKC-20	60	2440	1.0
MK-10	50	2433	1.5
MK-20	75	2427	1.0

Figure 1 presents the compressive strength of the tested samples (Table 5). It is generally observed that when metakaolin substitutes cement, higher strengths than the OPC concrete are achieved. More specifically, it is seen that the metakaolin concrete shows lower 2 day strength (with the exception of MK-10), but it has a very positive effect on the strength after 2 days and specifically at 28 days and 90 days. As far as the metakaolin type is concerned, it is observed that MK has a more substantial effect on strength development than MKC. Concrete with 10% MK showed the best results.

Figure 1. Compressive strength development of metakaolin concrete

Table 11 presents the chloride permeability, the gas permeability, the sorptivity and the mean pore size of the tested specimens. The results given in Table 11 are the average values of three different specimens.

The addition of metakaolin causes a significant decrease of concrete chloride permeability. The chloride permeability of metakaolin concrete varies from 240 to 760 C (Coulomb), while the OPC concrete presents a chloride permeability of 2460 C. The concrete with 20% MKC has the lower chloride permeability.

Table 11. Chloride permeability, gas permeability, sorptivity and mean pore size of metakaolin concrete

Sample	Chloride permeability (C)	Gas permeability ($\text{m}^2 \times 10^{-16}$)	Sorptivity ($\text{mm} \times \text{min}^{0.5}$)	Mean pore size (nm)
OPC	2460	2.94	0.114	96
MKC-10	730	1.68	0.097	70
MKC-20	240	1.45	0.089	55
MK-10	690	1.35	0.080	74
MK-20	760	1.60	0.067	62

Concrete with metakaolin exhibits lower gas permeability values compared with the OPC concrete. The gas permeability of the metakaolin concrete varies from 1.35 to $1.68 \cdot 10^{-16} \text{ m}^2$, while the OPC concrete presents a gas permeability of $2.94 \cdot 10^{-16} \text{ m}^2$. The concrete with 10% MK shows the lower gas permeability.

The addition of metakaolin causes a relative decrease of concrete sorptivity. The sorptivity varies from 0.067 to $0.097 \text{ mm/min}^{0.5}$, while the OPC concrete presents a sorptivity of $0.114 \text{ mm/min}^{0.5}$. The concrete with 20% MKC has the lower sorptivity.

Concrete with metakaolin exhibits lower pore size compared with the OPC concrete. The mean pore size of the metakaolin concrete varies from 55 to 74 nm , while the OPC concrete has a mean pore size of 96 nm . The concrete with 20% MKC shows the lower mean pore size.

The enhanced properties of metakaolin concrete are attributed to the high reactivity and high fineness of metakaolin. It is generally accepted that the use of metakaolin leads to concrete with performance characteristics comparable to those of silica fume concrete [33].

In order to indicate more clearly the contribution of the metakaolin to the concrete durability the ratio (p/p_0) has been used, where p is the value of a specific property of metakaolin concrete and p_0 is the value of the same property in OPC concrete. Therefore, (p/p_0) values less than 1 indicate that metakaolin favors the concrete properties and improves the concrete performance. The (p/p_0) values presented in figure 2, show that the metakaolin addition has a positive effect on all the studied concrete properties. It is also concluded that metakaolin affects especially the chloride permeability and the gas permeability of the concrete.

Figure 2. The effect of metakaolin on concrete durability (p : value of a specific property of metakaolin concrete, p_0 : value of the same property in OPC concrete, Clp: chloride permeability, gp: gas permeability, S: sorptivity, mps: mean pore size)

4. CONCLUSIONS

The following conclusions can be drawn from the present study:

- ❑ Kaolinite is completely converted to metakaolinite after 3 hours at 650⁰C. At these conditions the metakaolin exhibits the higher pozzolanic reactivity.
- ❑ Metakaolin has a very positive effect on the concrete strength after 2 days and specifically at 28 days and 90 days. Metakaolin concrete exhibits significantly lower chloride permeability, gas permeability, sorptivity and pore size compared with OPC concrete.
- ❑ The produced metakaolin as well as the commercial one indicate a similar behavior concerning cement strength development and the concrete strength development and durability and lead to production of cement and concrete with an excellent performance.
- ❑ Metakaolin, originated from poor Greek kaolins, can be efficiently used as a cement and concrete constituent.

HYDRATION PROCESSES OF CEMENTS BLENDED WITH LIMESTONE POWDER: EXPERIMENTAL STUDY AND NUMERICAL SIMULATION

Xiangjun Xiong and Klaas van Breugel

Faculty of Civil Engineering and Geosciences, Delft University of Technology,
Delft, The Netherlands. E-mail: x.xiong.k.v.breugel@ct.tudelft.nl

ABSTRACT

Although limestone powder or crushed limestone has been used in the manufacture of composite cement since the 1980s, there were only a few researches focusing on the reaction mechanism of the cement blended with limestone powder. This paper focuses on the influence of limestone powder on the kinetics of the hydration processes of Portland cement in the early ages using isothermal Calorimetry. The temperature of isothermal calorimeter study was 20, 30 and 40 °C. The weight percentage of limestone in the binder was 14% and 22% and water-solid ratio was 0.43 and 0.53. In order to facilitate the comparison, experiments are also done with blast furnace slag cement blended with the same limestone powder percentage levels with a water-solid ratio of 0.53.

Apparent activation energy for the cements blended with limestone powder was also determined based on experimental results and used in a numerical simulation program for cement hydration. Comparison between numerical simulation results and that of the experiments suggests a good correlation between the numerical hydration model and the experiments.

1. INTRODUCTION

Limestone is a very important material for the manufacture of cement. It was also reported by several authors that the addition of limestone might improve the properties of cement paste such as water demand, workability and strength. Of course, the use of limestone as replacement filler in concrete will reduce the cost and bring along significant environmental benefits because the manufacturing of cement produces huge amounts of CO₂. Actually, as a replacement of clinker, limestone has been used in Europe for about 25 years [4] and half of the French composite Portland cement is limestone filler cement [14]. There are mainly two types of Portland limestone cement specified in the European Standard prEN 197-1: type II/A-L containing 6-20% limestone and type II/B-L containing 21-35% limestone [3].

Finely ground limestone powder has a physical filler effect in the hydration process of ordinary Portland cement [3, 4, 5, 6, 8]. Due to its fine size, limestone powder particles will 1) improve the grain packing of the cements [11], 2) act as the nuclei and facilitate the nucleation and growth of hydration products such as calcium hydroxide crystals at early ages of hydration [12]. However, limestone would react with calcium aluminate to form calcium aluminate carbonates, which is more stable due to its lower solubility [9, 10]. This actually increases the rate of the hydration of C₃A.

In a system containing C₃A and CaCO₃, a high carbonate form of carboaluminate C₃A · 3CaCO₃ · 32H₂O and a low carboaluminate form C₃A · 3CaCO₃ · 12H₂O could be formed [7]. These resemble the high sulphate form Ettringite and the low sulphate form monosulfoaluminate, which are formed as a reaction product of C₃A and gypsum. In a blended system with C₃A, gypsum

and CaCO_3 , there could be competition between the CO_3^{2-} and SO_4^{2-} ions for the C_3A . Mixed Ettringite like materials with CO_3^{2-} substitution for SO_4^{2-} was also observed [13] and in the presence of carbonate, the conversion of ettringite to monosulfoaluminate is delayed [3]. In addition, limestone powder was found to accelerate the hydration of C_3S and modify the Ca/Si ratio of C-S-H gel [5]. Vernet [19] suggested that the carbonate participates in the hydration quite actively.

This paper focuses on the influence of limestone powder on the hydration processes of ordinary Portland cement under different temperatures. In order to make a comparison and understand the behavior of paste with blast furnace slag cement and limestone powder, experiments were also done with blast furnace slag cement blended with the same limestone powder percentage levels using isothermal calorimetry.

Apparent activation energy for the cement blended with limestone is then calculated based on the heat released during the hydration processes and used in the numerical simulation program HYMOSTRUC [1] model developed in Delft University of Technology. Good correlations are found between numerical simulations and that of the experiments.

2. DESCRIPTION OF EXPERIMENT

2.1 Experimental Instruments

The isothermal Calorimetry study was carried out with a 3114/3236 TAM Air isothermal calorimeter, manufactured by Thermometric AB, Sweden. It is an eight-channel calorimeter operating in the milliwatt region. The capacity chosen in this research was 600 mW per sample with a precision of ± 0.01 mW. It can operate in the temperature range from 5 to 60°C with a fluctuation of the isothermal temperature $\pm 0.02^\circ\text{C}$.

The calorimeter was located in a room where temperature was set to 20°C and RH 65%. At measurement temperatures higher than the environmental temperature, in order to prevent thermal shock to the calorimeter due to the temperature difference between the sample and calorimeter, both cement and water were kept in the oven for 24 hours at the desired mixing temperature before mixing and isothermal measurements. An industrial computer was used to record the heat release and the measurement was done over the first 7 days of the hydration.

2.2 Materials

The cements used are ordinary Portland cement (later referred to as OPC) and blast furnace slag cement (later referred to as BFSC). Both the cements and the limestone powder are produced by ENCI B.V., The Netherlands. The oxide composition of the cements and the limestone powder was measured using XRF analysis using a Philips X-Ray spectrometer (PW 2400) and the oxide contents were calculated using Uniquant software. The measured oxide contents are shown in Table 1. The mineral composition of the clinker in the OPC was calculated using the modified Bogue method [20] as C_3S 59.3%, C_2S 11.0%, C_3A 7.2% and C_4AF 10.4% and Q_{pot} , the total amount of heat that will be liberated at complete hydration, is 433 kJ/kg. The clinker content in the BFSC is 28% and the slag percentage is 68%. According to the European standard, the CaCO_3 content in limestone must be greater than 75% for using in the blended cement. The CaO content in the limestone used in this study is about 54.5 percent, which is quite close to the theoretical content (56%) and therefore, the CaCO_3 content is around 97%.

The particle size distribution of the two cements and limestone powder were measured using laser diffraction. The equipment used was a Coulter LS 230 and the results are shown in Figure 1. It can be seen from the figure that limestone powder has a much finer particle size distribution and the volume percentage has a plateau of about 2% volume percentage within the range of 2 to 40 micron.

Table 1. Chemical Composition of the Cements and Limestone Powder

Oxide Analysis (wt%)	Ordinary Portland Cement	Blast Furnace Slag Cement	Limestone Powder
CaO	62.86	45.27	54.47
SiO ₂	19.63	30.79	0.225
Al ₂ O ₃	5.02	9.88	0.074
Fe ₂ O ₃	3.31	1.40	0.062
K ₂ O	1.23	1.17	0.304
Na ₂ O	0.30	0.22	-
SO ₃	3.01	3.01	-
MgO	2.28	6.59	0.614
TiO ₂	0.36	0.48	-
MnO	0.12	0.22	-
P ₂ O ₅	0.45	0.14	0.008
Ignition Loss	1.06	0.76	44.10 ^{*)}

^{*)} The high value of ignition loss is due to the release of CO₂

Figure 1. Particle size distribution of the cements and limestone powder

2.3 Mixture Composition

The mixture composition can be found in Table 2 and 10 gram cement paste was needed for the isothermal calorimetry measurement. Two weight percentage levels of limestone were used, namely 14% and 22%. The water-solid ratio was 0.43 and 0.53 for ordinary Portland cement blended with limestone.

Another mixture of blast furnace slag cement blended with limestone powder with the same level of limestone percentage was also prepared in order to make comparisons. The water-solid ratio used was 0.53. Isothermal calorimeter measurement was done for each mixture at three temperature levels, viz.: 20, 30 and 40 °C.

3. EXPERIMENTAL RESULTS

Because the rate of heat release decreases quite significantly after 1 day, only the results in the beginning 30 hours are shown in the figures for a clear view. The rate of hydration or the thermal power is calculated based on the total weight of binder in the pastes.

Table 2. Mixture Composition for the Isothermal Calorimetry Study

Water-solid ratio	Cement	Limestone Powder	Note
0.53	6.54 g	0 g	Reference paste (100% OPC)
	5.62 g	0.92 g	86% OPC+14% LM
	5.10 g	1.44 g	78% OPC+22% LM
0.43	6.99 g	0 g	Reference paste (100% OPC)
	6.01 g	0.98 g	86% OPC+14% LM
	5.45 g	1.54 g	78% OPC+22% LM
0.53	6.54 g	0 g	Reference paste (100% BFSC)
	5.62 g	0.92 g	86% BFSC+14% LM
	5.10 g	1.44 g	78% BFSC+22% LM

3.1 Thermal Power

It can be seen in Figure 2 that at $T=20^{\circ}\text{C}$, the rate of hydration of blended cement pastes with both water/solid ratios are higher than that of reference paste in the first few hours. In the case of w/s ratio 0.43, cement paste containing 14% limestone powder shows a moderate acceleration of the hydration while higher content of limestone increased the hydration quite significantly and it also increased the value of the first peak. When the paste is older than 12 hours, the hydration of both blended pastes progresses slower than the reference paste. At a higher w/s ratio 0.53, paste with 14% limestone hydrates slower than the reference paste up to 5 hours. But it speeds up quite noticeably thereafter. Paste with 22% limestone shows a faster rate of hydration but it slows down quite significantly after 7 hours. After the first peak, blended paste exhibits an increasingly obvious shoulder or second peak with the increase of the limestone content.

Figure 2. Rate of heat release of the pastes, $T=20^{\circ}\text{C}$

At $T=30^{\circ}\text{C}$ (Figure 3), the reactions have been accelerated and the value of the first peak increases for all the samples. Paste with 22% limestone hydrates and w/s ratio 0.53 quite fast in the beginning and exhibits an obvious second peak, whose value is even larger the first peak. Paste with 14% limestone powder and w/s ratio 0.43 also shows the same behaviour. However, hydration of both of them is slower than the reference paste after 5 hours of hydration. Again, paste with 14% limestone powder and w/s ratio 0.53 has the highest value of the first peak, followed by paste with 22% limestone powder and w/s ratio 0.43. A more obvious shoulder or second peak is found again in all the blended pastes.

Figure 3. Rate of heat release of the pastes, $T=30^{\circ}\text{C}$

Figure 4. Rate of heat release of the pastes, $T=40^{\circ}\text{C}$

When the experiment temperature goes to 40°C (Figure 4), hydration of paste with 14% limestone and w/s ratio 0.53 exhibits the highest value of first peak and that of paste with 22% limestone and w/s ratio 0.43 second. Both of the pastes show a much more obvious second peak than the lower degree cases, especially for paste with 22% limestone and w/s ratio 0.43. Similar to 30°C , hydration of these two pastes slows down quite noticeably after the second peak.

3.2 BFSC blended with limestone

Figure 5 shows the thermal power of blast furnace slag cement blended with limestone powder. At $T=20^{\circ}\text{C}$, the reference paste has the second peak at about 27 hours after the first peak. The addition of limestone powder has shortened the time interval of the first peak and the second peak by about 6 hours. When the temperature is 30°C , the speed of hydration is increased and paste with 14% limestone has a much higher second peak while the paste with 22% limestone shows a plateau at around 1.7 mW/g . At $T=40^{\circ}\text{C}$, the heat release of paste with 14% limestone shows a very high peak immediately after the first peak, which makes the first peak into a small plateau.

Figure 5. Rate of heat release of blended paste with blast furnace slag cement and limestone

The time interval between the two peaks is also shorter. It is worthwhile to point out that paste with 14% limestone with water/solid ratio 0.53 again shows significant change of the processes of the hydration. In comparison with the blended cement using Portland cement, the change is on the value of the second peak in this case.

4. DISCUSSIONS AND EVALUATION

4.1 Effect of limestone

Several authors, among others, Kakalis et al [3], Poitevin [4] and Pera et al. [5], suggest that limestone exhibits chemical activity during the hydration processes of Portland cement blended with limestone. Kakalis et al. [3] made a comparative study of the chemical activity of limestone and its effect on the hydration of C_3S , C_3A and Portland cement using XRD and TGA. They found that “the ettringite transformation to monosulphate is delayed and calcium mono-carboaluminate is preferably formed instead of monosulphate even at early ages”. Moreover, they also found an increase of CH content in cement pastes with limestone powder and this is clearly an indication of the acceleration of the calcium silicate hydration.

Since the focus is on the reactions where C_3A is directly or indirectly concerned, it is necessary to point out that in the hydration of C_3A in OPC paste, anions like CO_3^{2-} , SO_4^{2-} and OH^- can all occupy the interlayer positions of the solid solution formed as a reaction product of monosulphate, C_3A and CH. In the case of paste with limestone, the ion interaction theory of physical chemistry suggests that the formation of the less soluble calcium mono-carboaluminate hydrates will significantly increase the solubility of $CaCO_3$ and consequently further reaction will also be promoted.

The shoulder or the second peak of Portland cement hydration is generally believed to be the conversion of Ettringite to mono-sulphoaluminate. A higher second peak observed in the blended paste using Portland cement might be explained by the difference in the heat released in the reaction forming calcium mono-carboaluminate and that forming mono-sulphoaluminate. The former has a heat release of 328 kJ/mole, while the latter is only 238 kJ/mole.

In [18], the amount of bound water in cement blended with limestone powder was measured until the paste was 3 months old. Experiment results show that with the increases of the percentage of limestone powder in the mixture, the amount of chemically bound water is also increased at 20 and 30 °C. This also suggests that limestone powder could have participated in the reaction because it is generally believed that the nucleation and growth phase happens in the beginning hours of hydration of ordinary Portland cement hydration. Therefore, the physical “filler” effect of limestone powder as nucleation site for hydration products could only influence the early hours of the hydration.

4.2 Apparent Activation Energy

The isothermal calorimeter records the rate of the heat release or the thermal power. By integrating the thermal power with time, we can obtain the evolution of heat of hydration. Thereafter, the degree of hydration at time t can be defined as the heat released at time t divided by the potential heat that can be released at complete hydration, viz.:

$$\alpha = Q(t) / Q_{pot} \quad (1)$$

In order to describe the kinetics of the hydration processes of the blended cement, especially the temperature dependence of the hydration processes, Arrhenius equation is used, viz.

$$K(T) = A * \exp\left(-\frac{E_a}{RT}\right) \quad (2)$$

Where A is the collision number constant, R is the ideal gas constant, 8.314 J/mol·K and E_a is the activation energy. Because cement hydration is composed of several simultaneous chemical reactions and physical processes, apparent activation energy is used here instead. Obviously, apparent activation energy (E_a) is an experimentally obtained value from its definition.

From Equations (1) and (2), taking the rates of hydration K_1 and K_2 at two temperatures of isothermal curing T_1 and T_2 ($T_1 > T_2$, absolute temperature), apparent activation energy can be calculated using the formula below:

$$E_a(T, Q) = -\frac{R * T_1 * T_2}{T_2 - T_1} * \ln\left(\frac{K_1}{K_2}\right) \quad (3)$$

The calculated E_a is shown in Figure 6. In order to use the obtained E_a in numerical simulations, we use the following expression for the estimation of E_a :

$$E_a(\alpha, t, T) = (44.92 - 0.043 * T) * \exp\left(\gamma_{LM} * \frac{f_{LM}}{1 - f_{LM}}\right) * \exp(-\alpha(t)) \quad (4)$$

Where f_{LM} is the weight percentage of the limestone in the binder, $\alpha(t)$ is the degree of hydration of cement at time t , T is temperature (K). We define γ_{LM} as an activity factor of limestone, which considers the influence of the limestone to the hydration kinetics. It was found that γ_{LM} is not a constant and it is dependent on the temperature and water-solid ratio.

From Equation (4), we notice that the apparent activation energy becomes temperature dependent and it also changes along with hydration. For the complex heterogeneous reaction like that of cement hydration, van Breugel [1] calculated the values of the activation energy based on isothermal Calorimetry data on Portland cement carried out by Lerch and Ford and he suggested that E_a is a function of temperature, degree of hydration and the content of C_3S . D'Aloia [2] also confirmed that E_a shows dependency on the degree of hydration and the temperature.

Figure 6. Calculated apparent activation energy for cements blended with limestone powder

5. NUMERICAL SIMULATION

5.1 Hymostruc

In the HYMOSTRUC model, the hydration can be described as the continuous growth of particles and the hydration product is divided into inner product and outer product. The embedment of smaller particles in the growing shell of bigger particles is also considered in the model. The microstructure is formed by the development of contacts between expanding particles.

Figure 7. Simulated Initial 3D Random Distribution of Particles

5.2 Numerical Simulations

5.2.1 Numerical simulation result

Numerical simulations are performed for a mixture with 14% limestone powder and water-solid ratio 0.33. The isothermal curing temperature was 20 and 40 °C respectively [18]. Based on the measured particle size distribution, a 3D random distribution of both the cement and limestone particles is first made to form the initial state of the hydration (see Figure 7). The particles are assumed to be spheres and they follow the Rosin-Rammler particle size distribution. The value of the activity factor of limestone, γ_{LM} , is taken as 0.34. This is only a small extension to the HYMOSTRUC model because the interaction between the limestone particles and cement particles is not simulated explicitly. However, we think that for engineering purposes, such a treatment can deal with the practical problems concerning concrete using cement blended with limestone powder.

In addition, a numerical simulation is also performed using the original implementation of apparent activation energy to facilitate the comparisons, where simulation using HYMOSTRUC with Equation (4) is denoted as “New Ea” and simulation using HYMOSTRUC with the original implementation in HYMOSTRUC as “Old Ea”. The “Old Ea” in HYMOSTRUC is defined as

$$E_a(\alpha, T, C_3S) = 76 \times \alpha \times \exp(-2.52 \times 10^{-11} \times (C_3S)^{6.15} + 0.025 \times T^{1.5}) + 0.33 \times (C_3S) + 30 \quad (5)$$

Where C_3S stands for the weight percentage of C_3S .

It can be seen from Figure 8 that in the first few hours, the deviation between the calculated degree of hydration using Equation (4) and that of the experiment results is almost negligible.

Figure 8. Comparison between numerical simulation results and experimental measurement of blended cement paste with 14% limestone and w/s ratio of 0.33

6. CONCLUSIONS

It is found that the addition of limestone to Portland cement increases the hydration at early age and the author suggest that effect of limestone is both physical and chemical. The appearance of a larger second peak could be explained by the replacement of the reaction of Ettringite to mono-sulfoaluminate by the reaction between C_3A and carbonate forming calcium mono-carboaluminate.

Pastes with 14% limestone and water/solid ratio 0.53 produce a significant change of the hydration processes for both the blended cement using Portland cement and blast furnace slag cement. But the effects of limestone are different in the two cases. For blended cement using Portland cement, the value of the first peak is increased while for the blast furnace slag cement case, the value of the second peak is increased.

Based on the isothermal calorimeter measurement, apparent activation energy for the blended cement with limestone is calculated and the limestone activity factor γ_{LM} is dependent on the temperature and water/solid ratio. The relationship between apparent activation energy and temperature, degree of hydration and limestone content is also found and utilized in the HYMOSTRUC model. Numerical simulation exhibits a good agreement with the experimental results at the early ages. This is quite important for the calculation of thermal stress, control of thermal cracks and durability.

ACKNOWLEDGEMENTS

The financial support from The Netherlands Science and Technology Fund (STW) is gratefully appreciated. The authors would also like to thank Mr. E. Horeweg in the Stevin Lab II of Delft University of Technology for the kind assistance in the experimental work.

HYGIENIC, HEALTH AND ENVIRONMENTAL COMPATIBILITY OF CEMENTITIOUS CONSTRUCTION PRODUCTS

M. Schneider and G. Spanka

Research Institute of the Cement Industry, German Cement Works Association, Düsseldorf,
Germany. E-mail: Sch@vdz-online.de

ABSTRACT

Construction projects are essential to satisfy the requirements of the modern industrial society. However, each building activity is associated with an interference with the nature. The protection of the immediate environment of structural works belongs to the six essential requirements of the European Construction Products Directive (CPD). The German cement industry has dealt for many years with the environmental compatibility of cement and cementitious building materials in all phases of the product life. Mortar and concrete may contain small amounts of trace elements as well as organic substances deriving from, e. g. additives and admixtures. All investigations have shown that the hardened cement paste is a good binding and encapsulating matrix for these components and that their leaching rates are on a very low level. While for trace elements the leaching behaviour is important to be understood, for organic substances used in cementitious building materials also the release of volatile components must be taken into account. Investigations carried out so far have shown that cementitious materials, even when produced with organic additives or admixtures, cause only very slight emissions. Cement and cementitious construction products satisfy the fundamental requirements of the European Construction Products Directive and the corresponding national regulations.

1. INTRODUCTION

The modern Society relies to a great extent on houses, industrial installations, drinking water supply, transportation systems etc. Among many other building materials concrete plays by far the most important role in providing such reliable and durable infrastructure. The European Construction Products Directive (CPD) [1] allows construction products to be placed on the European common market if these products are fit for their intended use. Fitness for intended use must be assumed, if the construction products incorporated in the works satisfy – if properly installed – six essential requirements. In addition to the traditional essential requirements, e. g. mechanical resistance, the CPD directly addresses hygiene, health and the environment.

Cement and cementitious construction products satisfy the fundamental requirements of the CPD and the corresponding national regulations. Therefore, the European cement standard EN 197 [2] in general does not cover separate requirements in view of hygiene, health and environmental protection. In Germany further regulations are laid down in special cases where it appears necessary for constructive applications that require a particular protection of the water, soil and air. For new building materials to be approved the German Institute for Building Technology (DIBt) established a code of practice for the evaluation of the effects of construction products on the soil and ground water [3]. The DIBt was also involved in drafting a code regarding health-relevant evaluation criteria for interior-relevant construction products [4]. The German Gas and Water Association (DVGW) established the worksheet W 347 “Hygienic requirements for cement-bound materials for

drinking water supply – tests and evaluation” for cementitious materials in contact with drinking water [5]. These three regulations are to be classed together in one DIN technical report as a basis for further European standardisation work.

The German cement industry has dealt for many years with the environmental compatibility of cementitious building materials in all phases of the product life, covering the production of cement, the concrete processing, the use in constructions or buildings as well as recycling and final disposal. At the beginning the research was focussed on the behaviour of trace elements in the clinker burning process, emissions from the kilns and their impact to the environment. Later, the behaviour of trace elements in the clinker, cement and concrete was examined at full length allowing cementitious materials to be used as an encapsulating and binding matrix for wastes. With increasing use of secondary materials for clinker production the attention has been concentrating on the initial materials required in cement manufacture and on the cement. Today, the behaviour of trace elements is well understood throughout the life cycle of cement and concrete. All investigations have shown that the hardened cement paste is a very good encapsulating and binding matrix for trace elements and that the leaching rates of trace elements from cementitious materials are on a very low level [6-8].

Mortar and concrete may also contain small amounts of organic substances deriving from additives and admixtures as well as from recycled materials, e. g. bituminous or tar-containing road construction materials. Extensive investigations have shown that the hardened cement paste is also an encapsulating and binding matrix for organic substances [9, 10]. While for trace elements the leaching behaviour from cementitious materials is important to understand, for organic substances the release of volatile components to the surrounding must also be taken into account. Investigations carried out so far have shown that cementitious materials, even when produced with typical amounts of organic concrete additives or admixtures, cause only very slight emissions of volatile organic substances [11, 12].

2. EUROPEAN REGULATIONS

2.1 Construction Products Directive

The Construction Products Directive required that construction works must be designed and built in such a way that they will not be a threat to the hygiene or health of the occupants or neighbours. In a corresponding Guidance Paper of the European Union (EU) [13] the CPD limits its requirements to the direct environment of the works during use. Hence regional or global environmental aspects as well as aspects of workers health are outside the scope of the Directive.

According to the European Economic Treaty, EU Member States remain responsible for ensuring that buildings and civil engineering works in their territory are designed and completed in a way that does not endanger the safety of persons, domestic animals and properties. Therefore, national provisions laid down by law, regulations or administrative actions are supplementary to the European Construction Products Directive. These legal instruments ensure the works built with the construction products admitted onto the European common market fulfil the regulations valid in the place of use. To cope with different requirements, national provisions and harmonised technical specifications should express the relevant product characteristics in terms of levels and classes.

2.2 Chemicals legislation on Dangerous Substances

The Directive on Dangerous Substances [14], with its corresponding amendments, specified the approximation of laws, regulations and administrative provisions relating to the classification, packaging and labelling of dangerous substances in the European Union. Currently there are 15 classes of danger in the Directive, e. g. “very toxic”, “carcinogenic” or “dangerous for the environment”. This Directive forms the basis for chemicals management in the EU and provides a

legal foundation for future EU-legislation on dangerous substances in construction products. At present, the legislation on dangerous Substances in construction products in force in the individual

Member States have been compiled in a database with more than 100 substances, which are either totally banned or limited [15]. Due to the differences in geographical and climatic conditions or in way of life as well as in the levels of protection that may prevail at national level, the Member States provisions to protect the direct environment of buildings vary significantly. Currently European provisions to protect the direct environment of works or buildings do not exist. Therefore, the first generation of harmonized product standards refer with respect to dangerous substances to national laws, regulations and administrative provisions, which must be complied with, when and where they apply.

2.3 European Acceptance Scheme for Construction Products in contact with Drinking Water

Construction products in contact with drinking water, which are referred to in national regulations, fall within the scope of the Construction Products Directive (CPD) [1] and are mentioned in the European Drinking Water Directive (DWD) [16]. In 1999 the Regulators Group for Construction Products in contact with Drinking Water (RG-CPDW) was established, as a working group of both the Standing Committee on Construction (SCC) and the Standing Committee on Drinking Water (SCDW), to work out an European Acceptance Scheme (EAS) for Construction Products in contact with Drinking Water (CPDW). In the meantime the RG-CPDW has prepared an interim report “EAS on Paper” [17] and a corresponding mandate to CEN, for the preparation of the necessary test methods to be included in the EAS and for harmonized European product standards (hENs) to cover the CPDW as far as possible. The main principles of the draft EAS are:

- The EAS will offer a high level of consumer protection that does not compromise the existing protection levels of the national Acceptance Schemes.
- The EAS will provide a level playing field for all materials and products, in particular using the same basis for consumer protection.
- All stages of the EAS-process will be transparent.
- The EAS will enable the satisfaction of the requirements of the DWD and the CPD.

The ranges of assessments to be carried out to ensure that the drinking water after contact with a product poses no significant risk to health and is acceptable to the consumer are:

- Organoleptic assessments.
- General hygiene assessments.
- Toxicological assessment of substances.
- Enhancement of microbial growth.

However, not all of the assessments and conditions apply to all products. Considering existing experience it seems not to be relevant to control the main constituents of cementitious materials, i.e. cement, water, sand and gravel. However, other constituents of cementitious products, e. g. admixtures, additions or fibres, especially those of an organic nature will be controlled, possibly by a positive list approach. Final acceptance will be based on the assessment of the finished product. However, for cementitious materials an alternative proceeding has been proposed by the cement and concrete industry to replace the direct acceptance by an indirect acceptance based on corresponding positive lists of the constituent materials. This alternative proceeding is indispensable in particular for site mixed mortar and concrete but may also be of advantage for prefabricated products.

3. GERMAN REGULATIONS

3.1 Evaluation of effects of construction products on soil and groundwater

For new construction products which need a general technical approval, a task force of the German Institute for Building Technology (DIBt) has established an interdisciplinary concept on possible dangers to soil and groundwater, which resulted from intensive deliberations between water, soil and building authorities and industry [3]. Standardised and already technically approved construction products are not included in the scope of this concept, which distinguishes between buildings in direct contact with the ground water and buildings installed above the groundwater level. In the first case the contact water between the building and the groundwater is relevant for evaluation, and in the second case the percolating water when it enters the groundwater. The evaluation is made in two subsequent phases (Figure 1).

Figure 1. Assessment of water entering the groundwater

Phase 1 evaluates the material constituents of the construction product. Materials in which carcinogenic, mutagenic or terratogenic substances are actively used will be rejected. For materials for which undisputed positive evidence is given a generic acceptance without further testing will be possible in phase 1.

Table1. “No-Adverse-Effect-Levels” for inorganic parameters [3]

Inorganic Parameter	No-Adverse-Effect-Level [µg/L]	Inorganic Parameter	No-Adverse-Effect-Level [µg/L]
Antimony (Sb)	10	Nickel (Ni)	50
Arsenic (As)	10	Mercury (Hg)	1
Lead (Pb)	25	Selenium (Se)	10
Cadmium (Cd)	5	Zinc (Zn)	500
Chromium, total, (Cr)	50	Tin (Sn)	40
Chromate (Cr VI)	8	Cyanide, total (CN ⁻)	50
Cobalt (Co)	50	Cyanide, volatile (CN ⁻)	10
Copper (Cu)	50	Fluoride (F ⁻)	750
Molybdenum (Mo)	50		

Phase 2 evaluates those substances which are leached from construction products in standardised leaching tests. The leachates are to be analysed for general parameters, e. g. odour, colour and pH-value, for chemical parameters, e. g. trace elements and organic constituents, and if relevant for biological parameters. The chemical parameters in the leachates are transformed into values relevant for the water entering the groundwater on the basis of standardised calculation procedures, and are then evaluated against so called “No-Adverse-Effect-Levels” which have been fixed by the German Soil Authorities. Table 1 shows, as example, the “No-Adverse-Effect-Levels” for inorganic parameters [3].

3.2 Evaluation of effects of indoor pollution on human health

There is increasing discussion in public and among experts about the release of pollutants from building materials into the indoor air of residential accommodation. This has come about because, among other things, increasingly impermeable building claddings with less ventilation are being erected to save energy. Therefore, harmful substances released can build up as a result of the deficient air replacement. German Health Authorities have prepared a draft concept for the evaluation of volatile organic compounds (VOC) as basis for an approval scheme for construction products [4]. The scheme is based on a two phase evaluation similar to Figure 1.

In phase 1 the emissions, measured in a standardised testing arrangement, are controlled in view of carcinogenic, mutagenic or cytotoxic substances. In phase 2 the Total Volatile Organic Compounds (TVOC), determined after 3 days of exposure are evaluated. In order to assess the long term behaviour an additional TVOC-measurement is taken after 28 days. In addition to the TVOC also the Semi Volatile Organic Compounds (SVOC) are determined after 28 days. Since the toxic relevance of any individual VOC cannot be evaluated on the basis of TVOC and SVOC, it is proposed that any VOC with concentrations above a given level should be evaluated against an acceptable limiting value (Lowest Concentration of Interest LCI). The draft evaluation concept leaves many questions open and requires further intensive discussions. In particular the scientific background for the definition of the LCI for individual VOCs must be further analysed.

3.3 Hygienic requirements for cement-bound materials for drinking water supply

Due to the great importance of drinking water being supplied in perfect condition, all materials that come into direct contact with the drinking water are subject to strict drinking water hygienic specifications. According to § 31 of the German Foodstuff and Consumer Articles Act (LMBG) materials from which substances can be transferred into the water must not come into contact with drinking water. Exceptions are only proportions that are harmless to health and do not alter odour, taste etc., provided that they are technically unavoidable. For cementitious materials that have proven their worth in all sectors of the drinking water supply for decades, in 1999 the German Gas and Water Association (DVGW) established the worksheet W 347 “Hygienic requirements for cement-bound materials for drinking water supply – tests and evaluation” [5]. The worksheet is divided into four areas of application (see Table 2).

Table 2. Areas of application for cementitious materials in the drinking water sector

Area of application	Materials and structural elements
I	Cement mortar linings for cast-iron and steel pipes
II	Concrete pipes, concrete tanks, mortars for tank linings
III	Tile adhesives, jointing mortars, mortar linings for pipe fittings, repair mortars, e. g. for weld seams
IV	Concrete structural elements in drinking water protection zones

It specifies that all standardized or approved cements can be used, this also applies to standardized aggregates or additions. Also, concrete additions and admixtures contained in a “positive list” can be used if they have also passed the drinking water hygiene tests described in Table 3. The positive list covers all the currently in Germany used raw materials for concrete additions and admixtures. However, as the use of organic concrete additions or admixtures is viewed critically by drinking water hygiene specialists, such substances should only be used if they are necessary for achieving important mortar or concrete properties. Table 3 shows the tests to be performed for cementitious materials in the drinking water section in relation to the intended area of application. The 6-month-long microbiological test is only required if organic substances enter the cementitious material via concrete additions or admixtures. The tests are carried out on test pieces, e. g. standard mortar prisms, or on finished products, e. g. sections of pipes, after a prior storage and pretreatment appropriate for drinking water applications, e. g. rinsing with drinking water for 14 days.

Table 3. Scope of testing for cementitious materials in the drinking water sector

Tests to be performed	Drinking water supply	Raw water supply and constructions in drinking water protection zone I	Constructions in drinking water protection zones II + III
Migration tests			
Organoleptic tests	+	+	+
TOC release rate	+	+	-
Arsenic release rate ¹⁾	+	+	+
Lead release rate	+	+	+
Chromium release rate	+	+	+
Microbiological test			
DVGW Worksheet W 270 ²⁾	+	+	- ³⁾

1) Testing only required if fly ash from bituminous coal is used

2) Testing only required if organic additions, admixtures or indirect materials are used

3) Testing only required for mortar encasement of pipes, microbiological growth is allowed

4. CONTENT OF TRACE ELEMENTS AND ORGANIC SUBSTANCES IN CEMENT AND CEMENTITIOUS MATERIALS

Even with exclusive use of primary raw materials and fossil fuels, trace elements are introduced into the clinker burning process. The trace elements are bound in the clinker more or less to the same extent as introduced into the process, and no residual materials will remain. Therefore, the concentrations of trace elements in the clinker mainly originate from the natural element distribution in the starting materials, which can differ markedly from each other depending on the deposit. If secondary raw materials and/or secondary fuels are used in the clinker burning process under today's regular conditions – which are determined by the demands on product quality, suitability in terms of process engineering, as well as economic efficiency – the resulting concentrations of the respective trace elements may be increased negligibly, but also reduced. However, in most cases these changes are overlain by the natural concentration variations in the primary feed materials. In 1999 the Research Institute of the German Cement Industry investigated all Portland, Portland composite and blast furnace cements manufactured in Germany as defined in DIN 1164 for 17 trace elements [18]. Table 4 lists the bandwidths of the trace element contents of the German cements. These concentrations correspond to the concentration variations of trace elements found in natural rock, soil and clay.

On account of the high temperature of the clinker burning process with gas temperatures up to 2000 °C and the oxidizing kiln atmosphere, which prevails for reasons of product quality, organic substances are practically undetectable in Portland cement clinker.

Table 4. Bandwidths of trace element contents in German standard cements

Element	Content g/t (ppm)	Element	Content g/t (ppm)
Arsenic (AS)	< 1 – 55	Lead (Pb)	2 – 200
Beryllium (Be)	< 0.2 – 2.5	Antimony (Sb)	< 1 – 35
Cadmium (Cd)	< 0.1 – 8	Selenium (Se)	< 1 – 2.5
Cobalt (Co)	1 – 30	Tellurium (Te)	< 0.5
Chromium (Cr)	12 – 105	Thallium (Tl)	< 0.5 – 2
Copper (Cu)	5 – 280	Vanadium (V)	15 – 200
Mercury (Hg)	< 0.02 – 0.35	Zinc (Zn)	20 – 450
Manganese (Mn)	90 – 4200	Tin (Sn)	< 1 – 22
Nickel (Ni)	5.5 – 80		

During cement manufacturing grinding aids like glycols or triethanolamine are often added in concentrations less than 0.05 wt.%, e. g. to improve the utilization of energy. Higher amounts of organic substances may be introduced into concrete via additives or admixtures. Whereas organic additives play only a minor role for the production of concrete, modern concrete technology is to a great extent orientated towards the use of concrete admixtures. Today 80 to 90 % of all concrete is produced with admixtures in Germany, the majority being plasticizers and superplasticizers. However, in terms of quantity admixtures play only a minor role in the multi-component system concrete.

5. LEACHING BEHAVIOUR OF TRACE ELEMENTS AND ORGANIC SUBSTANCES

Numerous studies confirm that the chemical composition – i. e. the trace element content – of cement has no direct relation to the leaching characteristic of cementitious materials. They have also shown that the release of constituents, such as trace elements or organic substances, from cementitious materials in contact with water is mainly diffusion-controlled and affected by various chemical and physical retention mechanisms [6-8]. The transport in the fluid filled pores of the hardened cement paste is caused by diffusion of the dissolved substances in the fluid. Driving force for the diffusion is the difference in concentration of the substance in the pore solution and outside the porous solid. The concentration of trace elements and organic substances in the pore solution can be decreased to a great extent due to its

- incorporation in the crystal lattice of the hydrate phases,
- chemical binding to the surface of the hydrate phases,
- sorption onto the surface of the hydrate phases and
- formation of insoluble salts.

The transport speed is governed by the diffusion characteristic of the transported substances and the pore size distribution of the cementitious material. Therefore, for practical purpose the most important engineering tool to increase the resistance against leaching from concrete is to reduce the amount of connected capillary pores, in which transport processes can take place. For properly manufactured concrete the diffusion speed of the corresponding substances may be reduced by a factor up to 5000 compared with the free diffusion in water [7].

To investigate more closely the principal release mechanism of trace elements from hardened mortar and concrete, a special clinker was burnt from raw meal with artificially increased trace element contents in a pilot-scale rotary kiln. The cements manufactured from this clinker demonstrated element contents of up to 340 ppm for Arsenic, 1400 ppm for Chromium, 200 ppm for Molybdenum and 2000 ppm for Zinc. The leaching tests performed demonstrate similar leaching characteristics as cementitious materials made from ordinary Portland cements. For “regular” metals, such as Zinc, no significant increase in the eluted proportion occurs at pH values

that correspond to standard concrete applications ($\text{pH} > 8$). Also for Arsenic the increased contents in cements only lead to a slight rise in the eluted quantities. However, for Chromium and Molybdenum increased leaching occurs in line with higher concentrations in the cement [6]. Using the leaching of Chromium from uncrushed mortar prisms according to a trough method (64-day-test), Figure 2 shows that for the mortars investigated here a linear relationship exists between the Chromium content in the cements and the integral leached Chromium quantities. However, a deciding factor for the evaluation of these results is, that the leachable quantities are on a low level overall, and that the leaching rates decline considerably with progressing elution time. In summary these investigations confirm the large binding capacity of the hardened cement paste for trace elements. They further show that the release of trace elements from cementitious materials, even at clearly increased concentrations in the cement, is not environmentally relevant under normal application conditions, in which the natural alkalinity of the cementitious matrix is decisive for the leaching behaviour.

Figure 2. Relation between total Chromium contents in cement and the leached quantities after 64-day trough method test [6]

Intensive investigations into the behaviour of concrete admixtures have shown that these substances also are, to a great extent, rapidly adsorbed on the cement or precipitated in the pore solution [9, 10]. Further investigations on naphthalene sulphonates have shown that only monomeric sulphonates are eluted. Oligomers and polymers which form the major part of these plasticizing admixtures are immobilized in the hardened cement paste [9]. Figure 3 shows the results of trough leaching tests on hardened cement paste cylinders for test periods up to 3 days.

Figure 3. Dependence of the quantity of lignosulphonate and naphthalene sulphonate leached from hardened cement paste cylinders on time [10]

From the decrease of the release by time, it follows that with the quantities of plasticizing admixtures normally used in concrete - as a rule less than 1 wt.% as dry mass relative to the cement weight – only small quantities can be leached from impermeable concrete under practical leaching conditions.

6. EMISSION OF VOLATILE ORGANIC SUBSTANCES

Air borne emissions may be a threat to the hygiene and health of occupants in the indoor environment. Constructions made of traditional, proven building materials which are purely inorganic in nature, such as mortar, stucco, concrete, steel and glass, generally release insignificant amounts of harmful substances or none at all after installation [19]. However, today many cementitious materials are manufactured with organic additions or admixtures which may contain volatile substances, e. g. preservatives like formaldehyde, in small quantities. Figure 4 shows the cumulative amounts of formaldehyde released from cement pastes with five superplasticizers with different free formaldehyde contents.

Figure 4. Formaldehyde release of cement pastes with five superplasticizers with different free formaldehyde contents [12]

It is clear from the figure that the initially rapid release slows down considerably after one or two days and from then only extremely small quantities are released, which after seven days result in concentrations which are no longer detectable. From the course of the curves it can be concluded that there is no risk of any danger from the release of formaldehyde from cementitious building products made with concrete admixtures during the use of a building. Only under unfavourable conditions it is possible for the “maximum workplace concentration (MAK)” to be exceeded for short periods during production, e. g. in a concrete plant. However, workplace-specific measurements confirm that the formaldehyde concentration during concrete work is well within the “MAK” limit [20].

7. CONCLUSIONS

The leaching behaviour of trace elements and organic substances from cementitious materials is controlled by the degree of binding of these substances to the hardened cement paste and the pore size distribution of the cementitious matrix. The long-term leaching behaviour of substances from cementitious materials follows diffusion-controlled transport mechanism with low diffusion rates. This is especially the case for properly manufactured concrete. Therefore the most important engineering tool to minimize leaching from cementitious materials is to reduce the capillary porosity of the hardened cement paste matrix. For typical applications of organic additives or admixtures in concrete buildings the release of volatile organic substances is on a low level, and it

can be concluded that there is no risk of a nuisance or threat to the user. Cement and cementitious construction products satisfy the fundamental requirements of the European Construction Products Directive CPD and the corresponding national regulations.

HYGIENIC, HEALTH AND ENVIRONMENTAL COMPATIBILITY OF CEMENTITIOUS CONSTRUCTION PRODUCTS

M. Schneider and G. Spanka

Research Institute of the Cement Industry, German Cement Works Association, Düsseldorf,
Germany. E-mail: Sch@vdz-online.de

Dr. rer. nat. Martin Schneider

German Cement Works Association, Duesseldorf, Germany.
E-mail: sch@vdz-online.de

Dr. rer. nat. Martin Schneider studied physics in Mainz and Bonn, Germany. After 4 years of scientific work both in Bonn and in the USA, he joined the Research Institute of the Cement Industry, where he was in charge of the “Environment Protection” and “cement chemistry” sections. In 1998 he was appointed Managing Director of the German Cement Works Association, since January 2000 he is Chief Executive of the VDZ and Head of the Research Institute.

SULFATE-RESISTING PROPERTIES OF CEMENTS AND CEMENT/FLY ASH MIXTURES

M. Schneider, S. Puntke, H.-M. Sylla and K. Lipus

German Cement Works Association, Research Institute of the Cement Industry,
Düsseldorf, Germany; E-mail: pk@vdz-online.de

ABSTRACT

High-sulfate-resisting cements include low-aluminate Portland cements and *slag-rich* blastfurnace cements. Some countries also permit the use of cements containing fly ash and pozzolana as well as mixtures of cement and fly ash for producing sulfate-resisting mortar and concrete. Sulfate attack usually occurs in the soil at ambient temperatures around 9°C (average value). The investigations reported have shown that the classical sulfate-resisting cements also exhibit a high sulfate resistance at these low temperatures. However, mixtures of cement and fly ash proved to be significantly less favourable than at 20°C and did not provide high sulfate-resisting properties under such test conditions. At temperatures of less than about 15°C the damage mechanism due to a sulfate attack changes because thaumasite can form under suitable conditions. This can result in a loss in strength of the microstructure that in extreme cases leads to a complete destruction. This thaumasite formation itself is in contrast to the classical expansion reactions due to ettringite and gypsum not necessarily accompanied by expansion of the concrete, but an exclusive thaumasite formation was not observed. However, the importance of the presented laboratory tests for practical building work has not yet been adequately investigated.

1. INTRODUCTION

A high chemical resistance of the hardened binder matrix is one essential requirement for the durability of concrete. The safety concept in case of sulfate exposure which is implemented in the European concrete standard EN 206 [1] and is based on long-term practical experiences stipulates the utilisation of cement with high sulfate-resisting properties (SR criterion) and furthermore a dense concrete with a high resistance to diffusion. According to German standard DIN 1164 SR-cements are Portland cements (CEM I) with a maximum C₃A content of 3.0 % by mass and a maximum Al₂O₃ content of 5.0 % by mass as well as blastfurnace cements of type CEM III/B and CEM III/C. According to the German concrete standard DIN 1045-2 mixtures of cement and fly ash can be used as an alternative to high sulfate-resisting cements in Germany to produce concrete to resist a sulfate attack of up to 1500 mg sulfate/l in the attacking water [2]. In these cases at least 20 % by mass fly ash according to EN 450 must be added to the concrete when using Portland cement, Portland-limestone cement or Portland-slag cement, and at least 10 % by mass fly ash must be added when using Portland-burnt shale cement and blastfurnace cement of type CEM III/A. The water/binder ratio [w/(c+0.4f)] must be ≤ 0.50. The measures to produce sulfate-resisting concrete in Germany are summarised in (Table 1). In Germany, due to the implementation of these measures, damage caused by sulfate attack are nowadays practically unknown.

Table 1. Measures required in Germany to produce concrete with high sulfate resistance according to DIN EN 206-1/DIN 1045- 2

Exposure class [mg SO ₄ ²⁻ /l]	Degree of attack	Measures
< 200	not attacking	none
XA1 200 – 600	weak	water/cement ratio ≤ 0.60; minimum compressive strength C25/30
XA2 600 - 1500	moderate	water/cement ratio ≤ 0.50; minimum compressive strength C35/40; SR-cement or mixture of CEM II/A-T, CEM II/B-T, CEM III/A and minimum 10 % by mass fly ash or CEM I, CEM II/A-S, CEM II/B-S, CEM II/A-LL and minimum 20 % by mass fly ash
XA2 1500 - 3000	moderate	water/cement ratio ≤ 0.50; SR-cement; minimum compressive strength C35/40
XA3 > 3000	strong	water/cement ratio ≤ 0.45; SR-cement; minimum compressive strength C35/40; sealing

Within the framework of quality control it is not practicable to test the sulfate-resisting properties of cements by testing mortar and concrete pieces under realistic conditions. Such tests would take too much time. Tests that provide representative guide values are therefore required so that the desired information can be obtained rapidly from “accelerated” laboratory tests. To test the sulfate resistance against an external sulfate attack, usually expansions of defined mortar specimens are measured. Such test methods have to cover the “chemical resistance” of the cement to the chemical reaction with sulfate ions, i.e. the “internal sulfate resistance” and the “physical resistance” of the mortar to the penetration of sulfate ions into the sample, i.e. the “external sulfate resistance” [3,4].

In Germany the Wittekindt method [5] and the so-called SVA method, adopted by the committee of experts at the German Institute for Construction Technology (SVA) [6], are the common methods to test sulfate-resisting properties of cements. A CEN method, named after the CEN TC51 Technical Committee [7], is the preferred performance test in many other European countries. Results of several investigations showed that the test results of all three performance tests often differ because of the great scatter of the measured values. One target of the recent investigations of the FIZ (Research Institute of the Cement Industry) of the VDZ (German Cement Works Association) was to compare these three test methods using different types of cement and cement/fly ash mixtures.

Concrete is usually exposed to sulfate attack when it comes into contact with groundwater containing sulfate. The temperature of the soil is about 9°C on average and therefore quite different from the temperature of 20°C regularly used in the laboratory tests. Another aim of the investigations was therefore to clarify the influence of the test temperature on the test results of mortars with cements and cement/fly ash mixtures.

A special form of sulfate attack has been identified in over 80 cases in Great Britain during the last 15 years. In these cases harmful thaumasite had been formed under wet and cold conditions and in the presence of carbonate [8]. Investigations at the VDZ had the further task to understand the causes and mechanisms of this harmful thaumasite formation, depending on the different cement and cement/fly ash mixtures used.

2. EXPERIMENTAL WORK

2.1 Test methods to determine the sulfate-resisting properties of cements

In Germany, the Wittekindt, the SVA and the CEN method are accelerated test methods that have been used for investigations in different research projects as well as comparative test programmes at the VDZ over the past years.

The Wittekindt method has the longest tradition and has been used for many years in a slightly modified form at the VDZ. Flat mortar bars of $1 \times 4 \times 16 \text{ cm}^3$ are produced with standard sand in accordance with the German cement standard DIN 1164 of 1958 with a water/cement ratio of 0.60. The SVA method is quite similar to the Wittekindt method. The flat mortar bars are produced in accordance with European cement standard EN 196-1 with a water/cement ratio of 0.50. The CEN method is derived from the work of CEN TC 51 over the last 10 years with the target to be adopted in a common European standard. For this method $2 \times 2 \times 16 \text{ cm}^3$ mortar bars are produced in accordance with EN 196-1 with a water/cement ratio of 0.50. Further details of the three test methods are shown in Table 2.

Table 2. Comparison of sulfate resistance tests: Wittekindt, SVA and CEN method

Test conditions	Method		
	Wittekindt	SVA	CEN

In mould [d]	1	2	1
Preliminary storage [d]	13 days in H ₂ O	12 days in Ca(OH) ₂	27 days in H ₂ O
Sulfate storage [% Na ₂ SO ₄]	4.4	4.4	2.4
Test period/storage time [d]	56 days	91 days	not fixed
SR-criterion (expansion) [mm/m]	≤ 0.5	≤ 0.5	not fixed

In recent years, the sulfate-resisting properties of approximately 100 cements and cement/fly ash mixtures were assessed according to the test methods described.

The criterion for high sulfate-resisting properties of a cement is the relative change in length of the mortar bars, taken by the difference in the change of length between sulfate storage and water/calcium hydroxide storage after a certain storage period.

The accelerated test procedures must usually take place at a constant temperature of 20°C. Practical experience shows that sometimes construction parts are affected by sulfate attack, if they are located within the soil. There, sulfate-enriched ground water can come into contact with concrete structures. The average ground temperature in central European countries is about 9°C, which is different from the 20°C used in the test methods. Furthermore, due to thermodynamic calculations the known expansive minerals ettringite, gypsum and thaumasite are more stable at low than at higher temperatures. Therefore many of the reported investigations were also performed at 8°C.

2.2 Microstructural investigation

Besides the expansion measurements also the microstructure of the mortar specimens has been examined. By means of optical microscopy, scanning electron microscopy (SEM) combined with energy dispersive microanalysis (EDS), and X-ray diffraction (XRD), the mineralogical and chemical composition of the reaction products inside the deteriorated structures of the test pieces were analysed. From these results information could be obtained about the deterioration mechanisms of the sulfate attack for different cements and binder systems.

3. RESULTS

3.1 Comparison of the test methods

To compare the three test methods mentioned, samples of different cements and binder mixes were prepared. Therefore high sulfate-resisting cements (CEM I-SR and CEM III/B-SR), ordinary Portland cements and mixtures made of ordinary Portland cements combined with fly ashes (from melting and from dry chamber firing systems), blastfurnace slag, limestone meal and burnt oil-shale were used. The measurements showed that the specimens tested according to the Wittekindt and the SVA methods led to comparable results (Table 3), taking into account the different storage period.

Table 3. Expansion of test pieces made of ordinary Portland cement/granulated blastfurnace slag mixtures according to different test methods; cements: PC 1 with 7.7 % by mass C₃A, PC 2 with 14.3 % by mass C₃A; slags: ggbs1 with 12 % by mass C₃A, ggbs 2 with 17 % by mass C₃A

Binder mix	Expansion in mm/m		
	Wittekindt (56 d)	SVA (91 d)	CEN (140 d)
PC 1	0.61	0.54	0.18
PC 1 + 20% ggbs 1	0.50	0.65	0.23
PC 1 + 20% ggbs 2	0.68	0.68	0.29
PC 1 + 55% ggbs 2	0.45	0.48	0.18
PC 2	0.85	0.82	0.18
PC 2 + 20% ggbs 1	0.67	0.69	0.16
PC 2 + 20% ggbs 2	0.78	0.80	0.27
PC 2 + 55% ggbs 2	0.13	0.23	0.14

However, the Wittekindt method showed a larger spread and thus a clearer differentiation of the behaviour of the individual binder types. This can be explained by the higher w/c ratio. The test pieces made in accordance to the SVA method were denser because of the lower w/c ratio and took up less sulfate ions per time. As a consequence, it takes longer for mortar bars under the SVA method to come to the same expansion as under the Wittekindt method. The CEN method was proved to be the least suitable test for the assessment of binders with an accelerated time scale test. As compared with the other methods, fewer sulfate ions were taken up by the test specimens,

because they were as dense as the SVA pieces but had a smaller surface/volume ratio, were hydrated longer before the onset of sulfate exposure, and were stored at an SO_4 concentration in the test solution which was almost 50% lower.

Severe scattering of the expansion values was found in inter-laboratory tests using the three methods, even after the test instructions were precisely specified to ensure compatible test conditions. The CEN working group came to a comparable result for the CEN test method.

Because of the inadequate differentiation between individual cements and the inadequate comparability of the test results from different laboratories it has not yet been possible to recommend any test method for standardization. This will require further basic physical and chemical investigations into the sulfate resistance of mortar and concrete.

3.2 Sulfate resistance against conventional sulfate attack

3.2.1 Sulfate-resisting properties of standardized cements

Figure 1 shows the expansion values of test pieces of five different cements stored, according to the Wittekindt method, but at 8°C . The samples of both SR-cements expanded only insignificantly during 56 days and fulfilled the assessment criterion as expected. Based on that assessment even the samples of the cement with 8 % by mass C_3A show a high sulfate-resisting behaviour.

Figure 1. Expansion of $1 \times 4 \times 16 \text{ cm}^3$ mortar prisms made from different cements; Wittekindt-test conditions at 8°C

Table 4 shows the expansion values of flat mortar samples made from different cements tested at 8°C and 20°C . The ordinary Portland cements and the Portland limestone cement did not fulfil the requirements for high sulfate resistance, neither at 20°C nor at 8°C . The differences between the values of the 8°C and 20°C measurement are small and within the range of the uncertainty of the measurement [9,10].

Table 4. Expansion of different cements tested according to the Wittekindt method

	Expansion after 56 d storage at 8°C [mm/m]	Expansion after 56 d storage at 20°C [mm/m]
CEM I 7,7% C ₃ A	0.54	0.61
CEM I 14,3% C ₃ A	0.93	0.85
CEM I 12% C ₃ A	0.95	0,88
CEM I - SR	0.11	0.13
CEM II/A-LL	1.1	0.91
CEM III/B - SR	0.04	0.07

3.2.2 Composite cements and cement/fly ash mixtures with high sulfate-resisting properties

Investigations on Portland cement/fly ash mixtures have shown that dry chamber firing ash with fairly low content of glass and Al₂O₃ tends to exhibit a more favourable behaviour than fly ash from melting chamber firing systems with higher levels of glass and Al₂O₃ (Figure 2).

Figure 2. Expansion of test pieces made with mixtures of Portland cement and fly ash (tested by Wittekindt method, 56 days storage at 20°C in 29.800 mg sulfate/l; Portland cements: PC1 and PC2; fly ashes: MCA from melting chamber firing, DCA from dry chamber firing)

Mortar specimens made from mixtures of cement and fly ash exhibited significantly higher expansions at 8°C than at 20°C under the various test methods. Ordinary Portland cements, Portland-limestone cements and blastfurnace cements behaved therefore differently. The test criterion of the Wittekindt test could not be fulfilled by cement/fly ash mixtures at 8°C (Figure 3).

Figure 3. Expansion of flat mortar prisms made of mixtures from cement and fly ash (SFA) (tested according to Wittekindt method, 56 days' storage in 29800 mg sulfate/l, varying storage temperature)

These results are not affected by the k-factors, which was for these experiments $k = 1.0$ and $k = 0.4$, respectively

Additional investigations were also carried out at 1500 mg sulfate/l to conform with the use of fly ash permitted in the German standard, i.e. at significantly lower sulfate concentrations than in the usual laboratory tests. The behaviour of the cement/fly ash mixtures in such low concentrated sulfate solutions was different from that at higher concentrations. Mixtures with at least 20 % by mass fly ash showed here significantly higher sulfate-resisting properties than the pure cement. In particular, the test pieces made of mixtures with 40 % by mass fly ash exhibited only slight expansion and deterioration even after one year's sulfate storage.

3.3 Sulfate resistance against the thaumasite form of sulfate attack (TSA)

A research project to investigate the principles and mechanisms of thaumasite formation has been carried out at the VDZ [11]. The behaviour of various cements was examined with focus on limestone-containing cements and cement/fly ash mixtures on the one hand. On the other hand concrete samples made of carbonate-free cements and limestone-containing aggregates were investigated. Some results are shown in Table 5.

Table 5. Expansions of different cements and cement-limestone mixtures after 56 days storage in sulfate solution at 8°C (Wittekindt method), limestone 1 containing 92% CaCO_3 , limestone 2 containing 84% CaCO_3

Cement	Expansion [mm/m]	Cement	Expansion [mm/m]
CEM I (12 % C_3A)	0.93	CEM I - SR	0.08
+ 5 % CaCO_3	1.4	+ 5 % limestone 1	0.22
+ 15 % CaCO_3	2.0	+ 15 % limestone 1	0.16
+ 5 % limestone 1	0.45	CEM III/B - SR	-0.02
+ 15 % limestone 1	1.5		
+ 5 % limestone 2	0.34		
+ 15 % limestone 2	1.7		
		+ 5 % limestone 1	-0.01
		+ 15 % limestone 1	-0.02

Both SR-cements, CEM I and CEM III/B showed the same small expansion behaviour with or without an addition of limestone meal. The ordinary Portland cement (non-sulfate-resisting) behaved differently. An addition of 15 % by mass limestone meal increased the expansion clearly. An addition of only 5 % by mass limestone had no significant effect on the expansion.

To investigate the reaction mechanisms of the sulfate attack the mortar bars had been stored in sulfate solution longer than necessary for the assessment test. After 56 days the specimens were only partly affected or showed no deterioration. However, within 180 days, and even more after 360 days, some samples were totally decomposed (Table 6).

In addition to the tests with high sulfate concentration also tests with lower concentration were performed. Table 6 also shows that within a year even at low sulfate concentration tests specimens were severely deteriorated. Over this long test period only the two SR-cements showed sulfate-resisting behaviour.

Table 6. Degree of Damage of mortar bars made with different cements and mixtures of cement and limestone meal after storage in sodium sulfate solution at 8°C

Binder mix	Degree of damage after storage in sulfate solution			
	29800 mg SO ₄ /l			1500 mg SO ₄ /l
	56 days' storage	180 days' storage	360 days' storage	360 days' storage
CEM I (12 % by mass C ₃ A)	partial	total	total	severe
CEM I + 15% mass limestone	partial	total	total	very severe
CEM I (8 % by mass C ₃ A)	none	partial	total	very slight
CEM I + 15 % by mass limestone	none	partial	total	severe
CEM I-SR	none	none	none	none
CEM I-SR+ 15 % by mass limestone	none	none	partial	none
CEM II/A-LL	partial	total	total	severe
CEM II/A-LL + 20 % by mass fly ash	partial	total	total	partial
CEM II/A-LL + 30 % by mass fly ash	partial	total	total	slight
CEM II/A-LL + 40 % by mass fly ash	partial	total	total	very slight
CEM III/B-SR	none	none	none	none
CEM III/B-SR + 15 % by mass limestone	none	none	none	none

Expansion examinations did not allow to decide if a test piece was deteriorated due to ettringite, gypsum or thaumasite formation. Only by microscopic investigations of the structure, aligned with microanalytical and diffractometric techniques a characterisation of the secondary reaction products was possible. The observation of the deterioration process on test pieces made of Portland-limestone cements showed that after an initial expansion and formation of first cracks, due to secondary ettringite and gypsum, the specimens decomposed faster into fine components at 8°C than at 20°C. By using scanning electron microscopic analysis thaumasite was found besides ettringite in such samples (Figure 4). However, the mortar investigations did not show significant amounts of thaumasite, when high sulfate-resisting cements were used.

4. CONCLUSIONS

Many countries have had regulations in force for many years for the production of sulfate-resistant mortars and concretes and for the requirements of sulfate-resisting cements. Various test methods for the high sulfate-resisting properties of cements are based primarily on expansion measurements.

Continued...

Figure 4. Deteriorated 4 x 4 x 16 cm³ prism (a); powder x-ray diffraction pattern of the deteriorated material (b); scanning electron micrograph of thaumasite crystals inside a deteriorated region (c) and energy dispersive x-ray spectrum of this area (d); sample after 400 days storage at 8°C in sodium sulfate solution of 29800 mg SO₄/l.

In the accelerated test methods examined recently by the VDZ, mortar prisms were stored at 20°C in solutions containing sulfate and then tested at some defined time. The test results reported exhibit good repeatability within a laboratory, but the comparability between different laboratories is not satisfactory because of the great scatter of the measured values. For this reason it has so far not been possible to standardise any of the methods under discussion.

The SR-cements tested, i.e. Portland cements with low C₃A content and blastfurnace cements which contain at least 66 % by mass blastfurnace slag, fulfil the performance test criterion of the accelerated Wittekindt and SVA method at 20°C as well as at lower temperature (8°C). These cements are therefore also suitable for structures which are exposed to a possible sulfate attack of exposure classes XA1 to XA3 as defined in EN 206-1 at low temperatures. Mixtures of cement and fly ash, which according to German DIN 1045-2 can be used for a sulfate attack up to 1500 mg/l, fulfil the performance test criterion of the Wittekindt and SVA method at 20°C generally. However, at 8°C these mixtures showed substantially higher expansions and missed the criterion. Only at low sulfate concentration, mixtures of cement and fly ash showed better sulfate-resisting properties than the pure cement also at low temperature. The importance of these laboratory investigations for building practice has not yet been sufficiently investigated.

Because a number of cases of thaumasite damage were found at the end of the 90s in Great Britain the basic material requirements for possible thaumasite formation were investigated systematically in a VDZ research programme. The required carbonate was provided as a cement constituent in the form of limestone meal. Not only secondary ettringite but also thaumasite was formed in many test pieces regardless of the limestone used. *This removed all the strength* from the damaged parts. Even the use of at least 20 % by mass fly ash led to no increase in sulfate resistance in these cases. However, the mortar investigations did not show significant amounts of thaumasite, when high sulfate-resisting cements were used for the mortar bar production.

Clarification of the basic relationships of the sulfate-resisting properties of cements and cement/fly ash mixtures, at low temperatures, including in the presence of carbonate, will form the subject of more extensive investigations.

USE AND REACTIVITY OF CEMENT MAIN CONSTITUENTS IN GERMANY

Martin Schneider, Stefan Puntke, Christian Schneider and Christoph Müller

Research Institute of the Cement Industry, German Cement Works Association, Düsseldorf, Germany. E-mail: Germany; E-mail: pk@vdz-online.de, sch@vdz-online.de

ABSTRACT

In Germany, more than 93 % of the blended cements are produced by using granulated blastfurnace slag or limestone as cement main constituents, while natural pozzolana and burnt shale are still of minor or local importance. Beyond the traditional main constituents, the new European cement standard opens the possibility to use other main constituents such as calcareous fly ash, limestone with higher TOC content, artificial pozzolana and silica fume. Since the introduction of the European standard EN 197-1 in the year 2000, a total of 27 cement types are described and defined concerning composition, specification and conformity criteria.

Major research activities have been initiated by the German Cement Works Association to deepen the understanding of the role of cement main constituents during hydration reactions and their influence on the properties of cement. Selected results are presented, referring to the application of granulated blastfurnace slag, calcareous fly ash and limestone.

1. INTRODUCTION

Traditionally, Portland cements are the most used cement types in Germany. In the past years an increasing amount of other main constituents besides clinker have been used for cement production. As a consequence, the amount of Portland Cement in proportion to the total cement production decreased from over 75 % in the year 1995 to some 62 % in 2000. In Germany the most frequently used constituents are granulated blastfurnace slag and limestone with natural pozzolana and burnt shale being used less often. According to the EN 197-1 an extended range of materials that has not yet been established in Germany can be used for cement production. The European cement standard covers a range of 27 different cement types. However, not all of them are of local importance for reasons of availability.

Specifications concerning the composition of cement main constituents, as well as other criteria are described in the EN 197. These specifications are proven to be sufficient for cement production of constant quality, fulfilling the demands of the European cement and concrete standards. The knowledge of further physical, chemical and mineralogical parameters can help to evaluate the quality of the cement constituents to a higher degree and with a greater accuracy. This understanding allows an effective improvement of the material properties by selection of specific processing methods.

2. GENERAL REQUIREMENTS FOR CEMENT MAIN CONSTITUENTS

The majority of specifications according to the EN 197-1 are related to material properties and correspond to the description concept [1]. Only a few exceptions can be classified as real

performance criteria. Basic properties as well as the requirements of the EN 197-1 are described below for the use of granulated blastfurnace slag (GBS), calcareous fly ash (CFA), and limestone, respectively.

2.1 Granulated blastfurnace slag

In the year 2000, more than 66 % out of 7,53 Mio t blastfurnace slag were granulated and almost completely used as cementitious materials in Germany [2]. Middle European granulated blastfurnace slags usually consist of more than 95 % glassy particles. The EN 197-1 requires a glassy slag content of at least two-thirds by mass. Chemically, the slag has to consist of at least two-thirds of CaO, MgO and SiO₂, while the ratio of (CaO + MgO)/(SiO₂) should exceed 1,0. The fulfilment of these requirements is seen to be the prerequisite for the slag to possess latent hydraulic properties and so be suitable for cement production.

Additional chemical parameters have been established in practice as hydraulic activity indexes to describe slag properties. The application experience reveals that a simple consideration of the CaO, MgO and SiO₂ content is not always sufficient. High amounts of Al₂O₃ can enhance the reactivity of slag, whereas high TiO₂ and MnO contents can reduce its hydraulic properties. Moreover, the glass content of GBS plays a key role in view of the reactivity. Evidently, not only the absolute glass content but also the glass structure, which can be influenced by the chemistry as well as by the quenching conditions during granulation, are of importance.

2.2 Calcareous fly ash

Due to their chemical composition, German lignite fly ashes basically correspond to the category of calcareous fly ash according to EN 197-1. They may be utilized as cement main constituents, if they contain at least 10,0 wt-% reactive CaO. If the proportion of reactive CaO does not exceed 15,0 wt-%, the ash has to contain at least 25,0 wt-% reactive SiO₂. Calcareous fly ash containing more than 15,0 wt-% reactive CaO has to achieve a compressive strength of 10,0 MPa according to EN 196-1. For this test the fly ash has to be adequately ground and must replace the cement in the mortar by 100 %. The soundness of calcareous fly ash shall not exceed 10 mm when tested in accordance with EN 196-3 using a mixture of 30 wt-% of fly ash and 70 wt-% of a CEM I cement.

In Germany 8 Mio t calcareous fly ash per year are produced, which are predominantly used to recultivate the exploited coal mining fields and mines. About 10 % of the ashes are available for alternative uses. Actually, German lignite fly ashes play only a minor role as cement main constituents, although developments of cementitious binders containing CFA have been in progress during the past five decades in Germany. In 1972 fly ash was established as a cement component by the standards of Eastern Germany [3, 4]. For the past 4 years, selected calcareous fly ashes have been certified as concrete additions [5].

2.3 Limestone

In Germany Portland-limestone cements with a limestone content up to 20 wt-% were developed by the cement manufacturers during the 1980's and were established then as cements with technical approval. After practical experience of more than 10 years in building construction and structural engineering they were included in the national standard DIN 1164-1:1994 as CEM II/A-L. Limestone used in these cements meets the following requirements according to EN 197-1:2000:

- The calcium carbonate (CaCO₃) content calculated from the calcium oxide content shall be at least 75 % by mass.
- The clay content, determined by the methylene blue test in accordance with EN 933-9, shall not exceed 1,20 g/100 g. For this test the limestone shall be ground to a fineness of approximately 5000 cm²/g determined as specific surface in accordance with EN 196-3 (Blaine).

- The total organic carbon (TOC) content shall not exceed 0,20 wt-%. This type of limestone is marked with the letter „LL“ according to EN 197-1:2000. Therefore these Portland-limestone cements are now called CEM II/A-LL.
- The performance of concrete manufactured from Portland-limestone cement CEM II/A-LL, in terms of fresh and hardened concrete properties and durability, has been verified by extensive laboratory investigations and practical experience. In particular the freeze-thaw resistance of concretes, which fulfil the minimum requirements of the exposure class XF4 (freeze/thaw attack on concrete with high water saturation with de-icing salt or sea water) according to the German concrete standard DIN 1045-2, is generally high and can be compared to that of Portland cement concrete. In road construction Portland-limestone cement CEM II/A-LL may be used for the same applications as Portland cement. This was taken into account accordingly in drafting the supplementary technical terms of contract and guidelines for structural engineering (ZTV-ING). In general the strength development of concretes using Portland-limestone cement CEM II/A-LL is comparable to concretes with Portland cement CEM I of otherwise identical composition [6].

With the introduction of EN 197-1 further Portland-limestone cements have been standardized in addition to the CEM II/A-LL cements. Now it is possible to use limestone contents of up to 35 wt-% (CEM II/B-LL) as well as limestone with TOC contents of up to 0,50 wt-%. Portland-limestone cement with increased TOC contents in the limestone is labelled with the letter “L”.

Building practice experience with Portland-limestone cements of up to 35 wt-% is not available in Germany. Currently they may not yet be used for concrete with high resistance to freeze thaw or freeze thaw with de-icing salt.

3. ENHANCEMENT OF APPLICATION POTENTIAL

3.1 Granulated blastfurnace slag

With the aim to gain information about the glass structure of GBS and its influence on hydraulic activity, a number of industrial blastfurnace slags were examined in their as-received condition, after a subsequent laboratory granulation treatment, and after dotation with selected oxides. The samples were examined by differential thermal analysis, high-temperature X-ray diffraction, as well as optical and electron microscopy with cathodoluminescence devices.

The thermoanalytical results reveal characteristic differences even between slags of similar chemical composition (Figure 1). The curves exhibit up to 3 more or less overlapping endothermic signals caused by devitrification reactions in the range between 800 and 1000 °C.

High-temperature X-ray diffraction offers the opportunity to assign the devitrification peaks to the formation of crystalline products (Figure 3). Melilite, $\text{Ca}_2(\text{Mg},\text{Al})(\text{Al},\text{Si})_2\text{O}_7$, is the final main product of each of the examined slags. In some GBS, merwinite, $\text{Ca}_3\text{MgSi}_2\text{O}_8$, is formed as an intermediate product. In some cases merwinite stays stable until the devitrification is completed, while in other cases it is diminished with increasing temperature to the benefit of the formation of other phases as transition products.

Merwinite can also occur in industrial granulated blastfurnace slags without any further thermal treatment. These primarily formed merwinite crystals usually appear as segregation structures within the glassy particles and can be easily detected by their cathodoluminescence (Figure 2).

Figure 1. Devitrification peaks of different granulated blastfurnace slags measured by differential thermal analysis

A reasonably positive influence can be deduced from the tendency of a GBS to form merwinite [7]. Two reasons are considered to be crucial for this effect. One is the increase of the alumina content of the glass in the immediate vicinity of the merwinitic areas, as can be detected by EDX-analysis in the SEM. The other is a change of density by the formation of merwinite ($\rho = 3,3 \text{ g/cm}^3$) in comparison with the glass ($\rho = 2,9 \text{ g/cm}^3$). As a consequence, a microporosity with a locally increased surface area occurs and enhances the slag reactivity.

Figure 2. scanning electron microscopic pictures of merwinitic domains within GBS 3

Figure 3. Devitrification peaks of different granulated blastfurnace slags measured by high-temperature X-ray diffraction

3.2 Calcareous fly ash

German lignite coal deposits are located mainly in three major areas called the Rhenish, the Lusatian and the Middle German area. Although the composition of the fly ashes derived from the corresponding power plants is dependent on the geological conditions of the coal deposits, large chemical variations can be found even within single locations. For the current research activities one fly ash from the Rhenish area and one from the Lusatian area were chosen out of a larger set of ashes. Their chemical and mineralogical compositions can be considered as representative for the respective regions (Table 1).

Each of the examined lignite fly ashes contains less than 25 wt-% reactive SiO_2 . However the content of reactive CaO usually exceeds 15,0 wt-%. Compressive strength tests of hydrated mortars containing 100 % CFA show that 10 MPa after 28 days, which the EN 197-1 requires, are not achieved by all fly ashes.

Table 1. Chemical composition of the representative CFAs from the Rhenish and the Lusatian area chosen for the examinations (values in wt-%)

	BFA R1	BFA L1
SiO ₂	34,80	38,84
Al ₂ O ₃	3,80	8,41
TiO ₂	0,39	0,73
P ₂ O ₅	0,02	0,03
Fe ₂ O ₃	11,89	22,79
Mn ₂ O ₃	0,31	0,29
CaO	31,65	18,76
MgO	8,52	6,53
SO ₃	7,04	2,70
K ₂ O	0,35	0,72
Na ₂ O	1,21	0,17
loss on ignition	1,76	0,66
reactive CaO	26,99	17,29
reactive SiO ₂	7,79	12,79
free lime	8,85	0,34

Particularly the Rhenish fly ash contains higher amounts of free lime. Also free magnesia (periclase) can be detected by X-ray diffraction. To consider the influence of expansive components entirely, several soundness tests on cements containing up to 30 % CFA were applied (figure 4).

Figure 4. Results of different soundness tests on cements containing CFA

All cements show expansions lower than 10 mm when tested according to the Le Chatelier method. The limit of 8 mm/m under autoclave test conditions is exceeded by the cement containing 30 % Rhenish lignite fly ash. After long term water storage conditions cement mortar bars exhibited an

increase of expansion, with the increase of CFA content. The addition of 30 % Rhenish CFA resulted in an expansion of 0,26 mm/m after 270 days compared with 0,04 mm/m for 30 % Lusatian CFA and –0,01 mm/m for the plain Portland cement.

The examination of the development of compressive strength, according to EN 196-1, showed that the replacement of Portland cement clinker by CFA caused strength reductions that were partially compensated during progress of hydration. The strength level of the reference Portland cement after 28 days could only be reached if not more than 10 % of the cement was substituted by CFA.

It is known that the contribution of fly ash to the strength development of hydraulic binders can be increased by mechanical treatment [8 – 13]. As the specific energy consumption during grinding proved to be low for lignite fly ashes compared with clinker, the ashes were ground to fineness levels of 3500 cm²/g and > 6000 cm²/g, respectively. The mortar strength development of cements containing 20 % of unground and ground CFA is shown in figure 5. Again, the ashes caused strength losses after 2 days of hydration in a range of 8 to 13 %. The use of Lusatian CFA initially proved to cause greater strength reductions than the use of Rhenish fly ashes. In contrast an increase of relative compressive strength occurred already after 7 days for the cements containing ground and unground Lusatian CFA, whereas a significant positive strength contribution of Rhenish fly ash could be detected after hydration times longer than 28 days. An enhancing effect of grinding on the strength contribution was found to be more distinct for the Rhenish fly ash than for the Lusatian fly ash.

Figure 5. Relative compressive strength development of cement mortars containing 20 % Rhenish (R1) and Lusatian (L1) CFA in comparison with the Portland cement. The ashes were used in the as-received condition and ground to different values of fineness

3.3 Limestone

To reach the same compressive strength of concrete using CEM II-LL, in comparison to concrete with Portland cement CEM I, and of otherwise identical composition, the fineness of the clinker has to be increased. Increasing the fineness of the limestone without also increasing the clinker fineness has no significant influence on the compressive strength (figure 6).

Figure 6. Compressive strength of Portland-limestone cements CEM II/B-LL with limestone contents of 30 wt-% depending on the fineness of clinker and limestone (values in cm²/g in accordance with EN 196-6 (Blaine))

Using separate grinding and subsequent blending of clinker and limestone, the mechanical requirements of EN 197-1 for cements of the strength classes 32,5 N (compressive strength: 7 d $\geq 16,0$ MPa; 28 d $\geq 32,5$ MPa) and 32,5 R (compressive strength: 2 d $\geq 10,0$ MPa; 28 d $\geq 32,5$ MPa) have been reached using clinker with a fineness between 3000 and 4000 cm²/g and a specific surface of the limestone of 6000 cm²/g and 7000 cm²/g respectively. The specific surfaces of the Portland-limestone cements including calcium sulfate vary between 4080 and 5100 cm²/g. It can be seen in figure 7 as well that increasing the fineness of the limestone only leads to a slight increase of the early strength, but shows no significant increase of the compressive strength after 28 d.

The results of investigations on the freeze-thaw resistance of concrete from laboratory-made Portland-limestone cements with limestone contents of 20 and 30 wt-%, respectively, are shown in figure 7. The concretes demonstrated only minor scaling during the freeze-thaw test and thereby demonstrated a high freeze thaw resistance. The scaling of the concretes with 30 wt-% of limestone as a cement main constituent was higher than in Portland-limestone cements with up to 20 wt-% of limestone. However, it must be noted that the strength of these concretes was approximately 15 % lower than that of the reference concretes with Portland cements. In these investigations limestone with TOC $\leq 0,20$ wt-%, $0,20$ wt-% $<$ TOC $\leq 0,50$ wt-% and TOC $> 0,50$ wt-% have been used as a cement main constituent. Until now, no significant correlation between TOC and the scaling of concrete in laboratory investigations was established, but concretes using Portland-limestone cements with TOC $\leq 0,20$ wt-% always showed high frost resistance.

Apart from this, other investigations have shown that the use of up to 25 wt-% of limestone, as a cement main constituent, shows no significant negative influence on the resistance of concrete against the penetration of chlorides [14]. Slightly increased depth of carbonation has to be expected.

Figure 7. Freeze-thaw resistance of concretes made with Portland cement and Portland-limestone cement containing 20 and 30 wt-% limestone as a cement main constituent

4. CONCLUSIONS AND SUMMARY

A major aim of the activities in the Research Institute is to verify and to improve the usability of cement main constituents based on the extended range of standardized cements according to EN 197-1. For reasons of availability of materials the investigations are focused on granulated blastfurnace slag, calcareous fly ash and limestone.

The use of GBS as a cement main component has been well established over the past decades. However, a reliable prediction of the slag reactivity can only be accomplished if further properties exceeding the requirements of the EN 197-1 are taken into account. Besides the chemical composition and the glass content, the glass structure can act as a supplementary criterion to describe GBS properties. The morphology, as well as the glass composition, can be modified by the nucleation of crystalline segregations as merwinite. The tendency to form merwinite has been proven to be an indicator for enhanced slag reactivity.

The replacement of clinker by calcareous fly ash, derived from different German power plants, was found to decrease the compressive strength of cement especially after short hydration times. Continuous hydration leads to a compensation of the strength loss as latent hydraulic or pozzolanic particles within the ashes contribute to the cement strength development. An additional reduction of the initial strength loss can be achieved by grinding the ash to increased fineness. Sufficient soundness properties of cement are given for CFA contents up to 20 wt-%.

Recent investigations on Portland-limestone cements with more than 20 wt-% limestone showed that the performance of comparable Portland cements can be maintained if the cement fineness is increased. Apparently the fineness of the clinker is of more significant influence on the compressive strength development than the fineness of the limestone. Although building practical experience with these cements is not yet available in Germany, it can be presumed that Portland-limestone cements (CEM II/B-LL) and Portland-composite cements (CEM II/B-M (S-LL)) will be suitable for usual external components and structures of building construction, under the environmental exposure conditions given in Germany. Durability criteria such as resistance against frost and chloride diffusion are considered to be fulfilled by concretes made with Portland-limestone cements containing up to 30 wt-% limestone. High TOC-contents of up to 0,50 wt-% in the limestone do not seem to have a deteriorating influence on frost resistance. The Research Institute is conducting several research projects to confirm these presumptions.

Further investigations are planned to optimize the granulometric properties of cement main constituents. It is known that the strength development, as well as other properties of concrete, can be improved if the most dense grain structure is achieved by taking into account the grain fineness, grading and grain shape [15, 16]. A matrix optimization by adjusting the grain size distribution in consideration of the grain shapes promises further improvements in application of cementitious main constituents.

USE AND REACTIVITY OF CEMENT MAIN CONSTITUENTS IN GERMANY

Martin Schneider, Stefan Puntke, Christian Schneider and Christoph Müller

German Cement Works Association, Research Institute of the Cement Industry, Düsseldorf,
Germany; E-mail: pk@vdz-online.de, sch@vdz-online.de

Dr. rer. nat. Martin Schneider

Dr. rer. nat. Martin Schneider studied physics in Mainz and Bonn, Germany. After 4 years of scientific work both in Bonn and in the USA, he joined the Research Institute of the Cement Industry, where he was in charge of the “Environment Protection” and “Cement Chemistry” sections. In 1998 he was appointed Managing Director of the German Cement Works Association, since January 2000 he is Chief Executive of the VDZ and Head of the Research Institute.

Dipl.-Ing. Stefan Puntke

Dipl.-Ing. Stefan Puntke studied mineralogy and material science in Darmstadt, Germany and Orléans, France. After 7 years of work in the cement industry both in Germany and in France, he joined in January 2000 the Research Institute of the Cement Industry, where he is the head of the Cement Chemistry department.

CHEMICAL REACTION OF FLY ASH

H.J.H. Brouwers and R.J. Van Eijk

Department of Civil Engineering, University of Twente, P.O. Box 217, 7500 AE Enschede,
The Netherlands. E-mail: h.j.h.brouwers@ctw.utwente.nl

ABSTRACT

In a previous paper, Brouwers and Van Eijk [1] presented a theoretical study on the dissolution (reaction) of pulverised powder coal fly ash. This fly ash was modelled as hollow spheres, and a shrinking core model was derived for these hollow spheres that contain two regions (an outer hull and an inner region). The obtained analytical equations were applied to the dissolution experiments by Pietersen [2, 3], yielding reaction rates at various temperatures and pH for two class F fly ashes. Based on the observed trends, in the present paper a reaction mechanism is proposed for the glass phase which accounts for the oxide composition of the fly ash (and that is applicable to slags as well). Finally, using the reaction product, the following thermodynamic properties of the studied fly ashes are derived: the free energy, enthalpy and entropy of reaction. The values obtained are in line with those of known substances: silica and an aluminosilicate ($2\text{SiO}_2\cdot\text{Al}_2\text{O}_3$).

1. INTRODUCTION

The ability of fly ash and ground granulated blast furnace slag to react depends strongly on the alkali content and temperature of the ambient solution (Fraay et al. [4], Xu and Sarkar [5], Taylor [6], Hewlett [7], Song and Jennings [8], Song et al. [9]). To investigate the reactivity of fly ash, Pietersen [2, 3] performed dissolution experiments with two pulverised coal fly ashes. They were dissolved in sodium hydroxide (NaOH) solutions of pOH 0.3, 0.6 and 1, and at various temperatures. The two fly ashes originate from two different power plants and have broad and mutually different particle size distributions. One power plant was a “wet-bottom” type plant that operates at 1800 °C (“EFA”); the other FA originates from a low NO_x furnace plant (“LM”). For the dissolution experiments the particles were separated into a fraction of low density (“cenospheres”) with a density smaller than 1400 kg/m³ and in a fraction of high density (“solid spheres”) with a density of 2300-2600 kg/m³. SEM images of polished sections of these fractions revealed that the cenospheres were hollow thin-walled spheres. The dissolution experiments were executed with the hollow cenospheres and the solid spheres, which differ in density about a factor of two.

All dissolution experiments were executed with a sieved part of the fly ashes, the diameter lying between 38 µm and 50 µm. The fly ashes have also been ultrasonically vibrated to prevent agglomeration of small particles to large ones. As expected, dissolution rates (and related reaction rates as well) increased significantly with decreasing pOH (increasing pH) and temperature. The experiments revealed that for EFA and LM, Si, Al and K all congruently dissolve, implying bulk dissolution. Accordingly, the dissolution of one component, Si, represents an adequate measure for the dissolution of the entire glass mass.

In a previous paper [1], the fly ash particles were considered to be spherical, and a shrinking core model was derived and applied to aforesaid experiments of Pietersen [2, 3]. Based on this application, the dependence of the reactivity on the hydroxide content of the solution was obtained, indicating a dissolution rate proportional to $[\text{OH}^-]^{0.9-1}$ for the outer region and to $[\text{OH}^-]^{1.4}$ in the inner region of the fly ash particle. Furthermore, it seemed that the outer region (outer hull) of solid spheres and cenospheres are having the same thickness, about 2 μm .

In this paper a chemical reaction equation for the fly ash is put forward that accounts for the silica, aluminium oxide, alkali, alkaline earth, iron oxide and titanium oxide contents. From this application and proposed reaction mechanism, the solubility of the fly ashes as a function of pH is obtained. Finally, thermodynamic properties (such as the equilibrium constant and free energy of reaction) are determined of the considered fly ashes, and compared with similar substances.

2. CHEMICAL REACTION MECHANISM

In Table 1 the mass fraction of all glass phases in the studied fly ashes are listed, based on the data of Brouwers and Van Eijk [1]. A part of the fly ash is crystalline (quartz and mullite) which is non-reactive. Assuming the same mass density for glass and crystalline phase, the volume fraction of crystalline material corresponds to $1 - \phi$ (ϕ is the glass volume fraction, i.e. the porosity of the leached shell). The vitreous SiO_2 and Al_2O_3 follow from the total mass fraction of each substance minus the crystalline SiO_2 (in quartz and in mullite) and crystalline Al_2O_3 (in mullite only), see Brouwers and Van Eijk [1], respectively. Using the mass fractions of all oxides in the glass, the mean mole fraction of all components in the glass can be computed using the molecular mass of each component, which are included in Table 1 for the EFA and LM solid spheres only (between the brackets). From the composition of the fly ashes as presented in Table 1 it is clear that the glass phases of both fly ashes consist of SiO_2 , as well as the network formers Al_2O_3 , Fe_2O_3 , TiO_2 and P_2O_5 , and the network modifiers CaO , MgO , Na_2O and K_2O (Hemmings and Berry [10]).

Table 1. Mass and mole fraction (between brackets) of the glass phases in LM and EFA solid and cenospheres. Mass fraction is based on total fly ash mass, mole fraction is based on glass phase only.

	EFA		LM		M
	solid (\bar{x})	ceno	solid (\bar{x})	ceno	(g/mole)
crystalline					
$\text{SiO}_2 + \text{Al}_2\text{O}_3 (= 1 - \phi)$	5.1%	8.4%	33.3%	37.8%	
glass					
SiO_2 (S)	51.96% (0.648)	47.05%	38.79% (0.695)	40.41%	60
Al_2O_3 (A)	25.89% (0.190)	28.06%	16.48% (0.174)	13.54%	102

\bar{M}	71		72		

In Pourbaix [11] the prevailing equilibria of the various substances can be found for $\text{pH} > 12$ and an electric potential ranging from -0.3 to 0.2 V, values that are found in ordinary Portland and slag cement systems (MacPhee and Glasser [12]). Paul [13, 14] also presented hydration reactions for vitreous SiO_2 , Al_2O_3 , Na_2O and K_2O . Accordingly, from all this literature it follows that for $\text{pH} > 12$ vitreous silica is hydrated as

and that Al_2O_3 is hydrated according to

that CaO (and MgO) reacts as follows

that Na_2O (and K_2O) reacts as follows

that Fe_2O_3 reacts as follows

and that TiO_2 hydrates as follows

Accordingly, the following reaction of the fly ash glass is proposed as

Note that silica, aluminium oxide and titanium oxide consume hydroxides, whereas the earth alkalis (CaO , MgO), alkalis (Na_2O , K_2O) and iron oxide produce them. As slag contain the same components as fly ashes, it is believed that the model might be applicable to the dissolution of this material as well. In case a fly ash or a slag also contains MnO and SO_3 , the former reacts as CaO/MgO (to Mn^{2+}), and the latter likewise SiO_2 (to SO_4^{2-}).

As the activity of pure liquids and solids are unity, the equilibrium constant is defined as

$$K = \frac{[\text{AlO}_2^-]^{2\alpha} [\text{Ca}^{2+}]^\beta [\text{Na}^+]^{2\gamma} [\text{Fe}^{3+}]^{2\delta} [\text{HTiO}_3^-]^\varepsilon [\text{SiO}_3^{2-}]}{[\text{OH}^-]^{2+2\alpha-2\beta-2\gamma-6\delta+\varepsilon}} \quad (8)$$

Invoking $[\text{AlO}_2^-] = 2\alpha [\text{SiO}_3^{2-}]$, $[\text{Ca}^{2+}] = \beta [\text{SiO}_3^{2-}]$, $[\text{Na}^+] = 2\gamma [\text{SiO}_3^{2-}]$, $[\text{Fe}^{3+}] = 2\delta [\text{SiO}_3^{2-}]$ and $[\text{HTiO}_3^-] = \varepsilon [\text{SiO}_3^{2-}]$ yields

$$[\text{SiO}_3^{2-}] = \left(\frac{K}{(2\alpha)^{2\alpha} \beta^\beta (2\gamma)^{2\gamma} (2\delta)^{2\delta} \varepsilon^\varepsilon} \right)^{\frac{1}{1+2\alpha+\beta+2\gamma+2\delta+\varepsilon}} [\text{OH}^-]^a \quad (9)$$

with

$$a = \frac{2 + 2\alpha - 2\beta - 2\gamma - 6\delta + \varepsilon}{1 + 2\alpha + \beta + 2\gamma + 2\delta + \varepsilon} \quad (10)$$

Note that the powers appearing in the denominator of the first factor of equation (9), $(2\alpha)^{2\alpha}$ etc., are of order unity. The function x^x namely attains a value of 1 at $x = 0$ and $x = 1$, and has a minimum of $(1/e)^{(1/e)} (\approx 0.69)$ at $x = e^{-1}$. From Table 1 it can be seen that the values of α etc. are such that 2α etc. all fall in the range 0 to 1, so that $(2\alpha)^{2\alpha}$ etc. all have a value between 0.69 and 1. Furthermore, it will be demonstrated that K is (much) smaller than unity. So, with increasing α etc. (i.e. less silica) the power of the first factor decreases, and hence, the factor increases. Accordingly, when the silica content diminishes, the solubility (reactivity) is enhanced. This trend is also supported by the second factor on the right-hand side of equation (9). The power a decreases with increasing α , β etc., see equation (10). For β , γ and δ this effect is obvious. But this trend also holds for α and ε : the function $(2+x)/(1+x)$ attains a value of 2 at $x = 0$, and monotonically decreases towards the asymptotic value of 1 for large x . Considering that $[\text{OH}^-]$ is usually smaller than 1 mole/l, increasing α , β etc. imply a smaller a and also a larger second factor in equation (9), i.e. the same trend as the first factor.

Considering the equilibrium product it follows that the hydration of pure silica is quadratically dependent on $[\text{OH}^-]$ ($\alpha = \beta = \gamma = \delta = \varepsilon = 0$). In case of a pure aluminosilicate glass ($\beta = \gamma = \delta = \varepsilon = 0$), the power a is located between unity and 2, but depending weakly on changes in α . E.g., for α ranging from $\frac{1}{4}$ to 1, this power ranges from 1.66 to 1.33 (it equals 1.5 for $\alpha = 0.5$). For alkali silicate glasses ($\alpha = \beta = \delta = \varepsilon = 0$), it follows from equation (10) that the power a is smaller than unity when $\gamma > 0.25$.

With the mole fractions listed in Table 1, subsequently the mean α , β , γ , δ and ε and a can be computed for solid EFA and LM, which are included in this table as well. For this calculation it is assumed MgO to react as CaO and K_2O as Na_2O . P_2O_5 can be neglected, as its presence is minor (Table 1).

One can readily see that the power a takes a value of 1.022 (EFA) and 1.208 (LM), which is reasonably in line with the power obtained by Brouwers and Van Eijk [1]: 1.4 in LM inner region, 0.9 and 1 in EFA and LM outer region, respectively. This deviation can probably be attributed to the inhomogeneity of the fly ash. Inner and outer region may have different composition, which would result in each region having its own value for a . Experiments by Dudas and Warren [15] confirm that the glass components K_2O , Na_2O , CaO , MgO , and Fe_2O_3 are concentrated in the exterior (outer) hull. Smith [16] found a similar enrichment in the outer layer, and explained this inhomogeneity by the fact that the boiling point of silica and aluminiumoxide are practically the same (2950 °C and 2980 °C, respectively), and higher than the boiling points of all other components. This will result in a concentration of more volatile components (i.e. the other oxides) in the outer layer. Considering equation (10), one can see indeed that the power a is smaller/larger for larger/smaller values of β , γ etc. This confirms the hypothesis of K_2O , Na_2O , CaO , MgO , and Fe_2O_3 concentrated in the outer region.

3. THERMODYNAMIC ANALYSIS
