On the basis of the reaction times determined by Brouwers and Van Eijk [1] and the proposed reaction mechanism in the previous section, thermodynamic data for the fly ash can be determined. The first step in this analysis is the determination of $[\text{SiO}_3^{2-}]$ that appears in equations (8) and (9). This property follows from the scaled reaction time that reads:

$$\tau = \frac{x_s \rho_g R^2}{6\phi D_s C_{Sc}} \quad (11)$$

The values of τ for EFA and LM followed from the application (fitting) of a shrinking core model to the experiments of Pietersen [2,3] by Brouwers and Van Eijk [1]. In equation (11) ρ_g is the molar density of the glass, x_s the mole fraction of silica in the glass, D_s the bulk diffusion coefficient of the SiO_3^{2-} ion, R the outer radius of the fly ash particle, and C_{Sc} the SiO_3^{2-} concentration at the glass core (i.e. on the reacting surface) and ϕ the glass volume fraction (porosity of leached shell).

It is expected that the dissolution process will be governed by the ion that diffuses the slowest through the leached shell. Here, only the diffusion coefficients of $[\text{AlO}_2^-]$ and $[\text{SiO}_3^{2-}]$ are compared, which are not both directly available. Accordingly, D_A^0 was estimated using the diffusion coefficients of the similar ions NO_2^- ($1.912 \cdot 10^{-9} \text{ m}^2/\text{s}$) and ClO_2^- ($1.385 \cdot 10^{-9} \text{ m}^2/\text{s}$), yielding $D_A^0 = 1.7 \cdot 10^{-9} \text{ m}^2/\text{s}$ at $T = 298 \text{ K}$ (Lide [17]). Similarly, D_s^0 was estimated using the diffusion coefficients of CO_3^{2-} ($0.912 \cdot 10^{-9} \text{ m}^2/\text{s}$) and SO_3^{2-} ($1.064 \cdot 10^{-9} \text{ m}^2/\text{s}$), yielding $D_s^0 = 1.0 \cdot 10^{-9} \text{ m}^2/\text{s}$ at $T = 298 \text{ K}$ (Lide [17]). Note that the molecular mass of aluminium lies between the molecular masses of nitrogen and chloride, and silicon between carbon and sulphur, so that the estimation is expected to a yield reasonable result. As D_A (but also the diffusion coefficients of Ca^{2+} , Na^+ , K^+ and Fe^{3+} [17]) is larger than D_s , it is believed henceforth that the process is governed by the diffusion of SiO_3^{2-} and hence, $D_s C_{Sc}$ appearing in equation (11) to correspond to $D_s [\text{SiO}_3^{2-}]$. For deviating temperatures, D_s is determined via

$$D_s = \frac{T}{298K} D_s^0 \quad (12)$$

whereby T is in Kelvin. Combining equations (11), (9) and (12) yields

$$K = (2\alpha)^\alpha (\beta)^\beta (2\gamma)^{2\gamma} (2\delta)^{2\delta} (\varepsilon)^\varepsilon \left[\frac{x_s \rho_g R^2}{6\phi D_s^0 \tau} \frac{298K}{T} \right]^{1+2\alpha+\beta+2\gamma+2\delta+\varepsilon} [\text{OH}^-]^{-2-2\alpha+2\beta+2\gamma+6\delta-\varepsilon} \quad (13)$$

The physical properties that appear in this equation are known: R ($22 \mu\text{m}$), ϕ (Table 1), while ρ_g follows from the mass density of the glass (about 2450 kg/m^3) divided by the mean molar mass. The mean molar mass of the glass follows from the sum of the molar fraction of each constituent times its molar mass ($\bar{M} = \sum x_k M_k$), which are included in Table 1 as well.

Table 2. Reaction time τ for EFA solid spheres for various temperatures (pOH = 0.3).

T (K)	τ_o (days)	τ_i (days)	$t_{i-o}(1-\tau_i/\tau_o)$ (days)	K_o (l/mole)	ΔG_o (J/mole)
293	8000			$4.46 \cdot 10^{-17}$	$9.1717 \cdot 10^4$
303	3000			$2.84 \cdot 10^{-16}$	$9.0179 \cdot 10^4$
313	750	275	1.6	$4.02 \cdot 10^{-15}$	$8.6264 \cdot 10^4$
ΔH (J/mole)					$1.80 \cdot 10^5$
ΔS (J/moleK)					298
ΔG_{298} (J/mole)					$9.120 \cdot 10^4$

The τ at various temperature have been determined by Brouwers and Van Eijk [1] and are listed in Tables 2 and 3, as well as $[\text{OH}^-]$ and the temperature. The reaction time has been determined both for inner and outer region (denoted by τ_i and τ_o , respectively).

Using the data of Tables 2 and 3, the K of EFA and LM solid spheres, respectively, are computed using equation (13) and the result is included in both tables as well. For inner and outer region, K is denoted by K_i and K_o , respectively. For these computations the mean values α , β etc. and x_s have been used. Note that t_{i-o} is that the time when the outer region has fully reacted and the inner region starts to react (the outer region starts to react at $t = 0$ s. [1]).

Table 3. Reaction time τ for LM solid spheres for various temperatures (pOH = 0.3)

T (K)	τ_o (days)	τ_i (days)	$t_{i-o}(1-\tau_i/\tau_o)$ (days)	K_o (l/mole)	ΔG_o (J/mole)	K_i (l/mole)	ΔG_i (J/mole)
293	2000			$8.99 \cdot 10^{-14}$	$7.3181 \cdot 10^4$		
303	1500	900	1.0	$1.40 \cdot 10^{-13}$	$7.4563 \cdot 10^4$	$3.41 \cdot 10^{-13}$	$7.2322 \cdot 10^4$
313	700	190	1.0	$4.99 \cdot 10^{-13}$	$7.3716 \cdot 10^4$	$4.84 \cdot 10^{-12}$	$6.7805 \cdot 10^4$
ΔH (J/mole)					$8.00 \cdot 10^4$		$1.90 \cdot 10^5$
ΔS (J/moleK)					19		390
ΔG_{298} (J/mole)					$7.434 \cdot 10^4$		$7.378 \cdot 10^4$

The two tables indicate that K increases with temperature, implying improved dissolution/reaction with increasing temperature. Furthermore, the values of K and equation (9) confirm that $[\text{SiO}_3^{2-}]$ is much smaller than $[\text{OH}^-]$ indeed, so that the assumption that the process is governed by the diffusion of the SiO_3^{2-} ion is correct (Brouwers and Van Eijk [1]).

With these K one can determine the standard free energy of reaction ΔG by

$$K = e^{\frac{-\Delta G}{RT}} \quad (14)$$

ΔG is the sum of free energies of formation of the products in their standard states minus the free energies of formation of the reactants in their standard states (Paul [13, 14], Babushkin et al. [18]). In Tables 2 and 3 the resulting ΔG are included using $R = 8.31439$ J/moleK.

Figure 1. $R \ln K$ versus $1/T$ for LM (inner and outer region) and EFA (outer region only) solid fly ash.

The connection of ΔG with enthalpy and entropy of reaction is

$$\Delta G = \Delta H - T\Delta S \quad (15)$$

in which ΔH and ΔS are the sum of standard heats of formation and of the standard entropies, respectively, where each sum is constituted by the sum of the products minus the sum of the reactants. In order to specify ΔH and ΔS , $-R \ln(K)$ has been set out against $1/T$ for LM and EFA in Figure 1, taking the values of Tables 2 and 3. A straight line has been fitted through the experimental values, whereby

$$-R \ln(K) = \frac{\Delta H}{T} - \Delta S \quad (16)$$

see equations (14) and (15). The fitted values of ΔH and ΔS have been included in Tables 2 and 3.

Next, with the standard free energy of reaction ΔG , one is in a position to determine the free energy, enthalpy and entropy of formation of LM and EFA glass phase. In Table 4, the free energy, enthalpy and entropy of formation (ΔG^0 , ΔH^0 and S^0 , respectively) of some substances are listed ($T = 298 \text{ K}$), taken from Paul [13] and Babushkin et al. [18], employing $1 \text{ cal} = 4.184 \text{ J}$.

Table 4. Thermodynamic properties, taken from Babushkin et al. [18] (with exception of HTiO_3^- , which is taken from Paul [13]), and computed values.

Unfortunately, from SiO_3^{2-} and HTiO_3^- only ΔG^0 is available, so that it is only possible to determine ΔG^0 of the fly ash (and not ΔH^0 nor S^0).

Firstly, ΔG of the EFA and LM reaction is computed at 298K using equation (15) and the fitted values of ΔH and ΔS as listed in Tables 2 and 3. The resulting ΔG_{298} is being included in these tables as well. Considering reaction (7), ΔG^0 of EFA and LM glass now follow from:

$$\begin{aligned} \Delta G^0 = & -\Delta G_{298} - (2+2\alpha-2\beta-2\gamma-6\delta+\varepsilon) \Delta G_{OH^-}^0 + \Delta G_{SiO_3^{2-}}^0 + 2\alpha \Delta G_{AlO_2^-}^0 + \\ & \beta \left(\frac{x_C}{x_C + x_M} \Delta G_{Ca^{2+}}^0 + \frac{x_M}{x_C + x_M} \Delta G_{Mg^{2+}}^0 \right) + 2\gamma \left(\frac{x_N}{x_N + x_K} \Delta G_{Na^+}^0 + \frac{x_K}{x_N + x_K} \Delta G_{K^+}^0 \right) \\ & + 2\delta \Delta G_{Fe^{3+}}^0 + \varepsilon \Delta G_{HTiO_3^-}^0 + (1+\alpha-\beta-\gamma-3\delta) \Delta G_{H_2O}^0 \end{aligned} \quad (17)$$

Taking x_C , x_M , x_N , x_K , α , β , γ , δ , and ε from Table 1, the value of ΔG_{298} listed in Tables 2 and 3, and taking the free energies of formation from Table 4, ΔG^0 of EFA and LM is computed using equation (17) and included in this latter table as well.

Note that in reaction equation (7), β and γ represent the total molar content of earth alkalis and alkalis to molar content of silica, respectively. But to compute ΔG^0 , the actual contents of MgO, CaO, Na₂O and K₂O have to be accounted of. For that reason, the molar ratios $x_C/(x_M + x_C)$ etc. are appearing in equation (17).

From Table 4 one can conclude that with increasing α (i.e. A/S molar ratio) $-\Delta G^0$ increases. For EFA, α takes a value of about 0.29 and for LM about 0.25, and indeed, $-\Delta G^0$ of EFA is larger. Furthermore, one can see that for LM the values pertaining to inner and outer are very close. From this information it can be concluded that $-\Delta G^0$ is mainly governed by α .

In order relate the computed values of $-\Delta G^0$ with values reported in literature, values of $-\Delta G^0$ of silica (quartz and vitreous, $\alpha = 0$) and of 2SiO₂.Al₂O₃ ($\alpha = 0.5$) are also included in Table 4. One can see that $-\Delta G^0$ of LM and EFA are located between the values of silica and of 2SiO₂.Al₂O₃. Moreover, they are in line with the trend that for larger α , $-\Delta G^0$ also increases, confirming the reliability of the computed values of $-\Delta G^0$.

Figure 2. $-\Delta G^0$ versus α (A/S molar ratio).

In Figure 2, $-\Delta G^0$ is set out graphically against α , whereby the value of $-\Delta G^0$ is taken from vitreous silica ($\alpha = 0$) and from EFA and LM outer regions.

For most fly ashes, α lies in the range 0.25-0.29. For these fly ashes a tentative value of $-\Delta G^0$ can be obtained from the values of LM and EFA determined here, e.g. by interpolation. For values in the range 0-0.25 and 0.29 to 0.5, interpolation between silica and LM and between EFA and $2\text{SiO}_2\cdot\text{Al}_2\text{O}_3$, respectively, is recommended. The latter range generally holds for slags. A direct measurement (e.g. by dissolution experiments, applying a shrinking core model, the chemical reaction mechanism and the thermodynamic analysis) of $-\Delta G^0$ would be more accurate, but also more elaborate. Interpolation as proposed here will readily provide a value that can be useful for tentative reactivity computations.

4. CONCLUSIONS

Pietersen [2, 3] has carefully executed and reported dissolution experiments of several types of pulverised powder coal (class F) fly ashes (Table 1). To this end, the silica release in time was measured for various pOH and temperatures. In order to understand the dissolution and reaction behaviour of these fly ashes, in particular the EFA and LM fly ash, Brouwers and Van Eijk [1] derived a shrinking core model. They have applied the model to said experiments, yielding values of the reactivity time τ (eq. (11)) for both inner and outer region (τ_i and τ_o), which are summarised in Tables 2 and 3. Furthermore, it was found that the dissolution rate is proportional to $[\text{OH}]^{0.9-1}$ for the outer region (EFA and LM), and to $[\text{OH}]^{1.4}$ in inner region (information available about LM only).

Here, a reaction mechanism for the glass phase of the fly ash glass is put forward that accounts for its oxide composition (silica, aluminium oxide, iron oxide, titanium oxide, alkali and earth alkali content) and which also could be useful for slags.). From the proposed reaction mechanism and equilibrium constant, it follows that the solubility of the fly ashes is as a function of $[\text{OH}]^a$. The parameter a solely depends on the oxide composition of the glass phase. Using the average composition of EFA and LM fly ash, the power a takes a value of 1.022 (EFA) and 1.208 (LM). This result suggests that the outer layer is poorer in silica and aluminiumoxide, i.e. that K_2O , Na_2O , CaO , MgO , and Fe_2O_3 are concentrated in the exterior hull, which is in line with findings in previous publications.

Combining the equilibrium constant and the experimental data at various temperatures, also the free energy, enthalpy and entropy of reaction are computed of EFA and LM glass phase. Finally, these data are used to compute the free energy of formation ΔG^0 of both glasses. It follows that the free energy of formation is mainly governed by the molar ratio (α) of the major constituents SiO_2 and Al_2O_3 . The values obtained are in line with those of known substances, silica ($\alpha = 0$) and $2\text{SiO}_2\cdot\text{Al}_2\text{O}_3$ ($\alpha = 0.5$). With this information one can assess ΔG^0 of (fly ash and slag) glass phases with deviating A/S molar ratio, and subsequently, to assess their reactivity in a cement environment.

ABSTRACT

Temperature plays a major role on the domains of thermodynamical stability of hydrates. However, controversy still exists concerning some of them. This is the case with the sulphoaluminate phases. It has recently been alleged that ettringite is not stable at temperatures above 60 – 70°C while monosulphoaluminate would be. However, other experiments have indicated the presence of ettringite at a temperature of 90°C and thermodynamical calculations also support the fact that ettringite is a stable phase at 85°C.

Besides, the impact of alkali concentration on the domains of stability of the sulphoaluminate phases at elevated temperature is not well understood.

The most comprehensive analysis regarding this combined effect of alkali concentration - temperature on the domains of stability of sulphoaluminate phases has been carried out by Damidot and Glasser using thermodynamical calculations. They showed a very strong impact of the temperature and alkali concentration on the domains of stability of the sulfoaluminate phases. However, these data have not been validated experimentally.

Results of this present study, carried out on pure phases, validate the thermodynamical calculations. This study also discusses the impact of the alkali ions (sodium or potassium) on the solid phase assemblages and aqueous phase compositions and the influence of the alkali concentration and temperature on the domain of stability of the sulfoaluminate phases.

Keywords: thermodynamical stability, solubility, sulphoaluminate phases, ettringite, calcium monosulfoaluminate, alkali concentration, temperature.

1. INTRODUCTION

Temperature plays a major role on the domains of thermodynamical stability of hydrates. Various studies have been carried out in order to determine the influence of temperature and alkali concentration on the stability of the hydrated calcium sulfoaluminate phases, and mainly on the ettringite stability. However, there is a lot of controversy regarding the results. It has been alleged that ettringite is not stable at temperatures above 60 – 70°C, while monosulphoaluminate would be. However, other experiments have indicated the presence of ettringite at a temperature of 90°C.

For instance, Abo-El-Enin et al. [1], Kalousek [2], Brown and Bothe [3] and Mori and al. [4] showed the presence of ettringite up to a curing temperature of 80 – 90°C, even when the alkali concentration of the solution was very high, equal to 2 mol/l [3].

However, in the studies of Ghorab and Kishar [5, 6], and Berger et al. [7], ettringite was stirred in NaOH solutions and was no longer detected after 24 hours at 60°C when NaOH concentration was higher than 0.2 mol/l [5, 6] and one hour at 85°C when the NaOH concentration of the solution was higher than 0,87 mol/l [7].

The most comprehensive analysis regarding the combined effect of alkali concentration - temperature on the domains of stability of sulfoaluminate phases has been carried out by Damidot and Glasser [8, 9, 10] using thermodynamical calculations. They determined the influence of temperature on the phase diagram in the system “CaO-Al₂O₃-SO₃-H₂O” for different sodium concentrations varying from 0 to 1 mol/l and temperatures (25°C, 50°C and 85°C). They found that some ranges of solution compositions stable under which ettringite is in the whole range of temperature and alkali concentration investigated (even at 85°C in the presence of a very high alkali concentration of 1 mol/l). Calculations also show that at temperatures above 45°C, monosulfoaluminate becomes increasingly stable at the expense of ettringite. The higher the temperature, the more the domain of solution composition is reduced under which ettringite is stable, and the more the one under which monosulfoaluminate is stable it is widened. However, these data have not been validated experimentally.

The present study aims at validating experimentally these thermodynamical data to enable its use when cement hydration occurs at elevated temperatures. Even if the system is dynamic (not at the equilibrium), as occurs at the beginning of hydration, these thermodynamical data can be used to draw the kinetic path of the reaction, so as to determine if the solution is supersaturated or undersaturated with respect to stable hydrates and predict the hydrates which may potentially precipitate with time. Besides, after a relatively short period, local equilibrium tend to assert itself and the concentrations tend towards the values predicted from a stable diagram.

The concentrations at various invariant points of the phase diagram « CaO-Al₂O₃-SO₃-K₂O-H₂O » including Ca(OH)₂ have been determined experimentally at 70°C and 90°C for 2 concentrations in alkali (0,42 and 1,05 mol/l), and at 25°C for an alkali concentration of 0,42 mol/l. Experiments have been limited to the invariant points including Ca(OH)₂, since these are involved during the cement hydration.

In this paper, the impact of the alkali ions (sodium or potassium) on solid phase assemblages and aqueous phase compositions has also been discussed. In the last part of this paper, the influence of the alkali concentration and temperature on the domain of stability of the sulfoaluminate phases is examined.

2. EXPERIMENTAL

This study has been carried out using pure phase materials. Ca(OH)₂, C₃A (SSB = 450 m²/kg) and gypsum (high grade quality) were mixed in diluted suspension with KOH solutions. The specimens were prepared in diluted suspension in order to quicker reach the thermodynamic equilibrium.

Two KOH concentrations were used: 0.42 and 1.05 mol/l. The amount of C₃A and Ca(OH)₂ were kept constant for all the specimens, equal respectively to 0.07 and 0.05 moles per liter. Ca(OH)₂ was introduced in order to determine experimentally the compositions of the invariant points including Ca(OH)₂. Various amounts of gypsum have been used in order to cover the whole range of stability of the various sulfoaluminate phases. They are reported in the Table 1.

Table 1. Amount of gypsum introduced initially in the various mixtures investigated (moles per liter)

25°C	70°C		90°C	
[KOH]= 0.42 mol/l	[KOH]= 0.42 mol/l	[KOH]= 1.05 mol/l	[KOH]= 0.42 mol/l	[KOH]= 1.05 mol/l
0.445	0.445	0.71	0.445	0.71
0.365	0.26	0.46	0.295	0.565
0.31	0.16	0.32	0.19	0.42
0.26	0.13	0.27	0.16	0.32
0.21	0.065	0.175	0.085	0.225
0.14	0.02	0.07	0.04	0.15

The solids were stirred with the KOH solution in polypropylene flasks. Solid / liquid ratios between 40 and 7 were used depending on the initial amount of gypsum. The flasks were immersed in a thermostated bath and kept at constant temperature of 25°C, 70°C and 90°C during the whole experiment. At 70°C and 90°C, silicon oil was used to limit the evaporation.

The flasks were hermetically closed to avoid any carbonation and introduction of oil during the experiment.

Once the systems had reached their thermodynamic equilibrium (28 days at 25°C and 6 days at 70 and 90°C), the solid and liquid phases were separated by filtering. The solid phases, after being dried with acetone itself removed by ether, were analyzed by XRD. The solution concentrations were measured by ICP for calcium, sulfur (present here as sulphate only), aluminate and alkali ions, and by titration with a 0,05 N HCl solution in the presence of helianthine indicator for the hydroxide ions.

3. RESULTS

XRD analysis show that the C₃A had fully reacted after 6 days at 70 and 90°C, but not after 28 days at 25°C. In this last case, a significant amount of residual C₃A was still present for the systems containing high initial amounts of gypsium (0.445, 0.365 and 0.31 mole per liter). A trace of residual C₃A was also present for the systems containing 0.26 mole per liter.

The compositions of the filtrates and the solid phases in the mixtures are reported in the Table 2 for a potassium concentration of 0.42 mol/l and in the Table 3 for a potassium concentration of about 1 mol/l.

From now, the following abbreviations are used:

- Gyp. = Gypsum (CaSO₄.2H₂O) ,
- AFt = Ettringite (C₃A.3CaSO₄.32H₂O),
- AFm = calcium monosulfoaluminate (C₃A.CaSO₄.12H₂O),
- Syng. = Syngenite (CaSO₄.K₂SO₄.H₂O),
- Gorg. = Gorgeyte (CaSO₄)₅.K₂SO₄.H₂O),
- CH = calcium hydroxide (Ca(OH)₂).

4. DISCUSSION

Firstly, the compositions of the solutions, at the various invariant points determined experimentally, will be compared with those calculated by Damidot and Glasser. Then, the compositions of the various invariant points of the present study will be summarized. Finally, the impact of temperature and alkali concentration on the stability of AFt and AFm will be discussed.

The following notation have been used for the invariant points:

- A = Gyp., AFt, CH,
- B = Syng., AFt, CH
- C = Syng., Gyp., AFt, CH
- D = Syng., Gorg., AFt, CH
- E = AFt, C₃AH₆, CH
- F = AFt, AFm, CH
- G = AFm, hydrated calcium aluminate, CH

4.1 Comparison of the experimental and calculated values.

As experimental data were obtained using potassium and calculations using sodium (at 25°C potassium was also used), a preliminary discussion will be introduced on the impact of the nature of the alkali ions.

Then, the experimental and calculated values will be compared at 25, 70 and 90°C. Since the compositions of the invariant points predicted by calculation at temperature higher than 25°C are only reported in the literature for sodium concentrations of 0, 250, 500 and 1000 mmol/l and temperatures of 25, 50 and 85°C, the compositions for the alkali concentration and temperature investigated in the present study have been extrapolated using a polynomial extrapolation.

4.1.1 Difference between potassium and sodium

At 25°C, calculations showed that the system “CaO-Al₂O₃-SO₃-H₂O” behaves similarly in the presence of sodium or potassium as long as the alkali concentration is lower than 0.43 mol/l. The invariant points have similar compositions with both cations. This results from the fact that potassium and sodium affect the ionic strength identically. However, the system in the presence of K₂O is more complex due to the appearance of a new phase when the alkali concentration is higher than 0.43 mol/l, the Syng. which has no sodium counterparts. Thermodynamical calculations show that at a potassium concentration higher than 0.43, the phase diagram is similar to the one in the presence of sodium with Gyp. being replaced by Syng., and that the composition of the point B at 25°C is similar to the point A calculated for sodium and the same alkali concentration (table 4, line a).

Similarly, the composition of the point C is closed to the point A calculated for sodium and the same alkali concentration (Table 4, line b).

Table 4. Comparison of the experimental and calculated compositions at the points B - A (line a) and C - A (line b) at 25°

	[K ⁺ or Na ⁺] (mmol/l)	[SO ₄ ²⁻] (mmol/l)		[Ca ²⁺] (mmol/l)		[Al(OH) ₄ ⁻] (mmol/l)	
		with K ⁺	with Na ⁺	with K ⁺	with Na ⁺	with K ⁺	with Na ⁺
a	500	190	197	8.9	11.2	1.06*10 ⁻⁶	10 ⁻⁶
b	431	171	166	11.7	10.4	5.6*10 ⁻⁷	5.6*10 ⁻⁶

Therefore, at 25°C and beyond 0.43 mol/l, the compositions for either sodium and potassium remain similar whatever the alkali concentration, and the compositions of the points B and C can be compared to the point A calculated in the presence of sodium for the same alkali concentration.

At elevated temperature, the experimental data obtained using potassium and calculations using sodium are expected to remain comparable, since both cations are expected to affect the ionic strength identically similarly to room temperature. When Syng. will be present, the compositions of the points B or C will be compared to the point A calculated for sodium and the same alkali concentration.

4.1.2 Comparison of invariant point concentrations at 25°C

The experimental and calculated compositions for the points C and F are compared in the Table 5 (lines a and b respectively) and show similar compositions. Only differences have been noticed for the calcium concentration; calculation predicts lower concentration than experiments.

Since thermodynamic calculations do not predict AFm but C_3AH_6 to be the phase thermodynamically stable in the presence of AFt and CH at room temperature, in the Table 5 the experimental point F has been compared to the calculated point E. The presence of AFm in conjunction with AFt and CH in these experiments may be due to the fact that the system did not totally reach the equilibrium.

Table 5. Comparison of the experimental and calculated compositions at the points C (line a) and F (line b) at 25°C

	[K ⁺] (mmol/l)		[SO ₄ ²⁻] (mmol/l)		[Ca ²⁺] (mmol/l)		[Al(OH) ₄ ⁻] (mmol/l)	
	measured	calculated	measured	calculated	measured	calculated	measured	calculated
a	403	431	161	171	16.6	11.7	< 0.3	5.6*10 ⁻⁷
b	420		2.3	2.2	1.2	1.0	0.36	0.07

4.1.3 Comparison of invariant points concentrations at 70°C

Similarly to room temperature, most of the compositions of the invariant points determined experimentally are in good agreement with those predicted by calculation (see Table 6). This is the case for the invariant points C (line a), B (line b) and F (lines c and d).

In Table 6, the compositions of the invariant points B and C have been compared to A for sodium and similar alkali concentration. Therefore, as assumed previously and similarly to room temperature, the compositions of the invariant points B and C are similar to A.

Besides, similarly to room temperature, predicted calcium concentrations are lower than experimental ones.

Table 6. Comparison of the experimental and calculated compositions at the points C (line a), B (line b) and F (lines c and d), G (lines e and f) at 70°C

	[K ⁺] or [Na ⁺] (mmol/l)	[SO ₄ ²⁻] (mmol/l)		[Ca ²⁺] (mmol/l)		[Al(OH) ₄ ⁻] (mmol/l)	
	measured /calculated	measured	calculated	measured	calculated	measured	calculated
a	431	195	185	17.3	10.8	< 0.3	0.09
b	902	408	395	9.6	7.9	< 0.7	0.4
c	434	109	100	2.4	1.6	< 0.3	0.23
d	1024	382	361	2.8	1.1	< 0.7	0.3
e	425	3.8	27	1.2	0.6	6.7	2.5
f	1008 - 1001	116- 37	152	1.1	0.25	7 – 19.6	3.8

Disparities between experiments and calculations have only been observed for the invariant point G (Table 6, lines e and f). The sulfate concentrations measured were lower than those calculated. However, the accurate compositions of this invariant point have not been successfully determined probably due to the fact that the equilibrium was not totally reached. Indeed, thermodynamic predicts C_3AH_6 to be the most stable phase, but experiments always show the presence of C_4AH_{13} in conjunction with AFm and CH, and C_3AH_6 in addition to the others only in few cases. Besides, for most of the couples alkali / temperature investigated, AFm, hydrated calcium aluminate and CH have been observed in conjunction with two solutions of similar potassium concentration but different compositions, whereas thermodynamics predicts a sole composition. The different compositions are reported in the Table 6.

4.1.4 Comparison of invariant points concentrations at 90°C:

Similarly to 25°C and 70°C, most of the compositions of the invariant points determined experimentally are in good agreement with those predicted (see Table 7). This is the case for the invariant points D (line a), and F (lines c and d).

At 90°C, syng., AFt and CH have not been observed in conjunction with Gyp. (point C) but with Gorgeyite (Gorg.) (point D), indicating that this phase is probably more stable than Gyp. at this temperature. Therefore, the composition of the solution at the invariant point D determined experimentally has been compared to the composition of the predicted invariant point A.

The presence of Gorg. is consistent with the preliminary study performed by Damidot and Glasser in the presence of potassium and the work of Hill [11], which show the appearance of this phase in addition to Syng. and predict this phase to become stable at or above 40°C.

Table 7. Comparison of the experimental and calculated compositions at the points D (line a), B (line b), F (lines c and d), G (line e and f) at 90°C

	[K ⁺] or [Na ⁺] (mmol/l)	[SO ₄ ²⁻] (mmol/l)		[Ca ²⁺] (mmol/l)		[Al(OH) ₄ ⁻] (mmol/l)	
	measured /calculated	measured	calculated	measured	calculated	measured	calculated
a	397	174	180	9.7	9	< 0.3	0.17
b	1024	460	351	10.2	6.2	< 0.7	1
c	422	172	164	6.4	2.2	< 0.3	0.33
d	1077	482	460	10.8	1.7	< 0.7	0.4
e	425 - 443	25 - 15	45	0.8 - 0.7	0.4	7.6 - 13.4	4.6
f	1080	174 - 125	224	0.9 - 1.0	0.2	13 - 22.4	7

However, a deviation between predictions and experiments have been observed for the point B when the alkali concentration is high (1000 mmol/l) (Table 7, line b), probably due to the high ionic strength reducing the accuracy of the calculation of the activity coefficient. The predicted sulfate concentration is lower than the experimental one. Therefore, for very high alkali concentration, thermodynamic calculations are not able any more to predict accurately the composition of the solution at the invariant point B at 90°C.

At 90°C, differences between experiments and calculations have also been observed for the invariant point G (Table 7, line e and f). The sulfate concentrations measured are lower than those calculated. However, similarly to 70°C, the accurate values of the compositions at this invariant point have also not been successfully determined since AFm, hydrated calcium aluminate and CH have been observed in conjunction with two solutions of different compositions for the both alkali concentrations investigated. The different compositions are reported in the Table 7 (lines e and f).

4.2 Summary of the invariant points determined in this study

The invariant points determined in this study are reported in the Tables 8 and 9 for potassium concentrations of 0.42 and 1 mol/l respectively.

Table 8. Summary of the invariant points for $[K^+] \approx 0.42$ mol/l

Point	T (°C)	$[K^+]$ (mmol/l)	$[SO_4^{2-}]$ (mmol/l)	$[OH^-]$ (mmol/l)	$[Ca^{2+}]$ (mmol/l)	$[Al(OH)_4^-]$ (mmol/l)	Solid phases detected

4.3 Influence of temperature and alkali concentration on the domain of stability of AFt and AFm.

The present study shows that there exists some domains of solution composition under which ettringite is thermodynamically stable, whatever the temperature and alkali concentration in the whole range investigated, therefore even in the presence of a very high alkali concentration (1 mol/l) and for very high temperature (90°C). However, ettringite is not stable (i.e. is not the hydrate with the lowest solubility) whatever the composition of the solution. Therefore, this phase can disappear from a selected composition for instance, but it does not imply that it is unstable in the absolute thermodynamic sense, otherwise it must disappear from all compositions. This can explain at least partly why there are controversies regarding the influence of temperature and alkali concentration on the stability of ettringite.

The influence of temperature and alkali concentration will be examined respectively using a few thermodynamical rules which will be discussed first.

4.3.1 Few thermodynamical rules

In the present study, all the invariant points determined experimentally include CH, and one or two other phases. In the first case, the equilibrium conditions are represented by a curve. Therefore, if the sulfate concentration is fixed, the composition of the aqueous phase is fixed and is defined by the equilibrium between CH, and the hydrate which is stable in the presence of CH and has the lowest solubility. In the second case, only one composition of the aqueous phase describes the equilibrium.

4.3.2 Influence of temperature

At 25°C and according to the Tables 8 and 9, when the sulfate concentration is higher than the one at the point F (2.3 mmol/l for a potassium concentration of 422 mmol/l), the hydrate stable in the presence of CH and with the lowest solubility is ettringite (the equilibrium curve of ettringite is displaced to lower solubility than monosulfoaluminate and hydrated calcium aluminates). This hydrate is the one with the lowest solubility on a very wide domain of sulfate concentration varying from 2.3 mmol/l (point F) to 166 mol/l (point C) for a potassium concentration of 0.4 – 0.42 mol/l.

At 70 and 90°C, ettringite remains the hydrate which is stable in the presence of CH and the one with the lowest solubility when the sulfate concentration is higher than the one at the point F. This indicates that the equilibrium curve of ettringite starts to be displaced to lower solubility than monosulfoaluminate and hydrated calcium aluminates beyond this sulfate concentration. However, the sulfate concentration at point F drastically increases with the temperature (2.3 mmol/l at 25°C, 109 mmol/l at 70°C and 172 mmol/l at 90°C, for a potassium concentration of 420 - 430 mmol/l).

Besides, the points A, B, C or D mark the highest sulfate concentration at which ettringite is stable with the solution in the presence of CH. Table 8 and 9 show that the compositions of the solutions at these invariant points are very slightly influenced by the temperature from 25 to 90°C. Therefore, the domain of sulfate under which ettringite is stable in the presence of CH drastically reduces as the temperature increases. The influence of temperature on this domain is illustrated in the figure 1.

Figure 1. Influence of temperature on the range of sulfate concentration under which AFt and CH are stable.

Below the sulfate concentration corresponding to the invariant point F and above the one corresponding to G, ettringite and the hydrated calcium sulfoaluminate are metastable with respect to monosulfoaluminate, and the equilibrium solution is defined by the equilibrium between this latter phase and CH. The influence of temperature on the domain of sulfate concentration under which monosulfoaluminate is stable in the presence of CH is illustrated in the figure 2. It drastically increases with the temperature and is very wide at elevated temperature. Besides, this figure shows that monosulfoaluminate is stable in the presence of high sulfate concentrations at elevated temperature contrary to room temperature. This maximum sulfate concentration under which monosulfoaluminate and CH are stable increases with the temperature.

Figure 2. Influence of temperature on the range of sulfate concentration under which monosulfoaluminate and $\text{Ca}(\text{OH})_2$ are stable.

Below the sulfate concentration corresponding to the point G, both ettringite and monosulfoaluminate are metastable with respect to the hydrated calcium aluminates and mainly C_3AH_6 . Therefore, the equilibrium solution is defined by the equilibrium between C_3AH_6 which is the phase with the lowest solubility and CH. The tables 8 and 9 show that, when the temperature increases, the domain of sulfate concentration under the hydrated calcium aluminate are stable in the presence of CH increases.

4.3.3 Influence of the alkali concentration

Figure 1 shows that the higher the alkali concentration, the higher is the sulfate concentration beyond which ettringite is stable in the presence of CH, whatever the temperature. Besides, at 90°C , the domain of sulfate concentration under which ettringite is stable is small, and even more reduced as the alkali concentration is high.

The higher the alkali concentration, the higher is also the minimum and maximum sulfate concentration over which monosulfoaluminate is stable in the presence of CH (see Figure 2 at 70°C and 90°C). Therefore, at elevated temperature, the monosulfoaluminate is stable in the presence of CH when the sulfate concentration is high and even more so if the alkali concentration is high.

The displacement of the equilibrium curves with the alkali concentrations is due to a modification of the ionic strength which induced a modification of the activity coefficient.

5. CONCLUSIONS

The compositions of the invariant points determined experimentally are very consistent with those predicted by calculation, except for the invariant point B (AFt, AFm, CH) at 90°C when the alkali concentration is very high (1 mol/l). Under such conditions, there is a deviation between experiment and the composition predicted by thermodynamic calculations, probably because of the high ionic strength. Differences between experiments and predictions have also been observed for the invariant point G (AFm, hydrated calcium aluminate, CH) at 70°C and 90°C whatever the alkali concentration. However, experimental difficulties were faced in this last case and the experimental data are not accurate.

The results also show that the system “ $\text{CaO-Al}_2\text{O}_3\text{-SO}_3\text{-H}_2\text{O}$ ” behaves quite similarly in the presence of sodium or potassium. As long as the alkali concentration is lower than 0.40 - 0.43 mol/l, the invariant points are the same and have similar compositions with both cations. This results from the fact that potassium and sodium affect the ionic strength identically. The only

difference between sodium and potassium is the appearance of additional phases in the presence of potassium: the syngenite when the potassium concentration is higher than 0.4 – 0.43 mol/l whatever the temperature (from 25 to 90°C), and the gorgeyite more stable than gypsum at 90°C. However, the study shows that the compositions of the invariant points B (Syng., AFt, CH), C (Syng., Gyp., AFt, CH for $T \leq 70^\circ\text{C}$), or D (Syng., Gorg., AFt, CH for $T = 90^\circ\text{C}$) are similar to A (Gyp., AFt, CH), calculated in the presence of sodium and the same alkali concentration, whatever the temperature (from 25 to 90°C).

This study also shows that there exists solution compositions under which ettringite is stable even in the presence of a very high temperature (90°C) and alkali concentration (1 mol/l). However, the minimum sulfate concentration above which this phase is stable drastically increases with the temperature, and for a given temperature with the alkali concentration.

Besides, at room temperature, monosulfoaluminate can be observed only in the presence of a low sulfate concentration even when the alkali concentration is high. On the opposite, at elevated temperature, this phase is stable for sulfate concentration varying from relatively low to very high sulfate concentrations. The maximum sulfate concentration under which monosulfoaluminate is stable strongly increases with the temperature, and for a given temperature with the alkali concentration.

ABSTRACT

The influence of temperature on the thermodynamic stability of calcium sulfoaluminate phases has been investigated either by using calculation or experimentally on pure phases. However, it has never been established whether the composition of the liquid and solid phases present in mortar specimens directly after heating are consistent with these thermodynamic predictions. The present results show that this is the case.

Thermodynamics has also been used to determine the effect of cooling on the stability of hydrates formed at high temperatures. In agreement with the thermodynamic data at high temperatures, ettringite has only been observed in the presence of a very high sulfate concentration directly after heating at 90°C and remains stable under similar conditions at 25°C. In contrast, calcium monosulfoaluminate is stable in a wide range of sulfate concentrations at 90°C, but is not stable when the sulfate concentration is high at 25°C. Therefore, when the sulfate concentration in the solution directly after heating is high, calcium monosulfoaluminate is far from stable at room temperature and converts to ettringite which is the stable phase in these conditions. This has been confirmed experimentally.

The composition of the solution and the calcium sulfoaluminate phases formed with time during hydration at elevated temperatures have also been predicted using thermodynamics and have been confirmed experimentally on real OPC systems. In specimens treated at 90°C, ettringite forms first and converts later to calcium monosulfoaluminate even if the alkali concentration is high (1 mol/l). However, the lower the cement SO₃ content, the earlier this conversion occurs. Therefore, when the cement SO₃ content is relatively low, ettringite is not present directly after heating since it has already been converted to calcium monosulfoaluminate. Ettringite is still present at the end of the heat treatment only in cements with very high SO₃ contents (7% SO₃ in the present study).

Keywords: thermodynamic stability, calcium sulfoaluminate phases, ettringite, calcium monosulfoaluminate, stability, temperature, mortar, durability.

1. INTRODUCTION

The influence of temperature on the thermodynamic stability of calcium sulfoaluminate phases has been investigated by calculation by Damidot and Glasser [1, 2]. The calculations were in agreement with experimental data obtained by Michaud – Poupardin and Sorrentino [3] on pure phases.

This paper aims at confirming that the composition of the liquid and solid phases present in mortars directly after heating is consistent with the thermodynamic data.

The nature of the calcium sulfoaluminate phases formed during curing at elevated temperature will be discussed based on the thermodynamic and experimental data of the present study.

Finally, the effect of cooling on the stability of the calcium sulfoaluminate phases formed during the heat treatment is examined.

This study has been carried out in the presence of pore solutions very concentrated in alkali ions to clarify whether ettringite can be present in such conditions in heat treated mortars directly after heating at 90°C. It has been reported [4] that the formation of ettringite is suppressed when temperature and alkali concentrations increase. Besides, ettringite is usually absent directly after heating when industrial cements are used and heat treated at 80°C or above [5 - 9]. However, Heinz and Ludwig [10] detected the presence of ettringite after a heat treatment of 12 h at 90°C for a cement SO₃ content of 8.6 %, and Kalousek [11] observed this phase in a cement paste hydrated in an autoclave at 90°C for 24 hours when the cement SO₃ content was higher than 5.5%.

2. EXPERIMENTAL

This study has been carried out on Portland cements with different SO₃ contents ranging from 2.5 to 16%.

These cements have been prepared from a clinker with a low alkali content of 0.3 % Na₂O_{eq}. The clinker alkali sulfate content has been increased by adding K₂SO₄ to the mixing solution. The amount of K₂SO₄ added increased the clinker Na₂O eq. by 0.8% and the clinker SO₃ by 1%. The cement SO₃ contents reported in this paper are the total SO₃ contents of the cements included the SO₃ contributed by the alkali sulfate.

The cements containing up to 6% SO₃ were produced in the laboratory by intergrinding clinker with a mix of 50% gypsum / 50% hemi-hydrate in a ball mill to a fineness of 330 m²/kg. Higher SO₃ contents were reached by blending the 6% SO₃ cement with gypsum.

EN 196-1 Standard mortars were produced from these cements and 4*4*16 cm specimens were cast.

The heat treatments of these specimens were monitored in a climatic chamber regulated in hygrometry and temperature. The hygrometry targeted during the heat treatment was the highest one which can be reached at 90°C (determined by the Rosée curves), in order to limit the desiccation of the specimens.

The thermal profile used was 4 hours at 20°C, a heating rate of 20°C/h, then 12 hours at 90°C, and finally a cooling rate of 10°C/h.

2.1 Analysis of the liquid phases

The pore solution was extracted directly after heating using a high pressure apparatus. The solution was analysed by inductively coupled plasma atomic emission spectrometry (ICP - AES). The extraction was performed by applying a pressure slowly on the specimens (0.5 MPa/min up to 5 MPa, 10 min at 5 MPa, 0.5 MPa/min up to 6.3 MPa, plateau at 6.3 MPa). Solution was collected at the plateau at 6.3 MPa only, and the amount was small (2 – 3 ml).

This solution is likely to be the one contained in the macropores. The high pressure exerted on the specimens may affect the stability and / or the solubility of the hydrates. Such modifications will be discussed further.

2.2 Analysis of the solid phases

The hydration was stopped directly after heating (28 hours) and after 7 and 28 days of storage using ethanol. The hydrated phases were identified by X-ray diffraction (XRD), X-ray microanalysis (EDS) in a scanning electron microscope (SEM) on polished sections [12]. Some samples were also analysed with ^{27}Al nuclear magnetic resonance (NMR). The ^{27}Al NMR and SEM/EDS techniques have been used since they are more sensitive for detecting calcium monosulfoaluminate which is often undetectable by XRD directly after heating [12]. The XRD results presented here are consistent with this observation.

3. RESULTS

In this text, tables and figures, the following abbreviations have been used:

- AFt = ettringite ($\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$),
- AFm = calcium monosulfoaluminate ($\text{C}_3\text{A} \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$),
- HG = hydrogarnet type phase,
- CH = calcium hydroxide ($\text{Ca}(\text{OH})_2$).

3.1 Composition of the pore solutions and the solid phases directly after heating at 90°C

These are reported in Table 1. The nature of the solid phases has been determined combining XRD (Figure 1), EDS analysis, and ^{27}Al NMR for the cements containing 2.5, 6 and 9 % SO_3 .

Table 1. Composition of the liquid and solid phases directly after heating at 90°C

Cement SO_3 (%)	$[\text{K}^+]$ (mmol/l)	$[\text{Na}^+]$ (mmol/l)	$[\text{K}^+ + \text{Na}^+]$ (mmol/l)	$[\text{SO}_4^{2-}]$ (mmol/l)	$[\text{Ca}^{2+}]$ (mmol/l)	$[\text{Al}(\text{OH})_4^-]^*$ (mmol/l)	Solid phases present
2.5	792	116	908	178	2.4 – 6.6**	< 0.25*	C-S-H, AFm, HG, CH
4	880	120	1000	263	5.9**	< 0.25*	C-S-H, AFm., HG (ϵ), CH
6	888	128	1016	378	9.8**	< 0.25*	C-S-H, AFm., CH
7	871	126	997	366	5.5**	< 0.25*	C-S-H, AFm., AFt, CH
9	865	126	991	370	2.5**	< 0.25*	C-S-H, AFm., AFt, CH
16 ^(I)							C-S-H, AFt, Gypsum, CH

The precision of the concentrations is +/- 2 % except for those annotated by * or **:

* below the detection limit

** precision = 5%

(I): the pore solution has not been extracted

ϵ : low amount

Figure 1. XRD patterns of the 1-day old cured mortars at different SO_3 cement contents

At low SO_3 contents (2,5 and 4 wt %), AFm and HG are present directly after heating. For the samples with a SO_3 content of 6%, only AFm was present. AFt is present beyond this value. At high SO_3 contents (7% and 9%), AFt is present together with AFm. If the SO_3 content increases to 16%, gypsum and AFt are detected.

3.2 Comparison between the solid / liquid systems extracted directly after heating and the thermodynamic prediction at elevated temperature

The Table 2 shows that the sulfate concentrations of the solutions extracted directly after heating in the mortars containing 2.5 % SO_3 is in good agreement with one of the invariant points “AFm, HG, CH” predicted by thermodynamic calculations [1, 2].

Table 2. Comparison of the concentrations directly after heating for the cement containing 2.5 % SO_3 to the thermodynamic predictions (mmol/l)

	$[\text{K}^+] + [\text{Na}^+]$	$[\text{SO}_4^{2-}]$	$[\text{Ca}^{2+}]$	$[\text{Al}(\text{OH})_4^-]$
Conc. measured after heating. (present study)	908	178	2.4 – 6.6	< 0.25
Conc. at the invariant point “monosulf., HG, CH” at 90°C determined by calculation	908	175	0.2	7

The concentration of the solutions extracted directly after heating the mortars made with the cements at 7 and 9 % SO_3 are also in good agreement with the composition at the invariant points “AFt, AFm, CH” determined experimentally on pure phases [3] and by calculation [1, 2] (Table 3). However, the sulfate concentration given by thermodynamics is always higher than that determined in the mortars.

Table 3. Comparison of the concentrations directly after heating for the cement containing 7 or 9 % SO_3 to the thermodynamic predictions (mmol/l)

	$[\text{K}^+] + [\text{Na}^+]$	$[\text{SO}_4^{2-}]$	$[\text{Ca}^{2+}]$	$[\text{Al}(\text{OH})_4^-]$
Conc. measured after heating for 7% SO_3 cement (present study)	997	366	5.5	< 0.25
Conc. measured after heating for 9% SO_3 cement (present study)	991	370	2.55	< 0.25
Conc. at the invariant point “AFt., AFm, CH” at 90°C determined experimentally	1000*	445*	10.3*	< 0.7*
Conc. at the invariant “AFt., AFm, CH” at 90°C determined by calculation	1000	439	1.9	0.4

* The concentrations at the invariant points “AFm, HG, CH” at 90°C have been determined experimentally from pure phases only at alkali concentrations of 420 and 1080 mmol/l and have been extrapolated to an alkali concentration of 1000 mmol (linear extrapolation).

The sulfate concentrations and calcium sulfoaluminate phases detected directly after heating, and the calcium sulfoaluminate phases predicted to be stable by thermodynamics at 90°C for the same sulfate concentrations are reported in Figure 2.

Figure 2. Comparison between the calcium sulfoaluminate phases present directly after heating at 90°C (red experimental points and corresponding solid phases under arrows) and the thermodynamic predictions (in the presence of CH).

Figure 2 shows that the sulfate concentration and solid phases directly after heating are consistent with the thermodynamic prediction. AFt has only been observed in the presence of a very high sulfate concentration (370 - 380 mmol/l at an alkali concentration of 1000 mmol/l) and AFm on a wide range of sulfate concentrations (180 to 370 mol/l at an alkali concentration of 910 – 1000 mmol/l). HG has also been observed in addition to AFm in the mortar with 2.5% SO₃. The presence of HG in the mortar at 4% SO₃ is likely to be due to the fact that the specimen may not have been exactly at equilibrium during the heat treatment. As mentioned previously, AFt has been detected at a sulfate concentration of 370 – 380 mmol/l and an alkali concentration of 1000 mmol/l whereas thermodynamics predicts this phase to become stable at a higher sulfate concentration (\approx 440 mol/l, see Table 2).

To conclude, the composition of the liquid and solid phases present in mortars directly after heating are generally consistent with those predicted by thermodynamics. This also indicates that the pressure exerted on the samples to extract the pore solution does probably not modify significantly the concentrations of the pore solution.

The reason why AFt is detected for a lower sulfate concentration than the one predicted by thermodynamics may have different origins:

- It may result from the fact that the heat treated mortar specimens are not exactly the equilibrium during the heat treatment as indicated by the presence of HG in addition to AFm for the cement containing 4% SO₃.
- It may also result from the fact that the concentrations are different locally in the structure whereas the concentrations measured after extraction correspond to a global and average composition.
- Thermodynamic data [1, 2, 3] do not take into account the presence of C-S-H. The presence of this hydrate may also slightly modify the composition of the invariant points.
- Sulfate ions have been shown to sorb on the C-S-H [12, 13].
- The high pressure exerted on the specimens may slightly affect the solubility of the hydrates.

3.3 Use of thermodynamic data to determine the kinetic path during cement hydration at elevated temperature

At the beginning of hydration, since the system is dynamic, the accurate determination of the composition of the solution and the hydrates requires the knowledge of the supersaturation curves of the different hydrates. However, since they have not been determined, thermodynamic data in the system “CaO-Al₂O₃-alkali- SO₃-H₂O” have been used. They allow a first estimation of the kinetic path of the reaction and prediction of the composition of the solution and calcium sulfoaluminate phases with time at elevated temperatures since thermodynamics is the driving force of hydration.

The hydration of the simplified system: gypsum + C₃A + CH at 85°C in water will be discussed first. The hydration on the real OPC system at 90°C will then be discussed:

As soon as gypsum and CH are in the presence of water, they dissolve until reaching their surface of solubility. The kinetic path followed during this period is illustrated by the line (1) in Figure 3. Simultaneously, C₃A dissolves. Once the solution becomes supersaturated with respect to AFt, this phase precipitates and consumes calcium, sulfate and aluminate ions from the solution. As long as gypsum is present, it continuously dissolves and brings calcium and sulfate ions into the solution in order to maintain the solution saturated with respect to this phase. Therefore, the concentrations in the solution remain constant with time until the gypsum is totally depleted. From that time, the sulfate concentration decreases and the kinetic path followed is given by the line (2) in Figure 3. Beyond a certain time, AFm starts becoming stable. AFt dissolves and AFm precipitates. Once all the AFt has been converted to AFm, the sulfate concentration decreases (kinetic path illustrated by the line (3)). AFm remains stable until the sulfate concentration becomes too low. From this time, HG starts becoming stable.

Figure 3. Phase diagram in the system « CaO-CaSO₄-Al₂O₃-H₂O » at 85°C, in the absence of alkalis [1] and kinetic path followed during the hydration of gypsum and C₃A in the presence of CH in water.

Using the same approach as previously and the thermodynamic data obtained at 90°C, the sulfate concentration and calcium sulfoaluminate phases formed with time have been predicted at alkali concentration of a solution close to the one extracted directly after heating (1000 mmol/l). A schematic representation is given in Figure 4.

Figure 4. Thermodynamically predicted calcium sulfoaluminate phases and sulfate concentration at 90°C with time (alkali concentration = 1000 mol/l).

In 90°C-treated specimens, when alkali concentration of the pore solution is very high (1000 mmol/l), thermodynamics predicts that AFt forms first and converts later to AFm. AFm starts forming while the sulfate concentration is still very high. The sulfate concentration starts decreasing significantly only when all the AFt is totally depleted. Similarly at room temperature, the lower the cement SO_3 content, the earlier is the conversion of AFt to AFm, therefore, the earlier the depletion of AFt is expected to occur. As a consequence, the sulfate concentration decreases earlier.

The experimental results are consistent with this statement. For cement SO_3 contents varying from 2.5 to 6 %, AFt was totally converted to AFm directly after heating. Residual AFt is only observed after heating when the cement SO_3 content is very high (7% or higher). The sulfate concentration directly after heating decreases when the cement SO_3 content decreases from 6 to 2.5%. At 2.5% cement SO_3 content, the sulfate concentration directly after heating is so low that HG starts becoming stable. At that time, the invariant point “AFm – HG – CH” is reached.

The stage reached directly after heating by the mortars containing different cement SO_3 contents is illustrated in Figure 5.

Figure 5. Stage reached by the six different mortars directly after heating

For instance, directly after heating, the mortar containing 16 % SO₃ has reached stage (1) in which gypsum dissolves and AFt grows. On the other hand, the mortar containing 9 and 7 % SO₃ are in the stage (2) in which AFt dissolves and AFm grows.

3.4 Effect of cooling on the stability of calcium sulfoaluminate phases in the 28-hour mortars

The domain of stability under which AFm is stable depends on temperature [1, 2, 3]. At elevated temperatures, AFm is stable in the presence of CH for a large range of sulfate concentrations. In the present study, this phase has been detected for sulfate concentrations varying from 180 mmol/l (in the 2.5% cement SO₃ content) to 370 mmol/l (in the 6 %, 7 % and 9 % cement SO₃ contents) at an alkali concentration of 910 – 1000 mmol/l.

However, this phase is not stable anymore in such conditions at room temperature. Thermodynamics indicates that this phase is never stable below 45°C [1]. Even if AFm forms at room temperature because the system is metastable, this phase can only be present in conjunction with a very low sulfate concentration, irrespective of the alkali concentration. According to thermodynamic calculations, AFt is stable at a sulfate concentration higher than 11 mmol/l if the alkali concentration is of 1000 mmol/l at 25°C. The sulfate concentration and calcium sulfoaluminate phases detected directly after heating and the nature of the calcium sulfoaluminate phases predicted by thermodynamics to be stable at 25°C are reported in Figure 6.

Figure 6. Prediction of the stability of the calcium sulfoaluminate phases present directly after heating once the specimens have been cooled to 25°C

Irrespective of the cement SO₃ content, AFt is stable once the specimens have been cooled to 25°C. If AFm is present directly after heating, it is no longer stable after cooling to room temperature and tends to convert to AFt. The XRD analysis of the hydrated phases present after 28 days of water storage at 25°C for the 4 and 6 % SO₃ cements confirms this result (Figure 7). The higher the sulfate concentration of the solution, the farther is the AFm from stability at room temperature (i.e. the solubility curve of AFm is very far from the one of AFt at 25°C) and the more rapidly the AFm tends to convert to AFt. This is the case for the 6% SO₃ cement.

Figure 7. XRD patterns with time for the mortar containing 6% SO_3 .

On the other hand, if AFt is present directly after heating, the sulfate concentration is always high. AFt remains stable under such conditions at 25°C and does not convert to an other phase as illustrated in Figure 8 for the mortar made with the 9% SO_3 cement.

Figure 8. XRD patterns with time for the mortar containing 9% SO_3 .

4. CONCLUSIONS

- This study shows that the composition of the liquid and solid phases in mortar specimens directly after heating are consistent with those predicted by thermodynamics at elevated temperatures.
- The pressure exerted on samples to extract the pore solution does not significantly modify the compositions of the solutions.
- Thermodynamics has been used to predict the kinetic path during hydration at elevated temperatures. In specimens treated at 90°C, thermodynamics predicts that ettringite forms first and converts later to calcium monosulfoaluminate even if the alkali concentration is high (1000 mmol/l). The results of the present study are consistent with this and show that the lower the cement SO_3 content, the earlier this conversion occurs.

Below a certain cement SO_3 content, ettringite is not present directly after heating since it has already converted to calcium monosulfoaluminate. However, ettringite is still present at the end of the heat treatment when the cement SO_3 content is elevated (in agreement with Heinz et al. [10] and Kalousek et al. [11]).

- Thermodynamics has also been used to determine the effect of cooling on the stability of the hydrates formed at elevated temperatures. In agreement with the thermodynamic data at elevated temperatures, ettringite has only been observed in the presence of a very high sulfate concentration after heat treatment at 90°C (370 mol/l at an alkali concentration of 1000 mmol/l). It remains stable under similar conditions at room temperature. On the other hand, calcium monosulfoaluminate is stable for a wide range of sulfate concentrations (180 to 370 mmol/l at an alkali concentration of 910 – 1000 mmol/l) at 90°C , but is no longer stable when the sulfate concentration is high at room temperature. It can only be present in conjunction with a very low sulfate concentration, even when the alkali concentration is high. Therefore, when the sulfate concentration directly after heating is high, calcium monosulfoaluminate is far from stable at room temperature and converts to ettringite which is the stable phase in these conditions. This has been confirmed experimentally.

ABSTRACT

Counter-diffusion of miscible fluids has been evaluated as a technique for characterizing the pore structure of cementitious materials. A water-saturated specimen is placed in a large excess of a water-miscible fluid and a counter-diffusion process is observed by monitoring the mass change of the specimen over time. Values for porosity and apparent diffusivity of the porous medium are obtained. However, wider acceptance of the method by cement and concrete researchers has been slow. One reason for this lack of acceptance has been that analysis of the data collected, measurements of mass as a function of elapsed time, is complicated by the three-dimensional nature of the specimens. A detailed analysis has been developed, and is presented here, to address this limitation. Data are provided for cement paste specimens of varying water:cement ratios and degrees of hydration.

1. INTRODUCTION

Mass transport through porous materials is important in the study of cement-based materials. Advantages of concrete as a construction material include its durability, cost, energy efficiency (on a life-cycle basis), and formability. It is also fire resistant and made out of materials that form a large proportion of the earth's crust and are, therefore, widely available. The durability problems that concrete encounters depend in large part on its transport properties. In concrete, damage from freeze/thaw cycles, sulfate ion attack, alkali-aggregate reactions (AAR), deicer salt scaling, and chloride-induced corrosion of reinforcing steel are potential problems that are strongly influenced by the mass transport properties. Therefore, a simple technique for characterizing the transport properties of cementitious systems would be a beneficial tool to researchers and field engineers for use in evaluating concrete materials. The counter-diffusion technique holds promise as a method to be that tool. More details can be found in reference [1].

1.1 Overview of technique

The driving force for flow in the counter-diffusion technique is a concentration gradient. A porous specimen saturated with one fluid is immersed in a large volume of another fluid with which it is miscible. The concentration gradient arises from the high concentration of the external fluid outside of the specimen and the low concentration of that fluid internally (and vice-versa for the internal fluid). The rate and extent of the fluid flow caused by this concentration gradient can be evaluated by periodically determining a mass of the specimen during the counter-diffusion process. There are several requirements for the procedure to be effective: 1) a difference in density of the two fluids, 2) a sufficient volume of connected porosity for the mass difference to be detected, 3) a diffusivity low enough so that the mass changes can be measured on a practical time scale, and 4) a lack of

chemical interaction of the penetrating fluid with the solid. An advantage of the counter-diffusion technique is the relative ease of measurement, requiring only an analytical balance and a timer.

1.2 Review of literature

Although several authors have used counter-diffusion techniques to examine the pore structures in cementitious systems [2]-[12], only Feldman [6-7] and Gran and Hansen [8] have attempted to estimate diffusion coefficients from the data. In Feldman's research, the analysis used is not derived, but is stated [7] to be "a form of Fick's Law:"

$$\frac{M_t}{M_f} = 1.127 \sqrt{\frac{Dt}{L^2}} \quad (1)$$

where M_t is the mass of the specimen at time t , and M_f is the final mass, L is the half-thickness of the specimen, and D is the diffusivity. The equation appears to simplify the analysis of counter-diffusion to only account for diffusion across the faces of the disk, which may be reasonable, given the dimensions of the disks used (1.14 mm thick \times 30 mm diameter).

Gran and Hansen (1998) used an approximation for their specimens that only accounted for radial diffusion. Their specimens were cylinders with a much higher length-to-diameter ratio (20 mm long \times 5.5 mm diameter), so the approximation is also likely to be valid. However in the work partially presented here [1], specimens of different sizes and shapes were evaluated. Therefore, a slightly more complex analysis, taking into account diffusion on all faces, has been developed.

Because a plot of mass change as a function of time is non-linear, one method to characterize the data has been the time required for half of the exchange to take place [4], which has been given the symbol $\epsilon\tau_{1/2}$. It has been suggested that this is related to the diffusivity of the specimen. This is not necessarily the case. As shown schematically in Figure 1, which contains three idealized curves for counter-diffusion data, this parameter is related to both the diffusivity and the volume of pores. Curves a and b compare data for specimens with the same porosity; however specimen a has a smaller value of $\epsilon\tau_{1/2}$. Thus the pores in specimen a may be smaller or connected by smaller pores. Curves b and c compare specimens with similar rates of diffusion, but have different values of $\epsilon\tau_{1/2}$ due to a smaller volume of porosity in specimen c . Comparing the curves for specimens a and c illustrates that differences for $\epsilon\tau_{1/2}$ can also be due to differences both in diffusivity and porosity. Thus the meaning of the value of $\epsilon\tau_{1/2}$ is complicated and best used for comparison of specimens with similar volumes of porosity. (In this discussion, it is assumed that the specimen dimensions have been accounted for and the counter-diffusing fluids are the same.)

Figure 1. Diagram showing idealized counter-diffusion curves with different values of $\epsilon\tau_{1/2}$. Changes in $\epsilon\tau_{1/2}$ can be due to differences in porosity or diffusivity. See text for discussion of curves.

2. EXAMPLE ANALYSIS

2.1 Typical experiment and results

Details regarding specimen preparation are reported elsewhere [1]. After a saturated specimen is obtained, the specimen is then suspended in a thin wire mesh basket, and its mass determined while suspended in a large excess (on the order of 50:1 by volume of pores) of the replacing fluid. Its mass is measured periodically until the mass loss is less than 0.001 g in 24 hours (and generally several times thereafter to confirm that equilibrium has been reached). The counter-diffusion data reported here are based on suspended masses, rather than saturated, surface-dry masses, as suspended mass determinations are made more reliably.

In Figure 2, example mass data for a counter-diffusion experiment are plotted as a function of square root of time. When the data are plotted against the square root of time, it is possible to observe an initial portion of the curve that approximates a straight line, followed by an asymptotic approach to a constant mass. This is a characteristic of diffusion-controlled processes. The slope of the initial portion is indicative of the diffusivity of the specimen, but is also dependent on the size and shape of the specimen. If specimens of similar size and shape are compared, those with lower diffusivity will have a slope that is less negative. Because of this linear portion of the curve, the preferred method of plotting the counter-diffusion data in this paper is as mass change vs. square root of time.

Both methanol and isopropanol proved non-volatile enough to provide accurate masses. However the use of methanol was avoided as it appears to chemically react with calcium hydroxide in cementitious systems [12-13] and produce measurable dimensional changes [7], and enlarging the threshold pore diameter as measured by MIP [14]. As the extent of these interactions, and more importantly, their effects on the mass and volume of the specimen, could not be quantified, isopropanol was used as the replacing fluid in all the work reported here. Isopropanol has been shown to exchange with pore solution and not produce dimensional changes in Portland cement paste specimens [7]. Further, it is believed [15-16] that isopropanol accesses primarily the capillary porosity in cementitious systems, which are the pores usually expected to dominate the transport properties.

Figure 2. Example counter-diffusion data. Mass of a Portland cement paste specimen during counter-diffusion experiment is plotted against square root of time: $e\tau_{1/2}$ is the time to half the mass change, m is the slope of the initial portion of the curve, $M_i - M_f$ is the total mass change and is related to the porosity. Disk-shaped specimen of Portland cement paste, 3 mm thick, 26 mm in diameter, water:cement ratio of 0.70, after 28 days of hydration.

2.2 Apparent diffusivity

The approach used to estimate the diffusion coefficient from counter-diffusion data is based on solutions to Fick's second law. Analytical solutions to Fick's second law in one dimension for ideal cases (infinite slab, infinite cylinder) can be combined to provide closed-form solutions for more practical (three-dimensional) shapes (prisms, disks) by application of the superposition principle. This approach is discussed in a number of texts on diffusion [17-20], with a variety of solutions for common geometries. Figure 3 is an illustration for a finite cylinder formed from the intersection of an infinite cylinder and an infinite slab: a combination of the solutions for the two simple cases is used to provide a solution for the finite cylinder.

Figure3. Finite cylinder formed from the intersection of an infinite cylinder and an infinite slab.
After [19].

A specimen with initial concentration, C_o , throughout is placed in solution of different concentration, C . Counter-diffusion over time acts to bring the specimen back to an equilibrium condition. In the case of a large excess of solution, the equilibrium concentration in the specimen is essentially C .

Consider a finite cylinder of diameter $2a$, and height $2H$ as shown in Figure 4. In this case diffusion can take place both radially and through the ends. The concentration at point r (x , a) and time t ($t > 0$) in the cylinder is (see Figure 3) [18-19]:

$$C_{disk} = C_{slab} C_{cyl} \quad (2)$$

or

$$C_{disk} = \frac{8C_o}{\pi a} \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} \frac{(-1)^m J_0(r\alpha_n)}{(2m+1)\alpha_n J_1(a\alpha_n)} \cos \frac{(2m+1)\pi x}{2H} e^{-Dt(\alpha_n^2 + \frac{(2m+1)^2 \pi^2}{4H^2})} \quad (3)$$

Figure 4. Disk (finite cylinder) showing definition of variables in Equations 4 and 5.

The average concentration in the cylinder is obtained by integrating over, and normalizing by, the volume of the disk:

$$C_{disk\ avg} = \frac{32C_o}{(\pi a)^2} \sum_{n=0}^{\infty} \sum_{m=1}^{\infty} \frac{1}{\alpha_m^2 (2n+1)^2} e^{-D t \left[\alpha_m^2 + \frac{(2n+1)^2 \pi^2}{4H^2} \right]} \quad (4)$$

where α_m are the roots of a zeroth order Bessel function [21], and other variables are as previously defined.

The diffusivity of porous specimens is determined by optimizing the fit between curves predicted for average concentration as a function of time to data measured for suspended mass as a function of time during counter-diffusion experiments, by varying the diffusivity, D . Equations for average concentrations during counter-diffusion are converted to a mass basis using Equation 5:

$$M_t = (M_i - M_f) \frac{C}{C_o} + M_f \quad (5)$$

where M_t is the mass at time, t , M_i is the initial suspended mass of the specimen, M_f is the final suspended mass of the specimen, and C is the average concentration in the specimen, and C_o is the initial concentration. C/C_o is taken as 100% at $t = 0$, and approaches 0 for large values of time. The optimum value of D is determined by the best fit between theoretical values and experimental results.

Figure 5. Concentration profiles for a quarter cross-section of a finite cylinder given by Equation 3. Case of $a = 9H$ (see Figure 4), as for cement paste specimens in this research. The origin of each plot represents the center of the disk. $D = 5 \times 10^{-11}$, time parameter ($D t/H^2$) of: (a) 0.04, (b) 0.08, (c) 0.16, and (d) 0.32, representing 26%, 37%, 50% and 68% fluid replacement respectively.

Figure 5 shows time series plots of the normalized isoconcentration lines as a function of location in the cylinder (r/a), and the dimensionless time parameter, $D t / a^2$, for a specimen with a width $a=9H$, resulting from Equation 3. Figure 6 illustrates the average concentration in the slab as a function of the dimensionless time, using Equation 4.

Figure 6. Average concentration in a finite cylinder given by Equation 4.

Figure 7 illustrates the variation of the predicted counter-diffusion curves for various values of D .

Figure 7. Plot of results of Equation 4 with values of D indicated.

3. RESULTS FOR CEMENT PASTES

3.1 Water to cement ratio and degree of hydration

Table 1 provides the mean values determined for the apparent diffusivity: the initial slope of the mass loss vs. time curve, and the porosity. The values stated are averages of four disks, with the standard deviation in parentheses. Figure 8 shows an example of the suspended mass data plotted against square root of time for the specimens cast at a water:cement ratio of 0.60 by mass. The initial slope was determined from the equation of the best-fit line using a minimum of five points. In all cases the correlation coefficient, r , was greater than 0.99.

Table 1. Apparent Diffusivity of Neat Cement Paste Specimens determined using Counter-Diffusion: mean value (standard deviation).

Water: cement ratio, mass basis	Age, days	Degree of reaction*, (%)	Diffusivity, D ($10^{-12} \text{ m}^2/\text{s}$)
0.35	28	70	4.6 (0.93)
	259	76	5.6 (0.39)
	420	nd	5.7 (1.40)
0.40	28	70	5.4 (0.06)
	425	81	4.2 (0.26)
0.50	28	76	11.4 (1.91)
	320	90	8.7 (1.05)
	566	91	8.1 (0.59)
0.60	28	75	29.4 (1.25)
	280	92	6.7 (0.42)
	420	nd	8.0 (0.29)

nd: not determined.

*Degree of reaction determined based on loss of ignition tests assuming a non-evaporable water content of 0.24 g/g cement [22].

Figure 8. Mass loss as a function of time during counter-diffusion of 2-propanol into saturated Portland cement paste specimens A, B, C, and D. Dashed lines determined using Equations 4 and 5. Portland cement pastes cast at a water:cement ratio of 0.60, hydrated 28 days.

The trends for apparent diffusivity are that values decrease with age and increase with water:cement ratio. However, for the pastes with the two lowest water:cement ratios, the apparent diffusivity is low and relatively constant, while a larger decrease with age is noted for the pastes with higher water:cement ratios. This is likely to be related to the interconnectedness of the capillary pore structure. For example [23], the pores in a paste with a water:cement ratio of 0.35 will become disconnected when the cement is only about 55% reacted, while a paste with a water cement ratio of 0.60 will require almost complete hydration. Above a water:cement ratio of 0.70, the capillary pores do not become disconnected. By these estimates, at 28 days the pastes with water:cement ratios of 0.35 and 0.40 have a disconnected capillary pore structure. Increased hydration beyond 28 days does not substantially reduce the apparent diffusivity, because the capillary pore structure is already disconnected. For the specimens with a water:cement ratio of 0.60, the capillary pore structure is still connected at 28 days and the apparent diffusivity is high. At the later ages, the pore structures have become disconnected, leading to the observed substantial reduction in diffusivity.

3.2 Sensitivity

Figure 9 provides qualitative information on the sensitivity of the technique. The figure shows trial values of D plotted as a function of the degree of fit [25] between the experimentally determined values and those calculated using the procedures outlined in this work. The example shown is typical and represents Portland cement paste specimens cast at a water:cement ratio of 0.60 and hydrated 28 days. The data follows a relatively steep and symmetric curve, suggesting that the value of D is well-defined by the procedures developed.

Figure 9. Sensitivity of counter-diffusion derived values of apparent diffusivity: fit coefficient plotted against trial values for D for Portland cement paste specimens A, B, C, and D (see Figure 8) mixed at water:cement ratio of 0.60.

3.3 Comparison of results to prior data

Values for diffusion coefficients determined through the counter-diffusion technique would be more beneficial if they could be related to diffusion coefficients of species important to the durability of concrete. Chloride ions are one such species as they destroy the passivation layer that develops around reinforcing steel in concrete, thereby allowing corrosion to proceed. Figure 10 shows a comparison of the results of chloride ion diffusivity measurements on neat Portland cement pastes at 25 °C [24] and those determined for specimens at the same water:cement ratios using the counter-diffusion technique in this work. Although the amount of data is limited, and differences in cement chemistry and age of specimens at test (60 days for the chloride ion data, 28 days for the isopropanol counter-diffusion data), the results show a high linear correlation ($r^2=0.996$). The high correlation lends support to the idea that the counter-diffusion technique could be used to relatively quickly provide a quantitative characteristic important to the durability of cement-based materials.

Figure 10. Comparison of diffusion coefficients for neat Portland cement pastes determined using chloride ions, D_{Cl} [24], and the counter-diffusion method, D_{isop} , for specimens with identical water:cement ratios. Dashed line is the best fit (regression equation indicated).

4. CONCLUSIONS

An analysis method for apparent diffusivity has been developed that takes into account specimens of different shapes and sizes, including disks (finite cylinders). A suite of Portland cement pastes, with a range of water:cement ratios of between 0.35 and 0.60, was tested. For these specimens values of D on the order of $10^{-12} \text{ m}^2/\text{s}$ were determined. Qualitative examination of the sensitivity of the approach indicates that the analysis provides well-defined values. Furthermore the technique is simple and provides parameters that are important to the study of durability of cement-based materials, namely, the transport properties. Correlations between diffusion coefficients determined using this technique appear to be linearly related to those determined using other techniques.

ABSTRACT

The subject of this paper is the effect of foreign elements on the reactivity and the structure of clinker. One reference mixture and twenty two modified mixtures, prepared by mixing the reference sample with 1% w/w of chemical grade MnO₂, CuO, V₂O₅, PbO, CdO, ZrO₂, Li₂O, MoO₃, Co₂O₃, NiO, WO₃, ZnO, Nb₂O₅, CrO₃, Ta₂O₅, TiO₂, BaO₂, SnO₂, SrO, CaF₂, CaCl₂ and CaS were studied. The effect on the reactivity was evaluated on the basis of the free lime content in samples sintered at 1200°C and 1450°C. XRD was used for the identification of clinker phases, while SEM was used in order to examine the texture of the sintered samples. Selected clinkers were interground with gypsum and the setting time and the compressive strength of the prepared cements were measured. It was found that, the addition of certain elements in the raw mix is an efficient way to control the reactivity of the mixture. At 1200°C, the reactivity of the raw mix is increased in the presence of Sn, Cu, Li, S and Cl compounds. At the final stage of sintering, F, S, W, Ta, Sn and Cu compounds show the most positive effect, while Cr and Sr compounds have a negative effect on clinker burnability. The effect on the reactivity of the cement raw mix, at high temperature, is directly related to the electronic configuration of the added elements. Elements that show a positive effect are preferentially incorporated in the liquid phase. These elements do not considerably affect the strength development and the setting time of the cement.

1. INTRODUCTION

There is an increasing move towards the use of a variety of alternative raw materials and fuel in cement manufacturing aiming to obvious benefits. The main concern in these cases is the incorporation of the foreign elements in the clinker and their effect on the burning of the raw mix and the performance of the cement. It has been found that small amount of inorganic additives can considerably affect the sintering process, the structure and the properties of clinker and that is why their effect was successfully described as a catalytic one [1-5]. The role of minor components and their influence on clinkering is summarized, in general terms, from published reports as fluxing and mineralizing actions. Such compounds may lower the temperature of the first liquid phase formation and/or increase the amount of the melt (fluxes), accelerate the rate of the reactions occurring in the solid state, within the liquid phase, or at the liquid-solid interface (mineralizers), alter the viscosity and surface tension of the melt and affect both crystal growth and morphology. The technological consequences are evident: changes of the reactivity and burnability of the raw materials, formation of new phases in altered amounts, differentiation on hydraulic activity and properties of produced cements, chance of energy conservation and saving as well as alterations-precautions during clinker manufacture due to the high volatility of some compounds. The effect of foreign elements on the melt properties is well established in the literature [6]. In our previous work, it was shown that the well known effect of certain cations on the formation and the properties of the melt can be reflected on the overall reactivity of the cement raw mix [7,8].

When heavy elements are present in cement, the early hydration reactions are prohibited, probably through the formation of amorphous compounds that cover the unreacted cement grains. The hydration reactions start again after the crystallization and sedimentation of these compounds, which takes place when the Ca^{2+} and OH^- concentration becomes high enough [9-11]. The hydration process, however, of clinkers containing these compounds is expected to be different, since their incorporation in the clinker phases modifies their dissolution rate during hydration.

In this the paper, the effect of twenty-two elements (anions and cations) on the reactivity of the cement raw mix is evaluated and correlated with their electronic configuration. The modified clinkers were examined under SEM in an attempt to elucidate the way these elements affect the sintering process and examine their distribution in the clinker compounds. In addition, the effect of certain mineralizing elements on the cement properties is discussed.

2. EXPERIMENTAL

One reference mixture, composed of chemical grade CaCO_3 , SiO_2 , Al_2O_3 and Fe_2O_3 and having a composition very close to that of a typical cement raw meal, was prepared. Quartz and aluminum oxide were ground to a particle size less than $90\mu\text{m}$ and then were intensively mixed with Fe_2O_3 and precipitated CaCO_3 in a laboratory swing mill for 1 hour. Homogeneity was ascertained by measuring the loss on ignition (L.O.I.) in three individual samples of the mixture. The results indicated that L.O.I. values were very close to the estimated one (34.99%), certifying a good homogeneity of the raw mix. Table 1 shows the chemical and mineral composition (according to Bogue) of the reference mixture, after it was sintered at 1450°C .

Table 1. Chemical and mineral composition of the reference mixture after thermal treatment at 1450°C

Clinker chemical composition		Clinker mineral composition (according to Bogue)	
Oxide	wt (%)	Mineralogical constituent	wt (%)
CaO	68.08	C_3S	65.0
SiO_2	22.81	C_2S	15.0
Al_2O_3	5.84	C_3A	10.0
Fe_2O_3	3.27	C_4AF	10.0

Twenty two modified mixtures were prepared by mixing the reference sample with 1% w/w of chemical grade MnO_2 , CuO , V_2O_5 , PbO , CdO , ZrO_2 , Li_2O , MoO_3 , Co_2O_3 , NiO , WO_3 , ZnO , Nb_2O_5 , CrO_3 , Ta_2O_5 , TiO_2 , BaO_2 , SnO_2 , SrO , CaF_2 , CaCl_2 and CaS . All the cations were introduced in the form of oxides, in order to avoid the effect of foreign anions on the reactivity of the mixture. In the case of Cl^- , F^- and S^{2-} , calcium salts were used in order to avoid the effect of foreign cations. When necessary, the added compounds were ground in order to have, approximately, the same fineness with the reference sample. Very fine compounds (e.g. ZnO), were sieved, prior to mixing, in order to avoid agglomeration. The homogeneity was ascertained by dosing the added element, in some indicative samples.

All the samples were pressed to form pellets, then sintered at 1200°C and 1450°C for 30 min in an electrical furnace and cooled rapidly in air. The sintered pellets were ground and analyzed by the ethylene glycol method in order to estimate the free CaO (fCaO) content.

The samples were, also, examined using a Siemens D-5000 X-ray diffractometer, with nickel-filtered $\text{Cu K}\alpha_1$ radiation ($\lambda=1.5405 \text{ \AA}$), for the identification of the mineralogical phases formed during sintering. Scanning Electron Microscopy was applied in order to examine the fracture

surface of the obtained clinkers. A JEOL JSM-5600 Scanning Electron Microscope, interfaced to an OXFORD LINK ISIS 300 Energy dispersive X-ray spectrometer (EDS) was used.

The reference clinker and the clinkers containing CuO, ZnO, MoO₃ and WO₃ were interground with 5% w/w gypsum in a pro-pilot plant ball mill of 5 kg capacity. The gypsum was of industrial origin (98% w/w CaSO₄·2H₂O). The fineness of all the produced cements was found to be in the range between 3500 and 3700 cm²/g (Blaine). The compressive strength of the samples (EN 196-1) and the setting time (EN 196-3) was determined.

3. RESULTS AND DISCUSSION

3.1 Reactivity of cement raw mix

The free lime content in all samples was measured after thermal treatment at 1200°C and 1450°C, in order to evaluate the effect of the additives on the solid state reactions and on the reactions in the presence of the melt, respectively. Figures 1 and 2 show the free lime content in the samples, at these temperatures, in relation to the added compound.

As it was expected, most of the added compounds have only marginal effect on the reactivity of the raw mix, at 1200°C. However, the addition of CuO, Li₂O and CaS causes a remarkable decrease of the fCaO (Figure 1).

The addition of 1% CuO in the raw meal caused a decrease of fCaO by approximately 60%, showing the best result among the other doping agents. In fact, CuO was reported to be an efficient mineralizer and flux, its action beginning already at 1100°C [12]. The mineralizing action of CuO and SnO₂ seems to be related to their incorporation in solid solutions with calcium oxide and/or the acceleration of the reactions among the four main oxides. The dark color of these samples, even at 1100 °C, indicates a high degree of combination of the main constituents and especially of Fe₂O₃. This color change is observed above 1300°C, in the other samples.

Figure 1. fCaO content in samples at 1200°C, in relation to the added compound

The TGA measurements showed that, in the presence of CaCl₂ and Li₂O the decomposition of calcium carbonate starts at much lower temperature (50°C and 70°C lower than in the reference sample, respectively). Saraswat et al have also observed the same effect, as well as an accelerated formation of belite in samples containing Li₂CO₃ and they have attributed these effects to the

formation of higher reactive CaO [13]. XRD measurements showed, also, some indications for the formation of Ca-Al-Cl-O solid solutions at 1200°C, in the sample containing CaCl₂. Cl compounds were also reported to favor the formation of spurrite, but we were unable to detect any spurrite in this sample [2]. Therefore, the increased rate of fCaO combination at 1200°C, can be attributed to the accelerated decomposition of calcium carbonate and the incorporation of CaO in new Cl containing phases.

Based on their effect at 1450°C, the added elements can be divided into three groups (Figure 2). F, S, W, Ta, Sn, Cu, Ti and Mo show the most positive effect, decreasing the fCaO content by 30-83%, compared with the pure sample. Cr and Sr cause an increase of fCaO content, while the rest of the elements exhibit a marginal positive effect.

In the case of clinkers containing Cr and Sr oxides, the XRD and SEM studies confirmed a high content of belite and free lime in these samples. It seems that either alite is decomposed in the presence of Cr and Sr, or belite is stabilized in a way that further reaction with lime is inhibited.

Most of the foreign ions, present in the raw mix, are dissolved in the melt and affect its properties. In previous works, quaternary mixtures, having the typical composition of the liquid phase, were studied and the correlation between the electronic configuration of the added ions (atomic radius, electronegativity, field intensity) and their effect on the properties of the melt was well established [1, 4]. However, it is not clear whether any changes of the melt properties can be reflected on the overall reactivity of the CaO-SiO₂-Al₂O₃-Fe₂O₃ mixture.

Figure 2. fCaO content in samples at 1450°C, in relation to the added compound

The effect of the added ions to the reactivity of the mixture, at 1450 °C, was evaluated on the basis of their electronic configuration. Figure 3 presents the fCaO ratio (ratio of fCaO content in modified samples to the fCaO content in the reference sample) and the atomic radii of the added elements, in relation to their atomic number.

Figure 3. fCaO ratio at 1450 °C and atomic radii of the added elements, in relation to their atomic number.

Figure 4 presents the fCaO ratio and the electronegativity (according to Pauling) of the added elements, in relation to their atomic number. As it is shown, the changes of the free lime content closely follow the periodicity of the atomic radii and the electronegativity of the added elements. The presence of ions, having decreased size or increased electronegativity, favors the combination of the free lime and therefore improves the reactivity of the mixture. Our work confirms that the overall reactivity of the mixture can be correlated with the electron configuration of the added ions, in the same way as the properties of the melt. The addition of small amount of selected compounds can alter extensively the properties of the melt and these modifications of the melt properties are reflected on the reactivity and burnability of the raw mix, which is very important in the case of the cement production. The only deviation of this simple rule concerns two groups of elements: i) Cu and Sn and ii) Cr and V. The elements in the first group showed a positive effect on the reactivity, although they were expected to have a negative one. However these elements were proved to be efficient mineralizers even at low temperature and their action is probably irrelevant with their effect on the properties of the melt. The elements in the second group are preferentially concentrated in belite and they are not expected to affect the properties of the melt extensively.

Figure 4. fCaO ratio at 1450 °C and electronegativity (according to Pauling) of the added elements, in relation to their atomic number.

Our measurements, concerning the volatility of the added elements showed that these elements can be divided into three groups:

High volatile elements: Cd, Pb, S, Cl (less than 20% remained in sample)

Moderate volatile elements: Cr, Co, Ni, Mn, F

Low volatile elements: Ti, Cu, Mo, W, V, Zn, Zr, Ba, Nb, Ta, Li (almost 100% remained in sample).

As it is obvious, the content of the added elements is not constant in all burnt samples, since each element has a different volatility. However, we have chosen to have a constant percentage of added oxides in the raw meal for two reasons: i) it is more convenient to control the composition of the raw mix than the composition of the clinker and ii) even the elements with increased volatility and small retention in clinker may considerably affect the reactions that take place before their removal from the mixture.

3.2 Structure of modified clinkers

Some of the modified clinkers were examined under SEM. Photos of the pure clinker, as well as the clinkers containing W, Ta, Sn, Cu and Sr oxide are presented in Figure 5. The photos were selected to be representative as far as the distribution, size and form of alite and belite crystals are concerned. With the spot analysis of EDS, the composition of the principal phases was analyzed at five to eight points.

Figure 5. SEM photos of clinker
a. Reference, b. SrO, c. WO₃, d. CuO

In reference sample (Figure 5a) belite grains were uniformly distributed as small roundish grains, having a size of approximately 10-20μm. Alite crystals dominated the sample's texture, with particle size ranging from 20 to 30μm. Alite appeared as compact basal prismatic crystals of

slightly rounded hexagonal outline. The interstitial material had a fine-crystalline structure and it was generally adequate.

Clinkers containing Sr and Cr oxides (Figure 5b) present a similar texture that can be correlated with the similar behaviour during sintering. Belite, in both samples, forms clusters of rather rounded grains uniformly distributed in the sample. Free CaO grains are also evident as light white spherical crystals having a leaflet configuration. The coexistence of free lime with belite crystals indicates the decomposition of alite into belite and free lime. The XRD studies and the chemical test confirmed a high content of belite and free lime in these samples. EDS analysis resulted that Sr and Cr are preferentially incorporated in belite.

The elements that had a positive effect on the burnability of clinker during the final stage of sintering, had also a common effect on the texture of clinker (Figure 5c, 5d). These elements were mainly distributed in the liquid phase and they seem to favor the formation of big rounded alite crystals.

3.3 Cement properties

It is known that the presence of heavy metal compounds in cement causes a remarkable delay as far as the setting is concerned. The hydration process, however, of clinkers containing these compounds is expected to be different since the elements are incorporated in the clinker phases.

Figure 6 presents the strength development of the cements containing Cu, Zn, Mo and W oxides. The initial strength (2 days) fluctuated from 13.2 to 18.3 N/mm². After 28 days, the samples with CuO and ZnO presented slightly higher strength while the samples with WO₃ and MoO₃ had slightly lower strength than pure cement.

Figure 6. Compressive strength of cements in relation to the added oxides

Figure 7 presents the setting time of the produced cements. The sample containing ZnO showed the greater delay especially as far as the final setting is concerned (170 minutes). However, it must be noted that, according to our measurements, the addition of free ZnO in cement (0.5% w/w) delays the setting by 12-15 hours. When heavy elements are present in cement, the early hydration reactions are prohibited, probably through the formation of amorphous compounds that cover the unreacted cement grains. The hydration reactions start again after the crystallization and sedimentation of these compounds, which takes place when the Ca²⁺ and OH⁻ concentration becomes high enough [6-8]. ZnO, which greatly inhibits hydration when added in cement, does not have the same effect when added in cement raw mix. This must be associated with the different

dissolution rate of Zn^{2+} . The incorporation of Zn in the crystal lattice of clinker minerals delays the dissolution of Zn^{2+} . If Ca^{2+} concentration is high enough when Zn enters the solution, crystalline hydrated zincate salts are formed rather than amorphous zinc hydroxide and the retarding effect is decreased.

Figure 7. Setting time of cements in relation to the added oxides

4. CONCLUSIONS

From the present study the following conclusions can be drawn:

- ✓ The addition of selected elements in the raw mix is an efficient way to control the reactivity of the mixture. The effect on the reactivity of the $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3$ system, at high temperature, is directly related to the electronic configuration of these elements.
- ✓ At 1200°C , the reactivity of the raw mix is increased in the presence of Cu, Li, S and Cl compounds. At the final stage of sintering at 145°C , F, S, W, Ta, Sn and Cu show the most positive effect, while Cr and Sr compounds have a negative effect on clinker burnability.
- ✓ The incorporation of foreign elements in the clinker compounds eliminates their retarding effect on the hydration rate of the cement.

ABSTRACT

A new cementitious material has recently become available in the Western Cape region of South Africa. The product is a ground slag produced by the Corex process at the new Saldanha steel mill in South Africa. Detailed characterization of the new material was essential given the unique Corex process and the extensive optimisation of composition and grinding processes that was undertaken. Modern technology was able to produce a material with high performance characteristics not commonly found in ground slags. Detailed analysis of the raw material as well as analysis of the final concrete properties was therefore undertaken. Results from the laboratory research found that Corex slag not only enhances concrete durability properties but also produces good early strength and improves other structural properties. The emergence of this new slag source in the Western Cape has made a major impact on the durability and economy of concrete construction in the region. The high performance nature of the material has allowed durable concrete to be produced without compromising structural properties and at no additional cost.

1. INTRODUCTION

Slag is a by-product of iron manufacturing and has been used as a cementitious product in concrete for more than a century. The new Saldanha plant produces steel from Corex liquid iron and direct reduced iron thereby replacing the need for coke ovens and a blastfurnace. This change in technology has an influence on the chemistry and morphology of the slag that is produced at the end of the process. It was therefore important that Corex slag was fully characterized and compared to blastfurnace slag that has been successfully used in South Africa for several decades. This paper presents some of the results of an extensive investigation carried out during 2000 and 2001 at the University of Cape Town [1].

2. INTRINSIC CHARACTERISTICS

Corex slag from Saldanha (CS) was compared with blastfurnace slag from Vanderbijlpark (BS), which has a good track record as a cementitious material. Chemical and physical properties of the unreacted dry powders were analysed to predict the hydraulic activity of the two slag types. Portland cement (PC) of type CEM I 42.5 from Riebeeck West cement works was used in this testing program and was also characterized where appropriate.

2.1 Chemical Composition

The hydraulic reactivity of slag powders is influenced by the chemical composition of the material. Compounds that increase reactivity include CaO, MgO and Al₂O₃ while SiO₂ reduces slag

hydraulicity. Oxide analysis was done by standard XRF techniques and results are compared in Table 1. Analysis showed that CS had higher CaO, Al₂O₃ and MgO concentrations than BS, and lower levels of SiO₂. These differences in composition indicate that CS should have higher hydraulic activity than BS of equivalent fineness, when compared with most accepted hydraulic activity formulas [2].

Table 1. Oxide analysis of binders (% by XRF analysis)

Oxides	PC	BS	CS
CaO	67.2	34.0	37.2
SiO ₂	22.3	35.5	30.8
Al ₂ O ₃	4.4	15.4	16.0
MgO	1.01	9.40	13.7
TiO ₂	0.22	1.20	0.51
Fe ₂ O ₃	3.4	0.98	0.87
MnO	0.08	0.88	0.09
K ₂ O	0.56	0.87	0.35
Na ₂ O	0.21	0.16	0.12
SO ₃	0.58	2.49	3.19

2.2 Physical Properties

The reactivity of slag powders in cementitious systems is proportional to fineness (e.g. finer materials will have higher reactivity). The surface area of binders was determined by Blaine and BET fineness techniques. BET fineness results are significantly higher than Blaine values because adsorption also occurs on internal surfaces and microcracks. CS was found to be consistently finer than BS when measured by either BET or Blaine fineness tests (shown in Table 2). Particle size distribution of the two powders was also undertaken and showed that CS had a higher proportion of ultra fine particles in the range 1-10 microns. The increased fineness of CS should promote more rapid reaction than is commonly found with slag materials.

Table 2. Physical properties of Portland cement and slag powders

Method	PC	BS	CS
BET fineness (m ² /g)	-	991	1145
Blaine fineness (m ² /g)	310	390	467
% passing 1 micron	-	6	7
% passing 10 micron	-	45	51

Dry powder samples were examined using an analytical scanning electron microscope at magnifications of 2500 and 10000 times. Both types of slag were found to have angular particles with conchoidal marked faces as is typical for the material. CS grains were however slightly more chunky shaped and had a higher proportion of ultra fine particles compared to BS.

The extra fineness of CS was found to slightly decrease the workability of concrete compared with similar BS concrete. Greater fineness was also probably responsible for slightly shorter final setting times of CS pastes compared with BS pastes and lower bleed rates of concrete. Nevertheless some allowance needs to be made for the slower development of slag concretes within the first few days compared with PC concrete.

3. HARDENED CONCRETE PROPERTIES

A range of concrete mixes was cast using siliceous dune sand (fineness modulus of 2.5) and crushed 19 mm greywacke stone (Malmesbury shale). Concrete was proportioned using the Cement and Concrete Institute method except the stone content was fixed at 1100 kg/m^3 . Binders used were PC, CS and BS material with a range of replacement levels, however only 0 and 50 % replacement levels with slag are reported in this paper. Water/binder ratios (w/b) were varied between 0.4 and 0.8 to obtain a range of concrete strengths. All concrete was cast with a slump in the region of 50 to 100 mm using a constant water demand of 180 L/m^3 .

Reported results are average values taken from three samples for compressive strength and elastic modulus tests, two samples for creep and shrinkage tests and four samples for durability tests.

3.1 Compressive Strength

Concrete was tested for compressive strength in accordance with SABS 863 using 100 mm cube specimens [3]. Strength development was measured between 3 and 56 days and is shown in Figure 1. CS concrete was found to have rapid strength development between 3 and 14 days compared to BS and PC concrete and slower strength development between 14 and 56 days. Compressive strength of CS concrete was therefore 6 – 12 MPa higher than similar PC concrete. BS concrete in contrast showed slower early strength development but had better longer-term strength increase (i.e. between 14 and 56 days).

Figure 1. Compressive strength development of concrete (for varying w/b ratios of concrete)

The more rapid maturity of CS concrete results in higher 28-day compressive strength than either PC or BS concrete. Design charts for predicting 28-day cube strengths using Western Cape materials are shown in Figure 2.

Figure 2. 28-day compressive strength design chart

3.2 Elastic Modulus

Earlier research done by Addis in South Africa found that there was almost no difference in modulus of elasticity between slag and Portland cement concrete [4]. Static elastic modulus was determined on fully wet cured concrete at 28 days using a mechanical compressometer attached to 200x100x100 mm concrete prisms [5]. Elastic modulus results showed a consistent trend with changing compressive strength (shown in Figure 3). Since the aggregate types and proportions were similar for all concretes, no major differences in concrete stiffness were expected. PC concrete results were found to be less sensitive to changes in compressive strength but this trend appears to be slightly anomalous and untypical of its normal elastic behaviour.

Figure 3. Elastic modulus versus compressive strength at 28 days

3.3 Creep of Concrete

Comparing research findings on creep of slag concrete, total creep strains are generally higher than PC controls while basic creep is consistently lower [1]. The lower basic creep of slag concretes may be partly due to these materials having greater increase in strength under load compared with PC concretes, which effectively decreases the stress to strength ratio.

Concrete cylinders of 105 mm diameter and 300 mm long were used in creep experiments conducted at 22 °C and 65 % R.H. Specimens were loaded at seven days with the stress to strength ratio being in the range of 18 – 34%. Sealed concrete cylinders used in the basic creep testing were coated with a bitumen emulsion and wrapped in heavy-duty aluminium foil. Specific creep

measurements for total and basic creep of concrete with w/b ratios of 0.5 are shown in Figure 4 (stress to strength ratios were 0.20, 0.27 and 0.18 for PC, BS and CS concrete respectively).

Figure 4. Specific creep measurements for concrete with w/b = 0.5

Total specific creep strains were found to be similar for all three concrete types after 112 days of loading. CS concrete had slower initial creep strains whilst BS concrete had higher strains during the first month of loading. This may be ascribed to the varying rates of strength development and therefore restraint inherent in these different materials. Specific basic creep of CS concrete was much lower than either PC or BS concretes (note basic creep measurements were terminated early after 84 days). This has major implications for the structural performance of large concrete elements where the effects of drying are less critical than the mechanism of basic creep.

3.4 Drying Shrinkage

Olorunsogo observed that drying shrinkage of slag concretes increased with an increase in slag fineness, which may be ascribed to the higher hydration rate leading to a higher degree of hydration [6]. Drying shrinkage is influenced by the amount of hydrate since moisture loss from gel pores is primarily responsible for contraction forces causing shrinkage.

Drying shrinkage testing was performed on 100x100x200 mm prisms after initial wet curing of 14 days. Samples were exposed to a constant drying environment of 22 °C and 65 % R.H. for a period of four months. Generally the drying shrinkage of concretes was similar with no significant bias based on binder type. This is shown in Figure 5 below.

Figure 5. Drying shrinkage strain after 112 days drying

Slag concrete with a w/b ratio of 0.4 and 0.5 had lower drying shrinkage than PC concrete (typical results are shown in Figure 6). At higher w/b ratios, slag concrete had higher drying shrinkage than PC concrete. This reversal of the general trend may be due to the effect of early drying on slag cementing reactions in concrete with an open microstructure.

Figure 6. Drying shrinkage measurements for concrete with w/b = 0.5

3.5 Durability Index Tests

The use of slag in concrete should improve the microstructure due to improved packing efficiency, less bleeding and continued cementing reactions. Nevertheless slag concrete has often been found to have higher permeability than similar PC controls, even when fully wet cured. In contrast, slag concrete has been found to have excellent chloride resistance that may be largely ascribed to chloride binding of aluminate phases.

The potential durability of concrete was characterized at 28 days using a number of durability index tests [7]. Oxygen permeability testing uses a falling-head permeameter to assess the permeability of oven-dried concrete to oxygen. In order to avoid unwieldy exponential numbers, the oxygen permeability index (OPI) is defined as the negative logarithm of the Darcy coefficient of permeability. Values of OPI above 10.0 represent excellent quality in terms of impermeability, while values below 9.0 represent very poor quality. Figure 7a shows OPI values measured at 28 days for concrete with w/b ratios of 0.5. Slag concrete was found to have higher permeability than PC concrete, particularly when poorly cured. It is interesting to note that BS concrete improves consistently as duration of curing increases whereas CS concrete shows no improvement after 3 days of moist curing.

Chloride conductivity testing is able to quantify the potential chloride resistance of concrete using a rapid conduction technique. Oven-dried concrete samples are vacuum-saturated in a concentrated sodium chloride solution before being testing in a two-cell conduction rig. Chloride conductivity values below 0.75 mS/cm are recommended for high chloride resistance, such as marine structures. PC concrete with a w/b ratio of 0.5 only achieved chloride conductivity values of 1.5 mS/cm (see Figure 7b). In contrast, slag concretes that had received at least 3 days moist curing all achieved chloride conductivity values below 0.80 mS/cm.

Figure 7a. Oxygen permeability results for concrete with $w/b = 0.5$ (different periods of wet curing)

Figure 7b. Chloride conductivity results for concrete with $w/b = 0.5$ (different periods of wet curing)

3.6 Corrosion Protection

Slag concrete often has higher carbonation depths than similar PC concretes, particularly when poorly cured. This phenomenon has been blamed on inherently higher permeability of the material, sensitivity to curing and lower levels of carbonatable material in slag concretes. The use of slag in marine concretes has been promoted since slag concretes have been found to have excellent chloride resistance when exposed to seawater [8].

Longer-term durability performance of concrete was assessed by exposure to accelerated carbonation and actual marine environments. Accelerated carbonation of concrete was produced by limited exposure of concrete cubes in a controlled chamber at 30 °C, 85% R.H. and 10% carbon dioxide (with one week being equivalent to more than six months atmospheric exposure). Samples used for this testing were 100 mm cubes that had been wet cured for 28 days before exposure in the chamber. At intervals the cubes were split and the depth of carbonation measured using phenolphthalein indicator solution. Carbonation depths recorded after 20 weeks exposure in the chamber are shown in Figure 8a for concrete with a w/b ratio of 0.5 (note the good performance of CS concrete). Although CS concrete had poorer OPI values than either PC or BS concrete, carbonation depths of CS concrete were found to be lower than other concrete types.

Concrete blocks of size 200x250x300mm were placed in the tidal zone at Simonstown harbour with sheltered conditions and little wave action. Concrete used for this field exposure testing were cured in water for 28 days before being placed in the marine tidal zone. After eight months of wetting and drying in the sea, the blocks were removed and 45 mm diameter cores were drilled and cut into slices to assess the depth of chloride penetration (total acid-soluble chloride analysis) [9]. From the chloride profiles obtained, diffusion coefficients and surface concentrations were determined from the standard solution of Fick's second law of diffusion. The critical chloride depth (i.e. that depth at which the nominal chloride corrosion threshold level of 0.4% chloride by mass of binder had been achieved) was then calculated for each concrete and is shown in Figure 8b for concrete with w/b ratios of 0.4, 0.5 and 0.6. Whilst chloride penetration into PC and slag concrete appears fairly similar after eight months exposure, long-term differences are far more significant. Estimated time for corrosion activation of steel cast-in concrete with w/b ratio of 0.5, reasonable moist curing and cover to reinforcement of 50 mm could be less than 10 years for PC concrete but in excess of 100 years for slag concretes [8].

Figure 8a. Carbonation depths after 20 weeks accelerated exposure (different w/b ratios of concrete)

Figure 8b. Critical chloride depths after 8 months tidal marine exposure (different w/b ratios of concrete)

3.7 Alkali Silica Reaction (ASR)

The use of blastfurnace slag is widely accepted as a means of reducing the risk of ASR expansion. Research suggests that a minimum of 50% slag is required to prevent excessive expansion in the presence of sufficient alkalis and reactive aggregates [10].

Alkali-silica reaction testing was determined in accordance with SABS 1245 (accelerated mortar prism test) [11]. Malmesbury shale aggregate, noted for its ASR reactivity was used in the mortar. Total alkali contents (Na_2O_e) were 0.60, 0.90 and 0.50 % respectively for PC, BS and CS material. Active alkali components were 85, 42 and 45 % for PC, BS and CS powders.

Testing showed that PC mortar had considerably more expansion than any of the slag mortar mixes (Figure 9). When comparing equivalent replacement levels, BS was found to have better capacity to ameliorate ASR expansion than CS material. Replacement levels of 50% slag are generally required to guarantee negligibly low levels of expansion when using reactive aggregates such as Malmesbury shale (greywacke).

Figure 9. Alkali silica reaction expansion measurements of mortar bars

4. CONCLUSIONS

Extensive testing of Corex slag concrete found that the material displays all of the technical advantages expected from slag concretes. The improved fineness and chemical composition of the material produced rapid strength development and made the concrete less vulnerable to poor curing. Benchmarking of Corex slag with blastfurnace slag indicated that this new cementitious material performed within the expected norms of slag concretes. Given the evidence from this extensive laboratory testing, Corex slag concrete should perform excellently both in the shorter- and longer-term.

Corex slag has already had a major impact on the concrete market in the Western Cape province of South Africa. The product has been widely accepted because of economic, technical and environmental imperatives. Unlike some cement extender materials, Corex slag may be used without requiring much special attention during the construction process.

ACKNOWLEDGEMENTS

The authors wish to thank PPC South Africa for financial and technical assistance with this research project. They are particularly grateful for the expertise and valuable guidance provided by Steve Crosswell of PPC Western Cape.

ABSTRACT

This work describes the use of FTIR/ATR Spectroscopy (Fourier Transform Infrared/ Attenuated Total Reflectance) to the study of early-hydration of β - Ca_2SiO_4 . Here we present the influence of sodium chloride on the rate and hydration mechanism of this cement. Several NaCl concentrations were investigated (from 1 to 5%) and compared to the control (paste without addition). The hydration of normal paste is divided in two steps: in the first one, the hydration is faster (initial hydrolysis); the second step is much slower and proceeds indefinitely. The addition of sodium chloride makes the overall process even slower. These conclusions are based on the variation of the band areas of Si-O stretching (cement) and 1645 cm^{-1} (HOH bending).

1. INTRODUCTION

The study of cement hydration has long been a concern to researchers and technologists in this field. Although the term hydration, from the chemical viewpoint, may be related only to chemical reactions between water and the many components of cement, it is clear that this designation is generally understood as an overall process, relating to chemical, physical and mechanical aspects.

There are many techniques and methods currently used to investigate hydration or its effects. Among the methods applied to estimate hydration rate we can cite calorimetric methods [1], determination of calcium hydroxide released and chemically-bonded water [2], spectroscopic methods [3,4], diffraction and scattering [5,6]. Of course, this is not an extensive list. On the other hand, the effects of hydration are usually studied by physical and mechanical methods. For example there are many tests such as the Vicat test, slump loss and others, applied to fresh paste or concrete, in order to estimate their rheology.

This work describes the use of FTIR/ATR (Fourier Transform Infrared/ attenuated total reflectance) spectroscopy to study the initial hydration of cement. Although spectroscopic methods are usually restricted to structural information, this technique also provides some information about the hydration mechanisms.

1.1 Principles

In infrared spectroscopy most of the measurements are made by transmission, *i.e.* the infrared beam passes through the sample, interacts with it, and reaches the detector. Usually, a KBr disc is used to study solid samples. Liquid samples may be analysed using windows to support it. The most popular windows are made of KBr and NaCl and CaF_2 . Although CaF_2 is more expensive, it has the advantage of being water insoluble.

The study of initial cement hydration by infrared is quite limited. This is because the fresh paste can not be sampled using windows since the scattering of the beam is too high rendering none or very small signals. In order to study the fresh paste as a solid, it must be dried. This procedure certainly will change the state of the sample. These experimental problems hinder infrared transmission measurements.

The recent development in computational and instrumental resources made possible the development of several accessories in infrared spectroscopy at accessible costs. Here we will briefly describe reflectance measurements.

There are three possible ways for measurements to be carried out by reflectance infrared spectroscopy: the external (specular), internal and diffuse reflectance. Suetaka [7] and Coates [8] provide excellent information about specular and diffuse reflectance.

Infrared Attenuated total reflection (FTIR/ATR) is based on the fact that a beam may undergo a total reflection inside a medium under certain conditions. As example, one may consider two different media, 1 and 2, with refraction indices, n_1 and n_2 and that $n_1 > n_2$. In conventional refraction phenomenon the Snell's Law (Eq. 1) states:

$$n_1 \sin \theta_1 = n_2 \sin \theta_2 \quad (1)$$

For the particular case when the sine of the incident angle equals n_{21} ($n_{21} = n_2/n_1$), we have the so-called critical angle, θ_c . Beyond the critical angle, the incident beam does not pass through the interface between the medium 1 and 2; this is the case of a total reflection.

In FTIR/ATR spectroscopy the infrared beam interacts with the sample through the internal reflection element (IRE). The most usual experimental arrangement for the IRE is the trapezoidal plate, presented in Figure 1. As can be seen, the incident beam reaches the IRE at some defined angle and is reflected several times inside the IRE. Also, the IRE must be transparent to the infrared beam and should present a high refractive index. Table I presents some materials used as IRE in ATR/FTIR spectroscopy and some of its major characteristics.

Figure 1. Internal Reflection Elements (IRE) used in ATR/FTIR spectroscopy. Indices 1 and 2 refer to the different media; θ is the incidence angle.

The interaction between the infrared beam and the sample occurs on the surface of the IRE. The analysis is possible due to an evanescent wave that interacts with the sample near to the IRE surface.

The amplitude of the evanescent wave falls off with the distance from the interface according to equation (2):

$$E = E_0 \exp(-z / d_p) \quad (2)$$

where d_p is the penetration depth. The penetration depth is described by equation (3):

$$d_p = \frac{\lambda l}{2\pi(\sin^2\theta - n_{21}^2)^{1/2}} \quad (3)$$

The penetration depth is defined as the beam penetration when the energy of the beam, E , decays to a value of $E_0 \exp[-1]$.

The penetration depth has a pivotal role in spectroscopic analysis. In order to achieve good spectral analysis, the sample must be in close contact with the IRE. In the case of cement paste, the presence of water helps to create a good contact. Also, in much of the commercial equipment, it is possible to apply an external pressure on the sample in order to improve the contact. . Under the same experimental conditions, the penetration depth is variable, and is higher to higher wavelength. In the presence of strong absorbers, such as water, it may cause “distortions” in relation to transmission spectra. However, since this phenomenon is well understood, it may be easily corrected. Commercial IR equipment usually provides an automatic correction for this effect.

Table 1. Major Internal Reflections Elements used in ATR/FTIR Spectroscopy

Materials	Refractive Index	Characteristics
ZnSe	2.24	Soluble in acids
KRS-5	2.35	Slightly soluble in water
Si	3.24	Chemically stable
Ge	4.0	Chemically stable

2. EXPERIMENTAL

The synthesis of β - Ca_2SiO_4 has been presented before [9,10]. FTIR/ATR measurements were done using a FTIR (Spectrum One) and the ATR accessory (ZnSe, incidence angle of 45° and flat surface). Water was added to one gram of cement in order to produce a paste with w/c ratio = 0.40. NaCl was added to the cement or previously dissolved in water, to attain a final concentration of 1, 2 and 5% (in relation to the cement mass). The experiments were conducted at 20°C and relative humidity of 54%. The spectra were recorded using 32 accumulations.

3. RESULTS AND DISCUSSION

Figures 2 and 3 show spectra recorded for the control (paste without additions) and with addition of sodium chloride 5%, respectively. An important experimental issue is that the paste is not manipulated once put in contact with the IRE. All spectral variations are due to the hydration process. It implies that many experimental conditions can be easily varied, such as temperature, humidity, additions, etc.

Figure 2. FTIR/ATR spectra for the control recorded as function of time.

Figure 3. FTIR/ATR spectra for the fresh paste containing 5% NaCl recorded as function of time.

The major bands corresponding to water absorption are 3280 cm^{-1} (OH stretching), 2125 cm^{-1} (water association) and 1645 cm^{-1} (HOH bending). The major peak of unhydrated cement is located at 1000 cm^{-1} (Si-O asymmetric stretching). The analysis is conducted measuring the variation of the band located at 1645 cm^{-1} (water) and 1000 cm^{-1} (cement).

Figure 4 shows the variation of the peaks located at 1645 cm^{-1} for the control and the sample with 5% of NaCl. Previous results indicate that hydration proceeds in two distinct steps: initial hydrolysis (chemically controlled) and by water diffusion into cement grains (physically controlled). When we observe figure 4 the two steps are well defined, by a sharp fall in the band associated to water. For the control the second step starts at about 60 minutes while for the sample

with 5% of NaCl this step starts much later, around 130 minutes. This is a considerable delay, showing that NaCl retards the hydration of cement.

Figure 4. Variation of the area of the band located at 1645 cm⁻¹ for control and sample containing 5% of NaCl, as a function of time.

Figure 5. Variation of the area of the peak located at 1000 cm⁻¹ for control and sample containing 5% of NaCl, as a function of time.

Figure 5 shows the variation of the peak area of cement as hydration proceeds. The initial slope for each curve confirms that hydration is faster in the absence of sodium chloride. An important point is that after about 60 minutes the peak area for control is almost constant, with a small increase over time. This is probably the result of water migration into cement grains, lowering the relative intensity of the peak at 1000 cm⁻¹.

4. CONCLUSIONS

This paper describes some applications of ATR/FTIR spectroscopy applied to hydration of β - Ca_2SiO_4 cement. The technique is very useful in the initial hydration process, allowing the distinction between two processes, already known: 1- initial hydrolysis, which is controlled by chemical aspects, such as cement composition and the presence of admixtures, and 2- diffusion control, when water starts to migrate into cement grains. The distinction between these processes is very clear when the area variation of the peaks located at 1000 cm^{-1} (Si-O stretching) and 1645 cm^{-1} (H-O-H bending) is plotted against time.

PROPERTIES, APPLICATIONS AND PRACTICALITIES OF SPECIAL CEMENTS

Karen L. Scrivener

Swiss Federal Institute of Technology Lausanne, Switzerland, E-mail: karen.scrivener@epfl.ch

ABSTRACT

Special cements must offer something that Portland cement cannot. Due to the widely distributed raw materials and advances in production technology, Portland cements can be produced cheaply and efficiently all over the world. It is argued that cheaper or more environmentally friendly cements are unlikely to come from new clinkers, but from blending Portland clinker with other by-product materials.

The opportunities for special cements are in providing different properties, which overcome some of the limitations of Portland cement. Good examples of this are calcium aluminate cements, which have a wide range of applications.

1. INTRODUCTION

Portland cement, in the form of concrete is the most widely used material in the world. There are many reasons behind this success:

- The raw materials are widely available and easily extracted.
- It is cheap to produce, with low energy input, compared to alternatives such as steel and masonry.
- With the simple addition of water it sets and hardens at room temperature, with minimal volume change.
- It is highly durable and resistant to water penetration (if well made).

The major weakness of concrete, lack of tensile strength is dealt with through the use of steel reinforcement and many decades of experience have led to the establishment of codes of practice ensuring an exceptional degree of safety of concrete structures. In the light of this, *special* cements must indeed offer something *special* in order to be competitive in certain applications.

There are two areas where it may be imaginable to produce *new clinkers* to give cements with an advantage over Portland cements:

- Lower environmental impact or cost.
- Special properties, which overcome the limitations of Portland cement.

In fact, as will be argued here, only the latter is really feasible and even in this case the possibilities are severely limited by the comparative availability of raw materials. Successful special cements are still essentially based in the $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3$ system. Despite these limitations the opportunities that exist in this system are far from being fully exploited at the present time.

This paper considers present and possible future applications for special cements. The properties of Portland and special cements are discussed in terms of their microstructural development, which gives new insights into how cementitious materials with specially designed properties might be

developed from mixtures of cements currently available. As an example of successful special cement, the microstructural development and properties of calcium aluminate cements are discussed in detail.

2. LOWERING ENVIROMENTAL IMPACT

Sustainable development is rightly a major concern in the world today. Cement is NOT intrinsically a high-energy material. Comparisons are difficult, but on an equivalent performance basis concrete solutions have typically 4 to 6 times less energy requirement than alternatives, such as masonry, steel or plastic.

Nevertheless, the huge quantities of cement consumed, mean that overall cement production has a significant impact on energy consumption and CO₂ emissions and that worthwhile reductions can result from even small improvements.

In terms of special cements the potential advantage of lower firing temperatures is frequently cited as a means of reducing energy consumption, but the savings from such reductions in temperature are vastly overrated and more than cancelled out by other factors, for example:

- Availability and need for transportation of raw and finished materials.
- Efficiencies of heat recuperation and scale.
- Output of pollutants

2.1 Raw Materials and Transport

The major raw material for cement production, i.e. the calcareous component, is quarried within a few kilometres of the kiln; this allows direct transportation by a conveyor system, often enclosed, which minimises dust and noise. For the finished product, transport of cement by road is only economical within a radius of a few hundred kilometres. The energy required for transportation should thus be included in the calculation of energy consumption. Only raw materials that are widely available can be used for cement production, without significantly increasing energy consumption.

It is no coincidence that the five most important chemical elements in cement – oxygen, silicon, aluminium, iron and calcium are also the five most abundant elements in the earth's crust, together making up 91.2%. If the more important minor elements in cement are added – sodium, potassium, magnesium, titanium, and sulfur – 99.3% of the earth's crust is accounted for.

It is notable that most special cements currently produced stay within the CaO-SiO₂-Al₂O₃-Fe₂O₃-SO₃ system. The most important of which contain either CA (monocalcium aluminate, the basis of calcium aluminate cements, CACs) or C₄A₃\$* (Klein's compound, the basis of calcium sulfoaluminate cements CSAs) as the major ingredient. Even though aluminium is the third most abundant element, usable deposits of aluminium containing minerals (e.g. bauxites) are much rarer and less evenly distributed geographically, than the silico-aluminate minerals used in Portland cement production. This contributes to the higher cost of both calcium aluminate and calcium sulfo aluminate cements.

2.2 Efficiencies of Heat Recuperation and Scale

Since the 1960s, huge reductions in the unit energy consumption of cement production have been made through moves from the wet to dry process and through the installation of efficient heat exchange systems. By such methods, the heat consumption per tonne of clinker can be reduced by more than a factor of four. If heat recuperation is efficient the maximum temperature in the burning

* \$ = SO₃, otherwise conventional cement chemistry notation is used.

zone has little impact on overall energy consumption, as the heat input in this zone is recovered further back in the process.

Larger scale kilns are more efficient, with reduced heat losses and more stable operating conditions producing more regular products. Using waste materials as fuel has allows the effective energy consumption to be further reduced. Materials ranging from waste oils to industrial off-cuts of flammable materials (upholstery foam, packaging materials, wood, etc) have been successfully used in cement production. The temperatures occurring in the flame of a cement kiln (~2000°C) are much higher than those in incineration, destroying potentially dangerous organic materials.

Special cements are produced in much smaller quantities than Portland cements; this leads to enormous problems of producing them in large, efficient Portland kilns. For a major change in raw meal chemistry it may take several days to stabilise the production and only another few days to produce enough material for a year's consumption of a special clinker. This gives a very high ratio of poor quality to good quality material, which must be dealt with either through high wastage or more variable products.

2.3 Output of pollutants

As well as energy consumption and the related CO₂ emissions, attention must be paid to the emission of other volatile components. One of the most important elements in this respect is sulfur. Sulfur emissions from fossil-fuel fired power stations have been responsible for acid rain, although this problem is now being dealt with through flue gas desulfurisation (FGD). One of the most common forms of FGD is to inject calcite into the gas stream – this leads to the production of gypsum and the emission of CO₂. Cement plants already pay close attention to limiting sulfur emissions arising from the fuels used.

Special cements containing C₄A₃S require the presence of significant quantities of anhydrite or gypsum in the raw meal. Such increases in the sulfur content in the raw meal lead to higher emissions. The need to fit desulfurisation equipment would more than negate any marginal gains made by lowering firing temperatures in the production of calcium sulfo aluminate cements.

2.4 Impracticality of lower energy clinkers

For the reasons discussed above it is clear that novel low energy *clinkers* are not the way to produce lower energy cements. A much more realistic strategy is the one already being widely pursued, of mixing or intergrinding Portland clinker with the by-product materials of other industries, such as fly ash, slag and silica fume.

3. SPECIAL PROPERTIES

– OVERCOMING THE LIMITATIONS OF PORTLAND CEMENTS

In terms of properties, the limitations to Portland cement arise from the way in which the microstructure forms during hydration. The major hydration product, C-S-H, is deposited as a layer around the reacting cement grains. This has three important consequences:

- **As soon as the reaction starts it retards further reaction**, this means that one needs to wait a considerable time for the service strength to be developed – at one day a typical concrete has only 25% of the strength it will have at 28 days. This is highly inefficient for the construction process and frequently results in concretes of higher than necessary strength being used in order to have adequate strength at early ages. This leads to higher than necessary cost and energy consumption. Such concrete with low water to cement ratio may also be more sensitive to early age cracking.

- **It is difficult to fill large pores;** these remain points of vulnerability to the ingress of substances that degrade the concrete. The only way to limit the presence of large pores is through the addition of finer materials such as silica fume. While bringing many advantages to concrete, such materials increase cost and complexity and may also have adverse effects on properties such as workability and shrinkage.
- **A significant amount of cement remains unhydrated.** Although this is wasteful of raw materials, the unhydrated material nevertheless has the advantage of acting as a hard filler material, which can improve mechanical properties.

The most advantageous properties of special cements are those that overcome these limitations of Portland cement:

- Rapid strength development after setting
- Infilling of porosity to improved resistance to chemical and mechanical attack

Another property often sought is:

- Compensation of shrinkage to avoid cracking.

However, this is very difficult to achieve reproducibly over practical temperature and humidity ranges, due to the different chemical and physical mechanisms involved.

4. PROPERTIES OF CALCIUM ALUMINATE CEMENT – AN EXAMPLE OF A SUCCESSFUL SPECIAL CEMENT

One of the first non-Portland cements to be developed was calcium aluminate cement. Many researchers developed versions towards the end of the 19th century, culminating in a viable means of industrial production patented by Bied in 1908. These cements have a radically different chemistry to Portland cements as shown in Figure 1.

Figure 1. Composition ranges of Portland and Calcium Aluminate cements

There are three main areas of use of calcium aluminate cements today:

- Refractory concrete[†]
- As the main binder phase of special concretes
- As a component of formulated mixed binder systems with special properties.

[†] The field of refractory concretes is not discussed further here, as it is not related to application of special cements in construction.

This range of applications bears witness to the tremendous flexibility of calcium aluminate cements that, in different combinations with other materials, provide a wide range of properties. This flexibility is one of the critical factors for success as the sum of the materials used in the different applications provides a critical mass that can support the extra costs associated with small-scale production and need for specialist technical support.

In construction related applications, calcium aluminate cement produces radical changes in microstructure, which are responsible for many of the special properties discussed below:

- Rapid hardening of both pure and mixed binder systems
- Resistance to mechanical and chemical attack.

In addition mixed binder systems can be formulated to give shrinkage compensation.

4.1 Microstructural Development of Calcium Aluminate Cements and Rapid Hardening

The microstructural development of calcium aluminate cement is characterised by the deposition of the hydration products throughout the water filled space rather than around the reacting grains, Figure 1. It has been possible to observe this widespread nucleation directly in the X-ray microscope [1]. As hydration products do not block the surfaces of the reacting grains, the cement can continue to hydrate rapidly and it is possible to develop strengths of 20 MPa in 6 hours or less at a w/c of around 0.4.

Figure 2. Schematic representation of the deposition of hydration products for the hydration of Portland and calcium aluminate cement.

In terms of strength development, the phenomenon of conversion must be taken into account. The hydrates that form initially at ambient temperature are meta-stable and transform over time to the stable hydrates – C_3AH_6 and AH_3 . As the stable hydrates have a higher solid density, they occupy less space, so there is a lower volume of solid at the same degree of hydration. This results in a higher porosity and lower, but stable, strength. This stable long-term strength is slightly lower than that of Portland cement at the same water to cement ratio.

If the temperature of the concrete is maintained at or below 20°C during curing, then conversion may take several years to occur. However, for sections of any significant size, the heat generated during curing will be sufficient for temperatures of over 50°C to be generated in the concrete, which means that conversion occurs very rapidly (within the first day or so) and the strength development is essentially continually increasing (Figure 3).

Figure 3. Schematic strength development of calcium aluminate cement concrete, with and without self-heating. With no self-heating the initial, very high strength, decreases on conversion to a lower, stable strength. In the more usual case, where self-heating occurs, no reversion of strength occurs after initial curing.

Figure 4. Microstructure of 30-year-old CAC concrete from structure (w/c ~0.4) - fully converted. A fine dispersion of C_3AH_6 (light grey) in a darker mass of hydrated alumina. There are very few, small isolated pores. The bright areas are unreacted iron rich anhydrous phases.

Even after conversion the impact of the mode of product deposition on the microstructure is apparent. Figure 4 shows the microstructure 30-year-old concrete. There is a low capillary porosity and these pores are small and isolated.

4.2 Other Special Properties of CACs as the Main Binder Phase in Concretes

In addition to rapid hardening, CAC concretes also have a number of other special properties which justify their use under certain conditions despite their high cost [2]. These include:

- High resistance to mechanical abrasion
- High resistance to chemical attack, particularly acidic conditions produced by bacteria
- High resistance to temperature extremes and thermal shock.

The abrasion resistance of CAC concrete is also related to their unique microstructure. The deposition of hydrates throughout space leads to a dense interfacial transition zone (ITZ) between cement paste and aggregate. Thus at the same strength, CAC concretes have 2 to 3 times the abrasion resistance of Portland concretes [3]. This leads to their use in dam spillways, motorway toll booths and industrial floors [4].

The use of CAC concrete for the lining of sewage networks is well established [4,5]. Here the action of the CAC is threefold:

- Down to pH4, resistance of alumina hydroxide to dissolution. This combined with the dense microstructure blocks penetration of the acid into the concrete.
- Below pH4, high neutralisation capacity of the alumina, which slows attack for a given amount of acid.
- Suppression of the activity of acid producing bacteria, which limits the pH produced on the surface of the concrete to just below 4, rather than 1 or less which occurs for Portland concretes.

In a field trial carried out in South Africa [6] sections made from Portland cement concrete with both siliceous and calcareous aggregates were so badly eroded after 12 years as to make the sewer unsafe. The section with Portland / siliceous aggregate had completely corroded through the 60 mm pipe thickness in places, while the section with Portland / calcareous aggregate had corroded to the level of the reinforcement. In contrast, the section made from CAC and siliceous aggregate showed only localised erosion to a depth of 10-15 mm, Figure 5.

Figure 5. Sewage pipes after 12 year in a field trial in South Africa. The Portland/siliceous aggregate section (a) has completely eroded through its 60mm thickness in places. The CAC/siliceous aggregate section shows maximum erosion of 10-15 mm only at the water line.

The resistance of CAC concretes to temperature extremes and thermal shock is related to the nature of the hydrate phase, particularly the absence of calcium hydroxide. This feature leads to applications in foundry floor, cryogenic facilities and fire training buildings.

5. RAPID HARDENING AND EXPANSION IN ETTRINGITE FORMING SYSTEMS

Apart from uses of CAC as the sole binder phase in concretes, special cements with rapid hardening properties are mainly based on the formation of ettringite at early ages. Mixtures of CACs with Portland cement and calcium sulfate can also be made, which have such properties (Figure 6). Such cements can also be designed to expand during curing, to compensate drying shrinkage or give self-stressing.

Figure 6. Formulation zones for mixtures of CAC, PC and calcium sulfate

As indicated by its characteristic morphology of hexagonal needles, ettringite is formed through solution:

Various different starting phases may provide the calcium, aluminate and sulfate ions to solution. The relative solubility and reactivity of these will control the rate, morphology and distribution of ettringite formation, which in turn determines the rate of setting and hardening, and whether expansion occurs

The usual sources of aluminate are either CA, from calcium aluminate cement or $\text{C}_4\text{A}_3\text{S}$ from calcium sulfo aluminate cement (CSA). In both cases calcium sulfate, in the form of gypsum, anhydrite or hemi-hydrate (plaster of Paris), must be added. Although $\text{C}_4\text{A}_3\text{S}$ also contains sulfate, the ratio of sulfate to aluminate ($\text{S}/\text{A} = 0.33$) is very much lower than that in ettringite ($\text{S}/\text{A} = 3$) and only transitory ettringite formation is seen in CSA cements without additions of calcium sulfate. Extra lime may come from added free or hydrated lime, or from the hydration of alite.

If the system is correctly formulated, ettringite forms throughout the water filled space, bridging the spaces between the hydrating cement grains and leading to rapid strength development. The large number of species involved in the reaction to form ettringite means that it is possible to adjust these to formulate systems with the desired properties in terms of setting and hardening. Similarly if the system is formulated so that ettringite formation continues once the paste has set and hardened, expansion and shrinkage compensation can be produced. The precise chemistry and physics of the various types of reaction are extremely complex and not well understood. At present, rapid setting and hardening, and expansive systems are designed empirically. Because of this it is important to have regular starting materials

6. CALCIUM SULFO-ALUMINATE CEMENT

Studies in the USA by Klein, in the 1950s, led to the development of Type K, or shrinkage compensating cements. The key compound in these cements is C_4A_3S , also known as Klein's compound, present in amounts up to about 20%. Shrinkage compensating cements have been used successfully in concrete for a number of projects. However, due to their higher cost and the need to ensure wet curing over at least 7 days, they are now very little used. By adjusting the content of C_4A_3S , free lime, added sulfate; related cements are now being sold as rapid setting (and hardening) cements. Due to the small quantities produced and the short setting times, it is difficult to produce such cements with consistent behaviour.

A different type of CSA is produced in China. Locally available, silicate rich bauxites, which are unsuitable for aluminium production, are fired with limestone and anhydrite to give cements essentially composed of C_4A_3S (60-70%) and belite (C_2S). According to the amount of gypsum, which is inter-ground, rapid hardening, shrinkage compensating and self stressing cements may be produced.

As described above the special properties of such cements arise from the formation of ettringite at early ages. Due to the many parameters that influence ettringite formation it is possible to obtain a range of properties by adjusting the exact formulation of the cement.

7. OTHER CONSIDERATIONS FOR SPECIAL CEMENTS

The practical use of special cements involves many other aspects of their performance, for example elastic modulus, creep, and toughness. Studies on CAC concretes [7] have indicated that these properties are correlated with compressive strength in a very similar manner to Portland cement concrete. This suggests that porosity is the primary factor controlling mechanical properties and the precise nature of the hydrate phases is of secondary importance. Nevertheless lack of data on the properties and performance of concrete made with special cements is another barrier to their use.

Experience with special cements shows that, like Portland cements, the control of water to cement ratio is the key to good performance. Rheological properties are important and the interactions of special cements with admixtures must be considered.

8. CO₂ EMISSIONS

Due to the high volumes produced, the manufacture of cement makes a significant contribution to CO₂ emissions. For every tonne of cement, roughly 1 tonne of CO₂ is emitted. About half of this comes from the fuel used and the other half from the decomposition of the calcareous part of the raw meal. Thus the quantity of CO₂ emitted is directly related to the CaO content of the clinker.

The CaO content of Portland type cements is around 60-65% and on a molar basis CaO constitutes $\frac{3}{4}$ of the main reactive phase C_3S . In CAC or CSA cements the reactive phases contain only $\frac{1}{2}$ in their reactive phases (CA or C_4A_3S) is CaO. So the overall CaO content of the clinkers is lower – in the range 40 – 60 %. This gives the potential to reduce the chemical decomposition part of CO₂ emissions by up to 30%. Although this reduction is significant, the overall reduction would be reduced, by lower efficiency, higher fuel consumption and transport. Larger reductions in CO₂ are possible through the incorporation of supplementary cementitious materials into cement, reducing its clinker content.

9. CONCLUSIONS

- The viability of special cements lies in their ability to provide properties not obtainable with Portland cement. For example:
 - Accelerated hardening;
 - Increased resistance to degradation in aggressive conditions.
- Given the constraints of raw material location and the current level of optimisation of Portland production in terms of heat recovery and scale; it is not plausible to imagine that new clinkers can provide cements with lower energy consumption. This objective must be obtained through further advances in blending Portland cement clinker with by-product materials.
- Calcium aluminate cements are one of the most successful special cements, due their particular properties that allow a wide range of applications.

PREDICTION OF MICROSTRUCTURE AND PROPERTIES OF PORTLAND CEMENT FROM PRODUCTION CONDITION IN CEMENT MILL

PART I: EVALUATION OF THE PREDICTION MODELS

K. Svinning¹ and K. A. Datu²

¹NORCEM A/S, R&D Department, Brevik, Norway. E-mail: Ketil.svinning@norcem.no

²Mule, Porsgrunn, Norway.

ABSTRACT

The influence of production conditions in a cement mill on the microstructure and properties of rapid hardening Portland cement has been statistically investigated. In addition, the influence of the microstructure on the properties has been investigated. Properties being examined were water content required to achieving standard consistency, setting time and compressive strength at one day. Except for particle size distribution of cement, partial least square regression gave maximum explained variance in the cement properties and superficial microstructures of cement from 54 to 73 %. As low as 27 % explained variance in particle size distribution will make the prediction from the characteristics of this part of the microstructure too inaccurate.

1. INTRODUCTION

Since 1991 a general investigation of microstructure of clinker and cement has been carried out as part of several successive projects at the cement producer Norcem A/S.

More recently, the investigations have been organised in the three following subprojects:

1. Influences of the production conditions in the kiln and the cement mill on the microstructure of clinker and cement
2. Influences of the microstructure of clinker and cement on the cement properties
3. Establishment of models describing the influences of the production conditions in the kiln and the cement mill on the cement properties

Results from the previous investigations are presented by Svinning *et al.* [1] and [2], Svinning and Bremseth [3] and Svinning and Justnes [4].

In this paper the investigation on the influence of production condition in cement mill on the microstructure and properties of the Portland rapid cement is presented. In addition, the influence of the microstructure on the properties has been examined.

Properties being examined are as follows:

1. Water content required to achieve standard consistency.
2. Setting time.
3. Compressive strength at one day.

The properties: Setting time and compressive strength form together with fineness and soundness the basis of all specifications for cement. Therefore, a large number of papers on investigations of

correlation between the characteristics of cement and these two properties have been published. Some characteristics variables, which were reported by Lea [5] to have major impacts on setting time and which indicate the production conditions in a cement mill, are fineness, amount of di- and hemihydrate of CaSO_4 and aeration of cement. Assuming the amounts and structures of the clinker to be rather constant, the clinker quality is described by its component composition only. However, the pronounced influence of free lime on setting time as earlier reported in [3] and [4], makes it appropriate to include the amount of free lime as a variable in the investigations. The determination of setting time is affected to a marked degree by the quantity of water used in gauging. This water is required to be that necessary to bring the cement paste to a defined consistency. The variable: Water content required to achieving standard consistency (SC) is defined to be a response variable in this work but at the same time could be regarded as an input x-variable in the investigation of the y-variable: Setting time. SC indicates the flow behaviour of cement pastes. According to Mork [6], the more hemihydrate the better are the rheological properties over time, except initially, where the highest gypsum content gives the best rheological properties. In this connection the degree of dehydration of gypsum during grinding will be focused on and, likewise, how process conditions influence the degree of dehydration.

In this work the microstructure is defined to be particle size distribution and superficial microstructure describing the degree of prehydration of the clinker minerals and the degree of dehydration of gypsum. The superficial microstructure is characterised by thermogravimetric analysis (TGA). The correlations between the groups of variables describing production condition, microstructure and properties, respectively, were determined by application of partial least square regression (PLS).

The presentation of this work will be divided into the two following parts: Part I: Evaluation of the prediction model, and Part II: Prediction and sensitivity analysis [7]. The major part of the discussion of the results will be in Part II.

2. METHODS

2.1 Characterisation of superficial microstructure

As mentioned above, the superficial microstructure is characterized by thermogravimetric analysis (TGA). The apparatus used was a Netzsch STA – Apparatur 409 V/3/C[®]. A dynamic mode of thermogravimetry is used, in which the sample is heated in an environment whose temperature is changing in a predetermined manner, preferably at a linear rate. 4,2g of sample were analysed and the heating rate was 2°K/min. Limited space in the furnace due to the large amounts of samples restricted the measurement of temperature to that of the sample only. A more correct temperature measurement, to which the various mass losses are referred, should be that of an inert reference placed right beside the sample in the furnace. Due to the large volume of sample being analysed, the reaction involving mass loss of larger quantities of H_2O and CO_2 is partly diffusion controlled. The position [°C] of a respective DTGA (the differentiate form of TGA) –peak will be at a higher temperature with an increase in the amount of the compound being dehydrated or decarbonised. The position of the peak could also depend on the fineness of the compound. Figure 1 shows two examples of thermograms from DTGA of neat cement and cement with limestone used as filler, respectively. The thermograms are interpreted with respect to the most common reactions occurring during the heating.

The information on the superficial microstructure is included as x- or y-variables in PLS in the form of mass loss per 4°C in the temperature range 20 - 330°C and mass loss per 8°C in the range 330 - 940°C. No further interpretation of results from TGA, or to be more correct, from DTGA prior to PLS was done. Qualitative interpretation of the thermograms will, however, be an important part of the discussion of the results in Part II of this work.

Figure 1. Two examples of thermograms from DTGA of neat cement (red line) and cement with limestone filler (blue line), respectively.

2.2 Statistical modelling

In the case of a large number of variables relative to number of observations or objects, data compression by expressing the original x - variables by fewer latent variables or factors could be necessary. Partial least square regression (PLS) does calculations and optimisation of a number of factors for maximum explanation of variance in the y -variables. In addition, model parameters are calculated for prediction of y for new values of the x -variables. In this work PLS of several y -variables together expressed as a vector of several y -variables, are performed. The models which relate the PLS model terms, are then given by the two expressions in the equations below:

$$\mathbf{X} = \mathbf{TP}^T + \mathbf{E} \quad (1)$$

$$\mathbf{Y} = \mathbf{UQ}^T + \mathbf{F} \quad (2)$$

\mathbf{T} and \mathbf{U} are factor scores, \mathbf{P} and \mathbf{Q} are x and y variables loadings and \mathbf{E} and \mathbf{F} are the residuals in \mathbf{X} and \mathbf{Y} , respectively. Alternatively, equation 1 could be expressed in the form:

$$\mathbf{X} = \mathbf{t}_1\mathbf{p}_1^T + \mathbf{t}_2\mathbf{p}_2^T + \dots + \mathbf{t}_k\mathbf{p}_k^T + \dots + \mathbf{t}_l\mathbf{p}_l^T + \mathbf{E}$$

Where l is equal to maximum number of latent variables for maximum explanation of variance in \mathbf{Y} . In case of only one y -variable to be modelled (equation 2) could be replaced by the following equation:

$$y = \mathbf{T}\mathbf{q}^T + f$$

PLS with respectively one and several y -variables are denoted PLS1 and PLS2.

By scaling the variables, unreasonable dominance of variables with dominating standard deviations, $s(x)$, on the model can be avoided. The centring and scaling of $x_{i,j}$ is performed according to the following formula:

$$x_{ij, \text{centred and scaled}} = \frac{x_{ij} - \bar{x}_j}{s(x_j)} \quad (3)$$

The iterative algorithms for calibration, validation and prediction are described in detail in Martens and Næs [8]. The software applied for PLS was UNSCRAMBLER[®], version 7.5.

3. DESCRIPTION OF THE CEMENT MILL

The location of the cement mill being examined is Dalen Plant, Norcem A/S in Brevik, Norway. The cement mill is of the two-chambers Combidan ball mill type. The mill system with a classifier, dust filter and the silos and feeding system is shown in Figure 2. The classifier is an FLS-SEPAX[®] separator type 400-2s. The finished product leaves the separator at the top and is deposited in a set of four cyclones. During the production it is possible to intergrind iron(II)sulphate for dechromatising or reduction of Cr^{6+} in clinker, and limestone as a supply of filler, in addition to clinker and gypsum. The limestone filler being fed into the mill had a sieve residue of approximately 14 % at 90 μm . Internal water sprays can be used at both the inlet and outlet ends of the mill. The location of sampling of the cement is right after the cement cooler. The grinding aid used was of the type Technochem TC-84 N, which contains aliphatic amine acetate diluted in water (21 % conc.).

4. EXPERIMENTAL

The experiments were carried out in two stages. In the first stage experiments with 2^3 factorial designs with three variables and two levels were performed. Actual variables chosen were Blaine, amount of limestone, temperature of cement leaving the mill (TC), amount of gypsum, amount of water sprayed into the mill at the inlet (AW) and amount of grinding aid. Performing 3 experiments with 2^3 factorial designs give 24 observations. Each observation contains the value of each of the 24 process variables, averaged over one hour, and results of the characterisation and tests of the sample of the cement of 10 kg being sampled during the last 15 minutes of this hour. The following three variation of the respective three variables (abbreviation as explained above): determinations were undertaken to investigate

1. Blaine, amount of limestone, temperature of the cement (TC)
2. Blaine, amount of gypsum, amount of water into the mill (AW)
3. Blaine, amount of limestone, amount of grinding aid.

Figure 2. A schematic figure of the cement mill

There are at least two purposes for testing using factorial design. The first one is the possibility of calculation of the impact or effect of the respective variables being varied, and additional interactive effects on the response variable as cement properties and microstructure. The calculation of effects is described by Box *et al.* [9] among others. The second and a more significant reason for this type experiment is an achievement of a better span of the observed **X**-space. The calculations of effects after each factorially designed experiment were skipped to the benefit of PLS at the end with all the relevant variables and available observations included.

In the second stage more occasional observations with respect to process condition were collected, this to increase the total number of observations to be included in PLS.

5. RESULTS AND DISCUSSION

5.1 General

In the following chapters results from three independent PLS analyses are presented:

1. PLS1 (one y-variable at a time) of cement properties as a function of process conditions in the cement mill
2. PLS1 of cement properties as a function of microstructure of cement.
3. PLS2 (several y-variables together) of microstructure of cement as a function of process conditions in the cement mill

5.2 PLS of cement properties as a function of production conditions in the cement mill

The maximum explained variance from PLS of the respective y- variables and the number of PLS-components included for maximum explanation are presented in Table 1. The mean values and standard deviation of the production x-variables included in the PLS for prediction of water content required to achieve standard consistency, setting time and compressive strength at one day are presented in Table 2. The number of observations included was 50.

Table 1. Results from PLS of cement properties as functions of production conditions in the cement mill.

Response variable, y	Maximum explained variance [%]	The number of PLS-components or latent variables
water content required to achieving standard consistency	66	2
Setting time	66	4
compressive strength at one day	54	3

The regression coefficients \mathbf{b}_w : $b_{w1}, b_{w2}, \dots, b_{wn}$ applied in model $y = b_{w1}x_1 + b_{w2}x_2 + \dots + b_{wn}x_n$ from PLS with centred and scaled data for the three variables are presented in Table 2. The elements in \mathbf{b}_w , contrary to respective elements in \mathbf{b} used for prediction from the x-variables in their original forms, *i. e.* neither centred nor scaled, give the information about by how much each x-variables influences the y-variable.

Table 2. Variables included in PLS, mean values and standard deviations. Regression coefficients, b_w , from PLS of setting time (ST), water content to achieve standard consistency (SC) and compressive strength at one day (CS) with weighted data.

Variables	Mean value	Standard deviation	Regression coefficients, b_w

5.3 PLS of cement properties as a function of microstructure of cement.

The following data describe or indicate microstructure:

- Mass losses per 4 °C from DTGA in the region 85 – 217 °C
- Particle size distribution, volume fraction, 32 size classes between 103 and 0.7 µm

- Mass losses per 8 °C from DTGA in the region 324 - 524°C.
- Mass losses per 8 °C from DTGA in the region 604 – 946°C

The total number of x-variables included in the PLS was 141. As mentioned in the introduction the clinker quality is included in PLS as variables representing the chemical bulk composition and free lime. The maximum explained variance from PLS of the respective y- variables and the number of PLS-components included for maximum explanation are presented in Table 3. Figure 3 shows the structure of the PLS-modelling; the variation in the respective group of variables presented in the list above. Figure 4 shows regression coefficients of the PLS for prediction of the three cement properties. Table 4 contains regression coefficients for the variables describing the chemical composition included in the same PLS-models.

Results from PLS confirms the results in Section 5.2 about the large influence of free lime on setting time and the compressive strength being more influenced by the chemical composition than the production conditions in the cement mill.

Table 3. Results from PLS of cement properties as function of the microstructure of cement

Response variable, y	Maximum explained variance [%]	The number of PLS-components or latent variables
Water content required to achieving standard consistency	54	3
Setting time	61	4
Compressive strength at one day	64	10

I. Mass losses per 4 °C from TGA in the region 85 – 217 °

III. Mass losses per 8°C from TGA in the region 324 - 524°C.

II. Volume fractions of cement in 32 size classes between 103 and 0.7 µm

IV. Mass losses per 8°C from TGA in the region 604 – 946°C

Table 4. Regression coefficients, \mathbf{b}_w , for the variables representing the chemical composition part of the microstructure for prediction of setting time (ST), water content to achieve standard or normal consistency (NC) and compressive strength at one day (CS).

Variables	Mean value	Standard deviation	Regression coefficients, b_w		
			ST	SC	CS
x-variables					
29.SO3 [%]	3.37	0.35	0.024	0.075	0.520
30.Carbon [%]	0.19	0.19	0.021	0.001	0.028
31.Free CaO [%]	1.43	0.27	-0.668	-0.050	-0.017
32.Loss on ignition [%]	1.65	0.48	0.103	-0.069	-0.002
33.SiO2 [%]	19.60	0.28	0.030	0.005	-0.042
34.Al2O3 [%]	4.85	0.13	0.002	0.085	-0.120
35.Fe2O3 [%]	3.25	0.08	-0.008	-0.065	0.003
36.CaO [%]	61.93	0.64	-0.008	-0.018	0.216
37.MgO [%]	2.74	0.07	-0.006	0.031	-0.293
38.K2O [%]	1.21	0.07	-0.014	0.038	-0.100
39.Na2O [%]	0.35	0.07	0.016	0.056	0.151
y-variables:					
1. Setting time [min]	101	16			
2. Water content required to achieve standard consistency [%]	31.5	0.8			
3. Compressive strength at 1 day [MPa]	33.3	2.6			

5.4 PLS of microstructure as a function of production conditions in the cement mill

The parts of microstructure, \mathbf{y} , being modelled are presented in section 5.3 and the variations in Figure 3. The production x-variables included in PLS are presented in Table 2. The maximum explained variance from PLS of the respective groups of y-variables and the number of PLS-components included for maximum explanations are presented in Table 5.

Table 5. Results from PLS of microstructure of cement as functions of production condition in the cement mill.

Group of response variable, \mathbf{y}	Maximum explained variance [%]	The number of PLS-components or latent variables
Mass losses per 4 °C from DTGA in the region 85 – 217 °C	73	6
Volume fractions of cement in 32 size classes between 103 and 0.7 μm	27	5
Mass losses per 8°C from DTGA in the region 324 - 524°C.	63	6
Mass losses per 8°C from DTGA in the region 604 – 946°C	59	3

The large number of regression coefficients from PLS2 (regression of several y-variables together) makes a simple presentation of the coefficients in Part I of this work difficult. Therefore, parts of regression matrices \mathbf{B}_w will be presented in Part II: Prediction and sensitivity analysis. The low maximum explained variance in the particle size distribution of only 27 % does not justify further attention being given to the PLS-model on this issue in Part II. The explained variance in particle size distribution makes the prediction of this part of the microstructure too inaccurate.

6. CONCLUSION

Except for particle size distribution of cement partial least square regression gave maximum explained variance in the cement properties and superficial microstructures of cement from 54 to 73 %.

ABSTRACT

The influence of production conditions in a cement mill on the microstructure and properties of rapid hardening Portland cement has been statistically investigated by application of partial least square analysis. In addition, the influence of the microstructure on the properties has been investigated. Properties being examined were water content required to achieving standard consistency, setting time and compressive strength at one day. Sensitivity analysis by predictions from simulated variation of single x-variables and latent variables has been performed. Special attention has been paid to the influence of water sprayed into the first and second chamber, respectively, of the cement mill on the dehydration of gypsum and prehydration of clinker minerals and further the influence on the cement properties. The influence of grinding aid on the fineness of limestone filler was also examined.

1. INTRODUCTION

To enable statistical investigations of the influence of production conditions in a cement mill on the microstructure and properties of rapid hardening Portland cement prediction models have been evaluated. The models are presented in Part I of this work [1]. In more details, partial least square regression (PLS) -models for prediction of dependant y- or group of y-variables from the following x-variables have been evaluated:

Cement properties:

- Water content required to achieving standard consistency predicted from
- Setting time
- Compressive strength

All the three properties predicted from:

- Production condition in the cement mill
- Microstructure of cement

Microstructure of cement:

- Superficial microstructure from DTGA (85 – 217 °C), describing mainly the degree of dehydration of gypsum but also prehydration of clinker minerals
- Particle size distribution of cement
- Superficial microstructure from DTGA (324 – 524 °C), describing mainly the degree of prehydration of free lime
- Superficial microstructure from DTGA (604 – 946 °C), describing the degree of carbonation of clinker and the amount of limestone used as filler

All the four parts of the microstructure predicted from:

- Production condition in the cement mill

The location of the cement mill being examined with respect to how production conditions influence properties and microstructure, is Dalen Plant, Norcem A/S in Brevik, Norway. The cement mill is of the two-chambers Combidan ball type mill.

Except for particle size distribution of cement, partial least square regression gave maximum explained variance in the cement properties and superficial microstructures of cement from 54 to 73 %. Prediction from this part of the microstructure as low as 27 % explained variance in particle size distribution will make the too inaccurate.

The objective with sensitivity analysis is interpretation of a complex statistical model as for example PLS with respect to how much and in what direction a x- variable or selection of x-variables influences y. The type of sensitivity analysis applied is the same as used by Svinning *et al.* [2]. Here the sensitivity analysis is defined as examination of the predicted effect of an x-variable or a latent variable on the response y-variable relative to a defined confidence range of the predicted y. In addition, uncertainty testing on the regression coefficient can be performed. Martens *et al.* [3] have developed an improved method for uncertainty testing based on cross validation, Jack-knifing and stability plot. The method is included as an application in the Unscrambler® software, version 7.5.

2. METHODS

2.1 Sensitivity analysis of PLS models

Based on PLS-models as for example those given in [1], the influence of x-variables on the y-variable(s) may be evaluated in different ways [2]:

- Comparison of the regression coefficients of the different variables from PLS with centred and scaled data. Significance testing on the coefficients by application of Jack-knifing [3] with confidence interval of 0.95. Examples are shown in Figure 1.
- Prediction of variation in y including confidence intervals equal to $\hat{y} \pm s(y)$, from variation of one or several collinear x-variables while the others are kept constant and equal to their respective mean values. The region of variation in this work was limited to $\bar{x}_j \pm 1.5s(x_j)$. Examples are shown in Figures 2 and 3.
- Prediction of variation in y or y as a result of variation in one latent variable at a time from one ‘observed’ extreme to the other. By varying the k ’th latent variable $\Delta t \mathbf{p}_k$ the variation in Δx_j in its original form, i.e. not scaled, will be calculated in the following way:

$$\Delta x_j = (\Delta t p_{jk}) s(x_j)$$

An example is shown in Figure 4 where calculation of Δx_j ’s is demonstrated. Calculation of x_j , neither centred nor scaled, will then be as follows:

$$x_j = (t p_{jk}) s(x_j) + \bar{x}_j$$

In the two latter ways of sensitivity analysis presented above, artificial observation X-matrices were constructed prior to the prediction. In the first case the variable to be examined with respect to influence were varied in five equal steps giving six observations within a given range of variation while all the other variables are kept constant. In the case of variation of a latent variable all the variables were varied in five equal steps. As a third alternative an artificial observation X-matrix could contain a selection of x-variables which could be varied in equal steps while the others are kept constant and equal to their mean values. The pattern of variation could be determined by the

principal component or latent variables from the principal component analysis (PCA) of these variables.

An influence of an x-variable or several on a y-variable in this work is defined to be significant if there is no overlap of confidence regions of $\hat{y} \pm 1std.$ of the predicted maximum and minimum y, respectively. Evaluation of the significance of the influence of a variable x_i from Jack knifing the influence could be defined as significant if the uncertainty level is less than $2|b_{wi}|$.

3. RESULTS AND DISCUSSION

3.1 Prediction of cement properties from the production conditions in the cement mill

Figure 1 shows how each production variables, x_i included in the PLS, influences the three cement properties by watching the size, direction (pos. or neg. influence) and the uncertainties of the respective b_{iw} . All the variables presented in the figure are listed in Table 2 in Part I [1] of this work. Examples of prediction of variation in cement properties from variations of one x-variable while all the others are kept constant and equal to their mean value, are shown in Figures 2 and 3. As an example of the influence of a latent variable on a y-variable, Figure 4 shows prediction of variation in water content required to achieve standard consistency from variation of latent variable no. 1.

From Figure 1, some of the variables which have major and significant influence on each of the cement properties are presented below (negative or positive influence is marked with – or +, respectively):

Water content required to achieving standard consistency:

- Feed of iron(II)sulphate (-)
- Amount of water sprayed into the mill at the inlet (-)
- Amount of water sprayed into the mill at the outlet (+)
- Rotor speed, classifier (+)
- Material return (+)

Setting time:

- Amount of water sprayed into the mill at the inlet (+)
- Amount, of water sprayed into the mill at the outlet (-)
- Amount of grinding aid (+)
- Total effect, electrical consumption (-)
- Carbonate (+)
- Free lime (-)
- Temperature of clinker entering the cement mill (-)

Figure 1. Regression coefficient (vertical axis) for prediction of cement properties from variables (horizontal axis) describing production conditions in the cement mill: a) Water content required to achieve standard consistency, b) Setting time, c) Compressive strength at one day. The numbers on the x-axis refer to the list of variables in Table 2 in Part I of this work [1].

Figure 2. Predicted changes in setting time [min] (vertical axis) from changes in the amount of grinding aid [ml/min] (horizontal axis)

Figure 3. Predicted changes in water content required to achieve standard consistency [%] (vertical axis) from changes in the amount of water sprayed into the mill at the inlet [l/h].

Figure 4. Predicted changes in water content required to achieve standard consistency (SC) [%] (vertical axis) from changes in latent variable (PLS-comp. no 1) (scores, $4.884 > t > -4.884$, on the horizontal axis). Contributions of some of the x-variables are calculated.

Compressive strength at one day:

- Feed of clinker (-)
- Feed of gypsum (+)
- Effect mill motor (-)
- SO₃ (+)
- CaO (+)

As reported by Lea [4], the compressive strength at one day increases significantly with the increase in SO₃. The fact that the strength also increase significantly with the increase in feed of gypsum could indicate the significant influence of SO₃ is independent of whether form, as gypsum or as SO₃ in clinker, it is supplied. The lack of influence of gypsum on setting time could, according to Lea [4] and as indicated by Figure 3 in Part I [1] of this work, be due to variation in the degree of dehydration of gypsum.

Figure 2 shows a significant increase in setting time with an increase in the amount of grinding aid. Possible reason for this will be discussed further in the next chapter.

According to Figure 1, the two process variables: Amount of water sprayed into the mill at inlet and outlet, respectively influence both setting time and the amount of water required to achieve standard consistency (SC). It is a little confusing that setting time decreases with the increase with the latter process variable. The opposite was expected from earlier experiences [5] that water wherever sprayed into the mill would prehydrate the clinker minerals. The significance as indicated by Figure 3 of the influence of water sprayed into the mill at the inlet on SC is smaller than indicated by Figure 1.

Simulation of more realistic variations in \mathbf{x} should be based on variations of latent variables. Figure 4 shows that varying the latent variable no.1 gives a significant decrease in SC, gives an increase in the amount of water and a decrease in the amount of water at outlet, simultaneously. The presence of almost autocorrelation between the two variables, especially when defining only one PLS-component needed for obtaining maximum explained variance, could be explained by how the process is controlled and how the experiment is designed. In the experiments, by varying the amount of water sprayed into the first chamber the set point of the temperature of cement leaving the mill was kept constant. This is according to the usual procedure of the process control at this plant.

Both material return and the degree of material load in the mill while the clinker feed is almost constant varies the latent variable no.1 in the direction of negative Δ SC. This indicates that water sprayed into the first chamber eases the grinding and separation process in the classifier probably due to the tendency of less agglomeration. A shorter retention time in the mill combined with probably lower maximum temperature in the mill and higher partial pressure of H₂O could result in less dehydration of gypsum. According to Mork [6] a conversion of gypsum to CaSO₄·½H₂O will give poorer initial rheological properties and the water content required to achieve standard consistency will probably increase. This could be verified by TGA studies on cement.

Comparing Figures 3 and 4, it can be seen that the confidence intervals in the case of predicting the variation in y from the variation in a latent variable is much smaller than in the case of predicting from the variation of only one x -variable. The usability of PLS is connected to the existence of principal directions of variations in the observation X -matrix. The variation of a latent variable is within the space R^n where for this model $n = 2$. Limits of variation of a single x -variable, x_j , of $\bar{x}_j \pm 1.5s(x_j)$ are most likely outside R^2 and the simulated variation should therefore be considered as being less realistic. Svinning *et al.* [7] have developed a method of optimisation based on variations constrained by R^n .

3.2 Prediction of cement properties from the production conditions with focus on microstructure of the cement

In the studies of correlation between the cement properties and the production condition with focus on microstructure of cement two-steps predictions will be performed. In the first step variation in a part of the microstructure will be predicted from the variation of a single latent variable of the production observation X-matrix or a combination of several. In the next step variation in one or several of the cement properties will be predicted from the predicted variation in the selected part of the microstructure.

As indicated in chapter 3.1 the degree of dehydration of gypsum will be highlighted with respect to change in water content required to achieve standard consistency (SC) and setting time (ST). To extract the effect of the degree of dehydration of gypsum only a combination of latent variables no. 1 and 2, which gives $\Delta(\text{feed of gypsum}) \approx 0$ was chosen. Figure 5 shows changes in the superficial microstructure described by mass loss per 4°C from TGA in the region 85 – 217°C, predicted from the changes in the latent variable $t\mathbf{p} = t(0.61\mathbf{p}_1 + 0.38\mathbf{p}_2)$. However, in this temperature region mass losses from dehydration of prehydrated clinker minerals are also recorded. An increase in mass losses in the temperature region about 217°C could indicate a moderate increase in prehydration with the increase in the amount of water sprayed into the first chamber.

Figure 5. Predicted changes in the superficial microstructure described by mass losses [% of the total sample weight] per 4°C from TGA (vertical axis) in the region 85 – 217°C (horizontal axis), from changes in the latent variable $t\mathbf{p} = t(0.61\mathbf{p}_1 + 0.38\mathbf{p}_2)$ of the production observation X-matrix.

Comparing this latent variable with the latent variable presented in Figure 4 by comparing the change in the separate x-variable, it is easily seen that they are not quite identical. In spite of this lack of similarity the results as displayed in Figure 5 verify, as suggested in chapter 3.1, the correlation between the production conditions and the degree of dehydration of gypsum. An increase in the amount of water sprayed into the first chamber of the mill and a simultaneous decrease in the amount of water sprayed in the last chamber give a decrease in the conversion of gypsum to $\text{CaSO}_2 \cdot \frac{1}{2}\text{H}_2\text{O}$. Further according to Figure 6, this will give a significant decrease in SC. The significant increase in setting time, as shown in Figure 7, could be partly due the moderate prehydration of the clinker minerals.

Figure 6. Predicted changes in water content required to achieve standard consistency [%] (vertical axis) from changes in the superficial microstructure described by the DTGA-curves in figure 5 (scores, t , on the horizontal axis).

Studying the variation in the DTGA-curve in the temperature region 604 – 946°C in Figure 3 in Part I of this work [1], the occurrence of a pronounced variation in the position of the peak, designated for decarbonisation of the limestone filler, is easily seen. The reason for this variation could be changes in the fineness of limestone filler. Even before being fed into the mill the limestone is rather finely ground and is after the grinding in the mill expected to be finer than the clinker part of the cement. Considering the decarbonisation reaction during TGA to be a heterogeneous and diffusion-controlled reaction, the temperature of the maximum rate of the reaction will probably increase with the decrease in the fineness of the filler part of the cement.

Figure 7. Predicted changes in setting time [min] (vertical axis) from changes in the superficial microstructure described by the DTGA-curves in figure 5 (scores, t , on the horizontal axis).

In the search of probable causes of an eventual change in the fineness of the limestone filler the regression coefficients of the PLS-model of DTGA-curve of the actual temperature region as a function of the production variables were studied. The regression coefficients of some of the variables, which have major influences on the curve or the thermogram, are presented in Figure 8. The “coefficient” curves indicate that a change in the amount of grinding aid will give a change in the peak position while by changing the feed of limestone filler, the change in the area of the peak will dominate.

Figure 8. Regression coefficients of four production variables, a part of \mathbf{B}_w , from PLS of the superficial microstructure described by mass losses per 8°C from TGA in the region 604 – 946°C on the variables describing the production condition in the cement mill.

A realistic simulation of variation of the production conditions inclusive of the amount of grinding aid but keeping the feed of limestone filler constant, can be done by varying the latent variable no. 2, $t\mathbf{p}_2$. The predicted changes in the DTGA-curves from changes in the latent variable are exhibited in Figure 9. The change in the peak position with the change in the feed of grinding aid is pronounced. Coarser limestone filler in the final product could be explained by the tendency of lower agglomeration in the cement mill.

Figure 9. Predicted changes in the superficial microstructure described by mass losses [% of the total sample weight] per 8°C from TGA (vertical axis) in the region 604 – 946°C (horizontal axis), from changes in the latent variable $t\mathbf{p}_2$ of the production observation X-matrix.

Changes in setting time predicted from the changes in the superficial microstructure described in Figure 9 are shown in Figure 10. The influence is not significant at all. Further work could be studied on other parts of the microstructure to explain why the grinding aid has a significant influence on the setting time.

Figure 10. Predicted changes in setting time [min] (vertical axis) from changes in the superficial microstructure described by the DTGA-curves in figure 9 (scores, t , on the horizontal axis).

4. CONCLUSION

From the sensitivity analyses by prediction of cement properties and microstructure of cement from production conditions in the cement mill the following results should be mentioned:

- There were significant correlations between water sprayed into the first and second chamber, respectively, of the mill, and the degree of dehydration of gypsum and further the two properties: Water content required to achieving standard consistency and setting time
- The grinding aid influenced significantly the fineness of the limestone filler
- The significant change in setting time with the change in the amount of grinding aid cannot be explained as being due to the change in the fineness of the limestone filler

ACKNOWLEDGEMENTS

The authors wish to thank the supervisor Erik Stoltenberg-Hansson, Norcem R&D, Brevik, Norway, for his support and advice during this work.

ABSTRACT

The visualization of structures resulting from processes taking place in a few nanometers is immensely important when studying the properties of concrete and mortar. Electron microscopy is in principle capable of getting images of structural constituents in this size. Unfortunately, studies using conventional electron microscopes are subject to serious limitations. For these reasons an Environmental Scanning Electron Microscope with Field Emission Gun (ESEM-FEG) in different operating modes has been used to investigate wet materials in their native state. These methods provide deep insights into the moist micro and nano world. It even makes it possible to carry out sophisticated observations of hydration processes in complicated multi-phase systems, such as Portland cement. The article describes the investigations of the phase development during the hydration of OPC from the induction to the final period. The results are summarized in a scheme for a new model of ordinary Portland cement hydration. ESEM investigations were supported by the calculation of saturation factors from ion concentration in the pore fluid. To broaden the view on the influence of temperature on the formation of hydration products, ESEM investigations on cement paste hydrated at different temperatures were correlated with thermodynamic calculations.

1. INTRODUCTION

The model of cement hydration developed by Powers and his colleagues [1953] is now considered as the first pioneering draft scheme. The hydration products of Portland cement were initially described as spherical [1]. With the first electron microscope micrographs the concept of spheres was replaced by the model of groups of randomly orientated and layered units (cement gel). The cement gel was described as a solid substance with an average pore diameter of approximately 1.8 nm [2]. On this basis Powers developed a model for the creep and shrinkage of the hardened cement paste. Feldmann and Sereda (1968) investigated the different types of water bonding to hydration products. C-S-H phases - the main hydration products - were described as corrugated platelets [3]. Kondo and Daimon (1974) presented a model which conformed to the two above-mentioned models [4]. As early as 1965 Richartz and Locher [5] introduced two different types of C-S-H phases (type I and II). In the C-S-H (I) the C/S ratio was said to be approximately 0.8 to 1.5 and in the C-S-H (II) it should be between 1.0 to 2.0. According to this model the crystallinity of the phases decreases with increasing C/S ratio. C-S-H (I) is shown in electron micrographs as flakes, while C-S-H (II) forms fibers. In this model the fibers corresponded to rolled platelets with layered inclusions of CH (Figure 1).

According to Locher, Richartz and Sprung as well as Sylla and Rechenberg [6-9] the observed C-S-H phases grow initially as long fibers and later as short fibers.

To clarify the interaction of the hardened cement paste with water, Setzer [1977] described by means of a model the maxima in the pore radius distribution of hardened cement paste to be around

2.5 and 7.0 nm [10]. In the same year Wittmann introduced the hydration products of Portland cement as xerogels in which each particle is linked to its surroundings by different bonding forces [11]. Taylor [1992] designated the crystal structure of the hydration products, the C-S-H phases, as “similar to tobermorite”[12]. According to sheet silicates tobermorite consists of calcium layers located between silicate chains. Taylor also compares C-S-H phases with the mineral jennite, which has a higher C/S than tobermorite and is said to consist of distorted layers of CaO.

As a result of very intense evaluation of the literature Massazza and Daimon [1992] have pointed out five different morphologies of C-S-H phases, which grow during the hydration process [13]. There are descriptions of gel-like, needle-like and sword-shaped C-S-H phases as well as of flake-shaped phases. The morphological changes of the C-S-H phases during the hydration of C_3S were shown for the first time in detail by Meredith et al. [1995] on the basis of investigation with an Environmental Scanning Electron Microscope (ESEM) [14].

Jennings [2000] proposed a new model for the microstructure of calcium silicate hydrates in cement paste [15]. He referred to the “tobermorite-jennite model” by Taylor and proposed two types of C-S-H: LD C-S-H (low-density) which crystallize in the large capillary pore space during the main hydration period, and HD C-S-H (high density) which is formed in the significantly more restricted voids around the C_3S particles.

Figure 1. Rolled C-S-H (II) platelets: A and B C-S-H layers; C: interlayer region; D: space between the rolled leaves; E: internal space in the roll according to Richartz and Locher [5].

It can be concluded, that the existing theories on the morphology and structure of C-S-H phases arise from different kinds of investigation methods (mainly electron microscopy and NMR studies). Often these results are difficult to compare because of the lack of a unified classification of the hydration products and because of the artifacts produced during sample preparation for electron microscopy.

2. MATERIALS AND METHODS

Fortunately, the preparation of the specimens to be studied with the ESEM is uncomplicated, unlike that for conventional scanning electron microscopy, where drying and coating of the specimens is essential. In most cases with the ESEM it is unnecessary to stop the hydration process. The educts used for our investigations are synthetic C_3S , β - C_2S , and ordinary Portland cement (OPC). All pastes were prepared with a water-cement ratio of 0.3. This value has proven to be favorable for most types of cement. Higher water-cement ratios result in sedimenting out and bleeding structures and thus initiate a thinning effect: readily soluble salts – like K_2SO_4 , Na_2SO_4 - are dissolved in the excess fluid and settled on top of the specimen, i.e. they are not accessible for the hydration reactions. The hydration of the cement and the synthetic clinker minerals have been performed outside the microscope in airtight sealed containers at room temperature. While the paste is still plastic, a roughly pea-sized specimen was taken at preset times and applied to the sample holder on

a Peltier cooling stage of the ESEM. After setting the parameters inside the microscope chamber to the adequate pressure and temperature (to reach the desired humidity of 80-95%), the specimen is fractured with the aid of a micromanipulator. This fracturing is very important, because during the microscope adjustment to the relative humidity of 80-95% a skin consisting of alkali salts and presumably also carbonates is formed on the specimen surface. After the first setting of the paste fracture surfaces produced outside the microscope have been used for the examination.

The ESEM-FEG has been used in different operating modes: wet-[ESEM], low- as well as high-vacuum and low- and high-voltage mode. To identify the chemical composition of singular hydration phases we applied Energy Dispersive X-Ray Spectrometry (EDX) combined with the ESEM.

In addition to the ESEM investigations the concentration of important ions in the pore solution was analyzed. For this purpose pastes from the cement with a high K_2SO_4 (arcanite) content were prepared with a water-cement ratio of 0.4 and cured in sealed plastic containers at room temperature. At the times specified in Table 2 pore solution was obtained by filter suction (10 min – 90 min) or squeezed out from cement paste specimen (3 hours and later). Except for hydroxide, that was measured by titration with HCl after dilution, ICP was employed for analysis.

To monitor the hydration progress continuously, time resolved we measured the time resolved and evolved reaction heat with Differential Calorimetric Analysis (DCA). Powder-X-Ray-Diffraction (XRD) was applied to confirm the EDX-Analysis of the minerals.

3. RESULTS AND DISCUSSION

3.1 Hydration of C_3S (alite)

Calcium silicate hydrates (C-S-H phases) of variable chemical composition, as well as portlandite (CH), are formed during the hydration of C_3S . The hydration reaction can be divided into 5 time periods on the basis of the DCA (Figure 2). According to this five periods changes in the microstructure have been investigated with the ESEM. Systematic ESEM observations show typical morphological changes for each hydration period, these have been summarized in Table 1.

Table 1. Stages of C_3S hydration (adopted from Mindess and Young [16])

	period	time	reaction kinetics	chemical processes	phase description
1	induction period / initial hydrolysis	first minutes after mixing	chemically controlled rapid reaction	start of hydrolysis, ions go into solution	formation of a smooth reaction layer around the grains
2	dormant period	approx. 20 min to 2h	core and diffusion controlled, slow reaction	very small chemical activity	first heterogeneous nucleation
3	acceleration period	2h to 11 h	Chemically controlled, rapid reaction	start of the formation of hydration products	μm -large, thin laminated portlandite crystals as well as short needle-like C-S-H fibers
4	Deceleration period	11 h to 26 h	chemically and diffusion controlled, reaction	continuous formation of hydration products	one-dimensional growth of the C-S-H fibers, aggregation of this fibers, stronger interlocking of the particles; intergrowth of the platy CH crystals
5	final period	after approx. 26 h	diffusion controlled reaction	slow formation of hydration products	further growth in length of the C-S-H fibers, interlocking

Figure 2. Heat rate shown in hydration periods (Table 1) of C_3S (DCA measurement).

It can be assumed that at the beginning of the acceleration period all C-S-H phases grow in the form of fibers. These fibers grow in length during the hydration process (Figure 3) with hardly any change in thickness. In compacted concrete the C-S-H fibers appear to grow together. They also interlock. This minimizes the pore space between the fibers. In fact, the pore diameter of these fibres must be in the range of the size of gel pores. Changes in reaction conditions have an extreme effect on the C_3S hydration: A drop in temperature from 22°C to 5 °C, for example, results in a retardation of the hydration reaction by several hours.

Conventional Scanning Electron Microscope (SEM) imaging requires samples which are stable in high vacuum and are electrically conductive. The necessary preparation steps (drying, coating or sputtering, etc.), prevent noninvasive observation of the C-S-H structures (Figures 4 and 5). The morphology of the C-S-H phases is changed drastically by the thermal stress during the coating process and by the vapour-deposited layer itself. Furthermore, we doubt that the chemical compositions given for C-S-H (I) and C-S-H (II) determined with EDX can be very precise. The C-S-H phases are nanometer scaled needle-shaped crystals (crystal thickness of a few nanometers). The excitation volume of electrons with an accelerating voltage of 15 kV is about a few cubic micrometers. Monte Carlo simulation calculations for a beam voltage of, for example, 15 kV give an excitation depth of approximately 2.5 μm , if the density of C-S-H phases - about 2.2 g/cm^3 - is applied. In comparison the low energy operation of 2.5 keV yields a high spatial resolution for the X-ray microanalysis between 50 – 100 nm, which is related to the approximate thickness of a single C-S-H phase (see Figures 4 – 8).

Thus we have to admit that the former measurements made with the conventional SEM/EDX give only a rough orientation on the C/S ratio of the small C-S-H phases. Analysis of uncoated and non-conducting specimens on the nanometer scale can only be obtained by working in the range of low accelerating voltage (low voltage SEM with field emitters) in combination with a sensitive, high resolution X-ray spectrometer. The use of a standard SEM equipped with a tungsten filament is not advisable to produce high resolution images at these voltages and magnification levels. Further prospective methods are ultra high resolution EDX analysis or Electron Energy Loss Spectroscopy (EELS) in the Transmission Electron Microscope (TEM).

Although many classical investigations on the formation and composition of cement hydrates have been correct in their time with the available methods, now they cannot stand a critical examination. It is now clear and widely accepted that C-S-H phases are nanoscale fibers but not rolled platelets or flakes. The frequently used designation C-S-H “gel” is quite correct from a physical point of view as a gel implies a particle size. From the point of view of cement chemistry and mineralogy,

however, the C-S-H phases involved are definitely not gels (term derived from colloid chemistry) but are more probably highly disordered nano-crystalline minerals due to their large surface areas. This assumption is further supported by XRD measurements, where only very weak interferences occur. The term “amorphous to X-rays” is a very appropriate expression in the case of C-S-H phases. The formation of the C-S-H phases as long fibers initially and later as short fibers is also not sustainable [6]. In fact the C-S-H phases tend to start as short fibers and grow to a length of approximately 1.5 μm as the hydration progresses (Figure 3).

Figure 3. Longitudinal growth of C-S-H fibers during the C_3S hydration process.

Figure 4. Formation of needle-like C-S-H phases during the hydration of C_3S . After 600 days hydration time the fibers grow up to a length of 1.5 μm and the needle tips have a diameter of only approx. 5 nm.

Figure 5. The same sample as in Figure 4, but with an approximately 30 nm thick layer of carbon for imaging in conventional SEM. The morphology of the C-S-H phases are changed drastically by the thermal stressing during the coating process and by the vapour-deposited layer.

The ESEM images in Figures 6 and 7 show the formation of the microstructure at selected times during the hydration process at room temperature.

In a time period of 21 days the C-S-H phases grow continuously to a length of 900 nm, the needle tips have only a diameter of approximately 5 nm. The longitudinal growth starts from the surface of the clinker grain. As a result of this merely one dimensional growth, C-S-H phases develop a tight interlocking due to their extremely tipped, needle like shapes (Figure 7). In very dense structures we assume an intergrowth between the fibers as well as interlocking of the fibers with one another.

Figure 6. C_3S hydrated for 21 days: tipped, needle-like C-S-H phases (length up to 900 nm).

Figure 7. C_3S hydrated for 360 days: interlocking of the C-S-H phases (length up to 1200 nm) right and left portlandite.

3.2 Hydration of β - C_2S (belite)

The same fiber-shaped hydration products as formed during the C_3S hydration are observed for the hydration of β - C_2S . However, as already often reported by others, this hydration occurs significantly more slowly than that of the C_3S . After a hydration time of about one year, the fiber size in hydrated C_3S and β - C_2S are equal. Extremely long C-S-H fibers (up to 2.5 μ m) were imaged in an investigation of β - C_2S which hydrated for 3 years (Figure 8). This length growth is expected to be a contribution to the secondary hardening.

Figure 8. β - C_2S hydrated for 3 years: formation of extremely long (up to 2500 nm) C-S-H fibers – here in front of a portlandite crystal . Note: the strength contribution made by huge portlandite crystal, is likely to be small or portlandite even can act as a slip plane under load.

3.3 Hydration of Ordinary Portland Cement (OPC)

Investigations of the phase development during the hydration of OPC from the induction period to the final period (Table 1) are summarized in Figure 16. This scheme for the normal hardening process of OPC at room temperature was derived from investigations of Stark, Möser, Eckart [17] and Hader [18]. Here we would like to give only a short overview about the hydration behavior of OPC with a low alkali content (sodium equivalent 0.49 % with 0.33 % water soluble potassium oxide - ESEM-images: -a) and a high alkali content (sodium equivalent 1.2 % with 1.09 % water soluble potassium oxide [mainly arcanite – potassium sulfate] - ESEM-images: -b). The hydration of industrial ordinary Portland cement differs significantly from the hydration of individual clinker phases. A different chemical equilibrium is set up in the aqueous phase as a result of the interaction between the hydration reactions of several adjacent phases, and this has a significant effect on the formation and sometimes on the morphology of the hydration products.

The behavior with time of OPC hydration can, like C_3S hydration, be divided into 5 time periods:

Induction period: Immediately after mixing with water very small ettringite crystals were formed. Ettringite is the first product formed shortly after mixing. The small prismatic ettringite crystals have a length of between 300 to 500 nm and a thickness between 50 to 250 nm (see Figures 9a and 9b). If a high quantity of potassium sulfate (mainly arcanite) is available, calcium-potassium sulfate double salts, like syngenite [$K_2SO_4 \cdot CaSO_4 \cdot H_2O$] crystallize. Syngenite forms long (up to 10 μm) lath-shaped crystals and can stiffen the cement paste (Figure 9b).

Figure 9a. Microstructure after 10 min hydration time [low potassium content]: Only small hexagonal ettringite crystals were formed on the surface of the clinker grains, the distribution is inhomogeneous.

Figure 9b. Microstructure after 10 min hydration time [high potassium content]: Ettringite with the same morphology as cement with low arcanite content. Formation of syngenite (lath-shaped crystals).

Dormant period (low chemical activity): Syngenite formation was also observed in cements with a very low potassium content but at a later hydration stage (after about 30 minutes). Figure 10a shows the microstructure of this low potassium cement after 2 h hydration time: bent syngenite crystal aggregates and ettringite with the same morphology as after 10 minutes are observable. The microstructure of cements with high potassium content (2 h) show ettringite and syngenite with the same morphology as after ten minutes (compare Figures 9b and 10b).

Acceleration period (high chemical activity): At the beginning of the acceleration period the C-S-H phases grow topochemical on the C_3S clinker surfaces. In the case of cements with low potassium content small (< 200 nm long), isolated and strongly inhomogeneous distributed C-S-H clusters can

be observed after 3 h hydration time. Ettringite has nearly the same morphology as after ten minutes. After 5 h the microstructure shows formations of small C-S-H phases with a length of up to 300 nm arranged in clusters (Figure 11a). Individual clusters of fibers are formed.

Figure 10a. Microstructure after 2 hours hydration time [low potassium content]: Ettringite with the same morphology after 10 minutes, increased syngenite formation.

Figure 10b. Microstructure after 2 hours hydration time [high potassium content]: Ettringite and syngenite with the same morphology after 10 minutes.

Figure 11a. Microstructure after 5 hours hydration time [low potassium content]: Formation of small C-S-H phases (length up to 300 nm) arranged in clusters).

Figure 11b. Microstructure after 6 hours hydration time [high potassium content]: syngenite is starting to dissolve with formation of secondary gypsum (left).

As the hydration continues further, the tipped needle like C-S-H phases grow longitudinally (one-dimensionally – up to 600 nm long in 10 hours). Due to this one-dimensional growth, tight interlocking of the nanoscale C-S-H crystals occurs. The C-S-H phases formed in the hydration process of ordinary Portland cement during the first 24 hours exhibit a significantly faster growth than during the hydration of the pure C_3S clinker mineral. Up to 10 hours, the morphology of primary ettringite remains virtually unchanged. After a hydration period of 10 hours syngenite is no longer visible in the microstructure, but partial secondary gypsum is (Figure 12a).

In cement with high potassium content after 3 hours we observe many straight syngenite crystals in the form of stripes and plates and small but many C-S-H clusters. Ettringite has nearly the same morphology as after 10 minutes. Furthermore, first portlandite crystals are visible. After a hydration period of 5 hours the lath shaped syngenite crystals start to dissolve and formation of secondary

gypsum, potassium hydroxide and potassium sulfate (Figure 11b) is observed. After a hydration period of 10 hours only a few syngenite crystals are visible in a matrix of C-S-H and ettringite (Figure 12 b).

Figure 12a. Microstructure after 10 hours hydration time [low potassium content]: partial secondary gypsum, C-S-H (length up to 500 nm) and ettringite (length up to 600 nm).

Figure 12b. Microstructure after 10 hours hydration time [high potassium content]: sporadic syngenite, C-S-H (length up to 500 nm) and ettringite (length up to 600 nm).

Deceleration period: Cement with low potassium content: The gap between the C-S-H reaction rim (about 600 nm thickness) and the hydrated clinker grain becomes even bigger (distance between 0.6 and 1 μm – Figure 13a). As the reaction process continues the space is filled initially by ettringite and later also with C-S-H phases from adjacent clinker grains (Figure 14a). The main growth phase of ettringite is between 12 and 24 hours. The length of the crystals is then up to 2.5 μm and they keep their thickness all the time.

Cement with high potassium content: We also observe gaps between the hydration rim and the hydrated clinker grain. Ettringite crystals growing along their c-axis penetrate the gaps between the clinker grains and the hydration products (Figure 13b). The longitudinal growth of ettringite can possibly be attributed to the newly released sulfate (dissolution of syngenite and formation of secondary gypsum). Further reason for the growth of ettringite is the release of C_3A through the progressive C_3S hydration.

Figure 13a. Microstructure after 20 hours hydration time [low potassium content]: ettringite crystal penetrate the space between the clinker grain and new formations of C-S-H.

Figure 13b. Microstructure after 20 hours hydration time [high potassium content]: C-S-H phases on the surface of an incompletely hydrated clinker grain (gap).

Calculations as well as measurements have shown that in the first hours only 10 % of the C_3A content can react. Sporadic thin hexagonal-plate tetracalciumsulfoaluminate-hydrate clusters are visible. Tetracalciumsulfoaluminatehydrate is a solid solution of monosulfate and calcium-aluminate-hydrate. The voids and gaps were filled with C-S-H nanocrystals and ettringite (Figure 14b).

Figure 14a. Microstructure after 24 hours hydration time [low potassium content]: long prismatic ettringite (up to 2.5 μm), C-S-H (length approx. 600 nm).

Figure 14b. Microstructure after 24 hours hydration time [high potassium content]: voids in the microstructure are filled by C-S-H (length up to 600 nm) and ettringite.

Final period: During the final period there is further slow growth of the C-S-H phases. Further basic consolidation of the microstructure occurs during this process, to which the slow reaction of the $\beta\text{-C}_2\text{S}$ also contributes.

After a hydration time of 7 days C-S-H reaction layers of about 900 nm thickness are visible. Figures 15a and 15b show typical occurrence of C-S-H reaction rims: Figure 15a shows direct growth on the clinker grain, Figure 15b shows the C-S-H reaction rim around a completely dissolved clinker grain. Long prismatic ettringite (up to 2.5 μm) and thin hexagonal-plate tetracalciumsulfoaluminatehydrate crystals are observable within the void of the clinker mineral (Figure 15b). These completely hydrated clinker grains exist mainly in cements with a high soluble potassium sulfate content.

Figure 15a. Microstructure after 7 days hydration time [low potassium content]: long prismatic ettringite (up to 2.5 μm), and C-S-H (length approx. 900 nm).

Figure 15b. Microstructure after 10 minutes hydration time [high potassium content]: voids of completely hydrated grains are filled mainly with a solid solution of monosulfate and calcium-aluminate-hydrate (tetracalcium-sulfoaluminatehydrate).

Scheme for ordinary Portland cement hydration:

A scheme for hydration of OPC can be concluded from the above described observations. DCA and XRD measurements confirm this scheme. Figure 16 was derived to give a time resolved summary on the occurrence of hydration products.

In the first hours temporary syngenite formation is observed. The time of formation and the amount of the syngenite growth depends on the contents of soluble potassium sulfate (mainly arcanite). After a hydration period of about 5 hours the lath-shaped syngenite crystals dissolve and are replaced by secondary gypsum and potassium sulfate. Ettringite is the first hydration product shortly after mixing. The small prismatic ettringite crystals have a length of approximately 500 nm and a thickness of up to 250 nm. During the first hours the morphology of primary ettringite remains virtually unchanged. Minimal crystal growth is observed. The main longitudinal growth of these phase occurs between 12 and 24 h. The length of the crystals is then up to 2.5 μm and they keep their thickness all the time. Contrary to previous hydration models ettringite does not become unstable and does not gradually convert into monosulfate or tetracalciumsulfoaluminatehydrate. Both ettringite and tetracalciumsulfoaluminatehydrate are the final products of hydration of OPC in our investigations.

Figure 16. Scheme for ordinary Portland cement hydration at room temperature – derived from investigations by means of ESEM-FEG.

Tetracalciumsulfoaluminatehydrate is formed after approximately 24 hours in dependence of the content of the water soluble potassium sulfate. Thin hexagonal-plate crystals are formed. At room temperature these crystals are solid solutions of monosulfate and calciumaluminatehydrate.

C-S-H phases form on the C_3S clinker phase at the beginning of the acceleration period. Small (about 200 nm long), isolated and strongly inhomogeneous distributed clusters of C-S-H phases are observed. Within 24 hours the C-S-H phases grow continuously to a length of 600 nm, the needle tips have only a diameter of approximately 5 nm. The longitudinal growth takes place from surface

of the clinker grain outwards. The result is a strong interlocking of the microstructure due to the extremely tipped, needle-like shapes.

The structure of μm -scaled portlandite crystal aggregates is determined by stacks of crystals with a thickness between 20 and 200 nm. This leads to large $\text{Ca}(\text{OH})_2$ aggregates with a strongly inhomogeneous distribution.

3.4 Pore solution and phase development

To support the ESEM investigations the concentrations of important ions in the pore solution of the OPC with high potassium content were analyzed. From the measurements of concentrations and the subsequent calculation of activities, ionic products and saturation factors, the formation of phases in the microstructure can be traced. The results of the analyses are given in Table 2. Electrochemical balance showed some deficit in negative charges at all times. Activities reflected are by a simple thermodynamic convention that part of the concentration contributes to the formation of phases. They were calculated from the concentrations using the Pitzer approach for high ionic strength [19]. Interaction parameters given by Reardon [20] were applied to the mathematical framework to describe the behavior of the ions in pore solution. From the obtained activities, ionic products according to equations 1-3 were calculated for gypsum, syngenite and portlandite at the reaction times specified in Table 2.

Table 2. Analysis of the pore solution from the paste made from the OPC with high potassium content at $w/c=0.4$ [mmol/l]

time	SO_4^{2-}	K^+	Na^+	Ca^{2+}	OH^-
10 min	205	463	50	14,9	74
30 min	208	471	52	16,6	81
60 min	205	476	54	19,0	89
90 min	205	460	53	19,8	96
3 hours	188	425	51	17,0	112
6 hours	191	432	55	17,8	118
24 hours	59	655	97	2,4	497

$$\text{IP}_{\text{Gypsum}} = \{\text{Ca}^{2+}\} \cdot \{\text{SO}_4^{2-}\} \quad (1)$$

$$\text{IP}_{\text{Syngenite}} = \{\text{K}^+\}^2 \cdot \{\text{Ca}^{2+}\} \cdot \{\text{SO}_4^{2-}\}^2 \quad (2)$$

$$\text{IP}_{\text{Portlandite}} = \{\text{Ca}^{2+}\} \cdot \{\text{OH}^-\}^2 \quad (3)$$

$$\Omega = \text{ionic product/solubility product} \quad (4)$$

In Figure 17, the calculated ionic products are compared with relevant solubility products by calculation of saturation factors according to equation 4. Saturation factors greater than 1.0 are indicating formation of a phase, whereas from values below 1.0 dissolution or absence of the phase can be derived. Solubility data from Greenberg & Møller [21] were used for syngenite ($3.37 \cdot 10^{-8}$ at 20°C) while thermophysical data from Babuskin et al. [22] were used to calculate the solubility products for portlandite ($5.54 \cdot 10^{-6}$) and gypsum ($2.14 \cdot 10^{-5}$).

In Figure 17, it can clearly be seen, that there is a strong supersaturation for syngenite ($\Omega=1.3-1.9$) from the beginning of the hydration until up to 6 hours, whereby precipitation of gypsum is also indicated ($\Omega=1.3-1.7$). After 24 hours there is an overwhelming undersaturation for both phases ($\Omega<0.04$), showing them to be absent from the microstructure. Saturation factors for portlandite are

below $\Omega=1.0$ in the first hour of hydration and then constantly rise. So, formation of portlandite is not likely to take place in the first hour of the hydration of the investigated cement paste, but is strongly proceeding later on. All these conclusions are in good agreement with ESEM observations.

Figure 17. Indicated presence of relevant phases over reaction time calculated from pore solution concentrations.

3.5 Hydration of OPC at other temperatures

The investigations in hydration of OPC were mainly performed at room temperature. The phases found after 2 days were, as indicated in Figure 16, C-S-H phases (length up to 1 μm), ettringite (length up to 2.5 μm), portlandite and a tetracalciumsulfoaluminatehydrate. EDX-analyses of the latter phase showed a deficit in SO_3 -content, when compared to monosulfate ($\text{C}_3\text{A}\cdot\text{CaSO}_4\cdot 12\text{H}_2\text{O}$), indicating the formation of a solid solution between monosulfate and $\text{C}_3\text{A}\cdot\text{Ca}(\text{OH})_2\cdot x\text{H}_2\text{O}$, with x ranging between 13 and 19 [23]. However, the phase detected in the investigations described here is likely to change with temperature.

To quantify the influence of temperature, ESEM investigations were performed and correlated with thermodynamic calculations based on the data given by Babuskin et al. [22] using the Gibbs-Helmholtz approach (Eq. 5). For these calculations it was assumed that C-S-H, portlandite and ettringite are formed over the whole range of temperatures from 5°C to 65°C during the early part of hydration. After consumption of the sulfate from the set regulator (gypsum, anhydrite) and from the clinker surface (alkalisulfate) with water and C_3A to ettringite, further reaction of C_3A can lead to formation of monosulfate or C_4AH_x . The formal expressions considered for the further reaction of C_3A are given in equations 6 and 7. The dependence of the formation of $\text{C}_3\text{A}\cdot\text{CaSO}_4\cdot 12\text{H}_2\text{O}$ or C_4AH_{19} on temperature as obtained from thermodynamic calculations is given in Figure 18.

$$\Delta G_{T,P} = \Delta H - T \cdot \Delta S \quad (5)$$

Only a reaction according to equation 6 leads to a decrease in the primary formed ettringite and formation of monosulfate, as it is assumed in many textbooks on cement hydration. A reaction following equation 7 would yield a hydration of C_3A to a sulfate-free tetracalciumaluminatehydrate, so that there would be no reduction in the amount of the primary formed ettringite. As can be seen from Figure 18, the formation of monosulfate is not likely at room temperature, but becomes favourable with increasing temperature. At room temperature and below, C_4AH_{19} is the product to be formed as indicated by calculation.

Formation of C_3AH_6 and a solid solution between monosulfate and C_4AH_x was not considered in the calculations as there is an internal inconsistency in the data given by Babuskin et al. (C_3AH_6) or there are no thermodynamic data available (solid solution members).

Figure 18. Change in Gibbs free energy during reaction of C_3A to C_4AH_{19} or monosulfate in dependence of temperature.

Experimental investigations were carried out on a sample of OPC paste hydrated for 21 days at 5°C and for 3 days at 62°C.

Hydration of OPC at 5°C (Figures 19a and 19b): The observed ettringite crystals have a length of up to 4 μm , a much greater value as compared with room temperature. Monosulfate or tetracalciumsulfo-aluminatehydrate could not be detected. Only pure C_4AH_x is formed (Figure 19b), which is in agreement with thermodynamic calculations (Figure 18).

Figure 19a. Microstructure after 21 days hydration time at the temperature of 5 °C: very long prismatic ettringite (up to 4 μm).

Figure 19b. Microstructure after 21 days hydration time at the temperature of 5 °C: hexagonal calciumaluminatehydrate.

Hydration of OPC at 62°C (Figures 20a and 20b): At this temperature ettringite, monosulfate, C-S-H, portlandite, hydrogarnet and hydrotalcite were observed. Ettringite formed at 62°C has a similar length to that crystallized at room temperature. As indicated by calculations, monosulfate becomes a stable phase, detectable by ESEM, whereas no sulfate-free C_4AH_x could be analyzed by EDX. In the areas of completely dissolved clinker grains, formation of hydrotalcite $Mg_6Al_2[CO_3(OH)_{16}]4H_2O$ (thin plates with a thickness of approximately 25 nm) and hydrogarnet

were observed. Hydrogarnet is a series of solid solutions of C_3AH_6 , C_3AS_3 , C_3FH_6 and C_3FS_3 that crystallize in a cubic shape.

Figure 20a. OPC after 3 days at 62 °C: area of a completely hydrated clinker grain; hydrogarnet: solid solution of C_3AH_6 , C_3AS_3 , C_3FH_6 and C_3FS_3 .

Figure 20b. OPC after 3 days at 62 °C: area of a completely hydrated clinker grain: hydrogarnet and hydrotalcite $Mg_6Al_2[CO_3(OH)_{16}]4H_2O$.

At room temperature, monosulfate is metastable with respect to ettringite and calciumaluminate-hydrate. This can be illustrated by the following experiment: monosulfate and water were stored at 22 °C in a glove box. After a relatively short period of time, monosulfate dissolves and the formation of hexagonal-plate calciumaluminatehydrates as well as ettringite is visible (Figures 21a and 21b).

Figure 21a. Storage of monosulfate in water at 22 °C: dissolution of monosulfate and formation of ettringite and calciumaluminatehydrate.

Figure 21b. Storage of monosulfate in water at 22 °C: formation of aggregates of parallel-grown ettringite crystals.

4. CONCLUSIONS

It has been shown that the Environmental Scanning Electron Microscope offers distinct benefits over a conventional SEM on the observation of hydrate phases. The hydration process can be traced realistically and the structures can be reproducibly imaged. It is possible to observe images of the temperature- and vacuum-sensitive and only several nanometer-thick hydration products of OPC. More especially, new insights for the early hydration state can be obtained. Sample preparation artifacts are very limited.

Comparative studies using the ESEM-FEG in different operating modes, for example, wet- (ESEM mode) and high vacuum- (conventional SEM) mode have been carried out. It can be shown that with the traditional methods, (drying, coating, beam damage) changes in the morphology of the C-S-H phases are dramatic.

Furthermore, the article describes the investigations of the phase development during the hydration of OPC from induction to the final period. The results are summarised in a scheme for the normal hardening process and can be correlated with phase development derived from ion concentrations in the pore solution. The formation of syngenite during the early part of hydration, derived by means of ESEM, was confirmed by these calculations, as there is a strong supersaturation for syngenite indicated.

The comparison of the ESEM investigations with the DC analyses reveals that the two typical maxima in these DCA-curves give a good correlation to the microstructure development. The second maximum of the DCA-curves (acceleration period) corresponds mainly to the first appearance of C-S-H phases.

ABSTRACT

ESEM technology used in conjunction with a high resolution scanning electron microscope with Schottky type field emission gun promises a decisive expansion in the investigation capabilities in the field of building material research. With this instrument sensitive water-containing constituents of the microstructure can be observed electron-optically in their original state down to a range of a few nanometers. Artifacts caused by the sample preparation and the effects of high vacuum in the sample chamber, which are typical of conventional standard high-vacuum SEM, can be eliminated. The capability of ESEM-FEG to work in different operating modes (wet, low-vacuum-, high-vacuum- and low-voltage mode) were also used to explain changes in the nano- and microstructure which occur during the preparation and examination of some characteristic building material samples. By direct comparison of the same sample area using the different operating modes it was found that in the investigation of samples with different types of water-bonding, the original state can fundamentally be changed both morphologically and chemically. C-S-H phases which are the main binding phases in all Portland cement-based systems are thermally very unstable phases which can be destroyed by necessary preparation methods and by electron bombardment.

1. INTRODUCTION

The visualisation of structures resulting from processes that take place at the scale of a few nanometers is important when studying the properties of concrete and mortars. Electron microscopy is in principle capable of acquiring images of structural constituents at this size. Unfortunately, studies using standard conventional high-vacuum electron microscopes (conventional SEM) are subjected above all to serious limitations:

- The specimens must be solid.
- The specimens must be high-vacuum stable (essentially nonvolatile in nature) or correspondingly prepared.
- The specimens must in general be electrically conductive or be made conductive by a coating or sputtering of the surface.
- The specimens must be stable due to the electron-specimen interaction under high vacuum.

Therefore, the previous investigations carried out with conventional SEM have been based on special, multi-stage sample preparation methods. These methods (critical point drying, freeze drying, cryo preparation and so on) are extremely expensive both in terms of time and apparatus. In addition one has to take into account that the individual sample preparation stages take place without control of possible sample changes so that during the investigation of the samples there is no certainty whether or not, after a series of preparative stages, the “true” specimen structures are being observed and analysed or which specimen changes (artifacts) are caused by the preparation. In principle, it is also impossible by means of the conventional SEM to follow in-situ the dynamics

of dissolving, crystallisation, re-arrangement and re-organisation processes in which fluid media are involved. In-situ investigations also require uncoated samples.

Since the development of Environmental Scanning Electron Microscope with Schottky type Field Emission Gun (ESEM-FEG) we do not see these limitations anymore. The following important investigative capabilities are available with the ESEM-FEG:

- coating with a conductive film is not necessary
- all samples can, in principle, be investigated in the state in which they were found
- the behaviour of liquids can be observed in-situ
- it is also possible to investigate samples which contain oil or generate large quantities of gas
- it is possible to carry out wetting experiments with water from the supersaturated water vapour phase, since the pressure in the sample chamber can be raised to 1330 Pa [10 Torr]
- performing dynamic in-situ experiments within the microscope chamber (heating/freezing-, (de)hydration- and stress testing experiments)
- the production of quality images at low accelerating voltages < 5 kV (wet and low-vacuum mode) on samples with low mean atomic numbers and low density
- no sample coating and X-ray absorption interference in the Energy Dispersive X-ray analysis (EDX)
- less sample contamination caused by beam irradiation influences the high resolution image and the EDX analysis

The ESEM-FEG can be operated in different modes (ESEM, low-vacuum SEM, high-vacuum SEM and in the low-voltage mode). By using the different operating modes it was found that in the investigation of samples with different types of water-bonding the original state can be fundamentally changed both morphologically and chemically [1 - 3].

Investigations of frequently analysed building material samples show how the morphology and chemical composition of the sample is affected namely through high vacuum, contamination, temperature impact (application of an electrically conductive coating), and due to the electron beam of the SEM, as well as the coating film itself.

When using the previous traditional methods of electron microscopy the operator faces the difficult task of evaluating and interpreting the microstructure and the EDX analysis. One has to assess the influence of the high vacuum in the specimen chamber as well as the influence of the necessary preparation steps on the microstructure and the individual phases.

In the past it was not possible to provide a clear answer to these questions. So these factors were often ignored, assumptions as to possible effects were expressed [4, 5] but often interpreted incorrectly. Only through the use of ESEM technology with the capability of direct comparison between the original and the prepared states has it become possible to provide clear information.

The advantage of using the ESEM for the investigation of early hydration stages of a multi-component system as ordinary Portland cement (OPC) is explained in [6 – 9].

2. METHODS

Investigations were carried out using a high resolution ESEM with the high-brightness FEG source (FEI XL30 ESEM-FEG) which guarantees a resolution better than 2 nm at 30 kV at both 7 Torr and high vacuum conditions. This microscope is combined with an EDX for chemical analysis. A special Gaseous Secondary Electron Detector (GSED) is used in the water vapour atmosphere of the

ESEM to permit secondary electron imaging in a gaseous environment. During the investigation the sample can be cooled or heated between -10 and $+60$ °C. It is also possible to change the sample surface mechanically in the microscope chamber with a micromanipulator or to bring it into contact with liquids using the microinjector.

Microanalytical investigation of the chemical composition of the hydrated phases in their native state by EDX analysis is only partially possible due to small size (for example: C-S-H phases are nanometer scaled needle-shaped crystals), the surface roughness, the water content and because of the “beam skirt” in the ESEM mode. The gas pressure in the sample chamber causes significant scattering of the primary electron beam and results in the formation of a “skirt” of electrons. The diameter of this skirt can be many tens of microns wide [10 - 12]. Furthermore it comes to an interaction of the emitted X-rays with the gas molecules in the specimen chamber. By this, the X-rays are absorbed on their way to the EDX-detector. The absorption of characteristic X-rays and of the X-ray continuum in the atmosphere of the sample chamber leads furthermore to a fluorescence excitation of the gas molecules [13]. All these effects can be weakened down by reducing the gas path length and the sample pressure.

In order to assess how the sample preparation and high vacuum affect the material and morphological nature of the water-containing samples it is helpful to observe the same sample area under the following conditions:

2.1 ESEM-wet mode: (original state)

Some selected sample areas are observed, stored and analysed at different magnifications in a water vapour atmosphere using different relative humidities. The corresponding stage positions (x, y, z) of the selected sample areas are also stored.

2.2 Low-voltage mode (high-vacuum)

The effect of the high vacuum on the samples observed in ESEM-wet mode is shown when the sample chamber is evacuated down to the level which is normal for conventional SEM (about 4×10^{-4} Pa or 3×10^{-6} Torr, the water vapour pressure is then approximately 2×10^{-4} Pa). Since only non-conductive and non-coated samples were investigated here in order to observe the influence of high vacuum it was necessary to work with low accelerating voltages of the primary electrons of less than 2.5 kV. The stored stage positions are recalled and the sample areas are compared with the stored ESEM-wet images.

In order to improve the resolution, especially at very low accelerating voltages of 1 kV, a Sirion XL30 S FEG from FEI, and a new in-lens cold cathode field emission SEM S-5200 from Hitachi (FESEM: resolution 1.8 nm at 1 kV) were used.

2.3 Standard high-vacuum SEM (HV-SEM: high-vacuum, coating or sputtering)

A comparison with the preparation methods normally used for conventional SEM is carried out by removing the sample together with the sample holder from the microscope chamber after previously marking the position of the sample holder. The sample is then coated with a conductive film to avoid electrical charges at higher accelerating voltages (> 2.5 kV). This is realised either in a high vacuum by resistance vaporisation of carbon, or by sputtering with silver. For rough samples a layer thickness between 5 and 30 nm, depending on the coating material, is necessary for an adequate coherent coating on all sides. After coating with a conductive film, the sample is put back to the stage of the ESEM again, and the stored sample areas are examined.

By direct comparison of the same sample areas it is now possible to detect the changes in the water-containing samples being a result of the stressing by thermal radiation (carbon coating) and the effect of the carbon film or the sputtered layer, such as the inherent structure of the layer itself, the

covering of phases in the range of a few nanometers (masking), structuring through shadowing, etc. (vaporisation artifacts).

Possible artifacts which, for example, can occur during in-situ hydration experiments in the ESEM-wet mode, occur in the form of thin gel films on the sample surface and can easily be removed by the micromanipulator under direct electron-optical observation (in-situ preparation). During hydration experiments which are not carried out inside the sample chamber of the ESEM and during the storing of the hydration samples it should be borne in mind that these must take place in a CO₂-free atmosphere (glove box).

The Electron Backscatter Diffraction (EBSD) is a new and different application to obtain more crystallographic information at sub-micron resolution. It allows the linking between morphology (ESEM, SEM), chemistry (EDX and/or WDX) and crystallography for example for the phase identification of crystals with the same chemical composition (vaterite, aragonite and calcite).

3. RESULTS AND DISCUSSION

3.1 The structure of cement-based materials – comparative investigations

In principle investigations with a conventional SEM on samples in the early hardening stage seem to make little sense, even when much time and a very sophisticated apparatus is used in the preparation process. Investigations have shown that such structures (see Figure 1) - even when prepared very cautiously (dehydration through freeze-drying, critical point drying and others) are changed significantly through extraction, de-mixing, recrystallisation, emission of chemically and physically bonded water.

Figure 1. Microstructure of a OPC with low potassium content after 3 h hydration time. Individual clusters of C-S-H fibres (approx. 200 nm) and ettringite

Furthermore, mobile phases are enriched on the surface very often which are capable of disguising other phases completely. In Figure 3 for example one can recognise the sodium- and potassium containing salts (pore solution) efflorescing on the surface of the sample of a hydrated Portland cement due to drying, which cannot be observed in ESEM-WET mode at 95 % r. H. (Figure 2).

Figure 2. Early hydration of OPC after 6 h in ESEM-wet mode at 95 % r. H.

Figure 3. Same sample as in Figure 2 in standard HV-SEM: efflorescence of alkali salts on the sample surface during vacuum drying

Even samples in a hardened condition are in danger of forming artifacts and that even then when the magnification factor is small. It has been shown that a significant share of the cracks in the hardened cement paste matrix and in the contact zone to the aggregates become bigger (see Figure 4 and 5), or they are created in the first place during the drying of the samples in the high vacuum of the coating device and/or the HV-SEM.

Furthermore, it can be shown that even relatively stable crystal-water-containing crystals like gypsum give up some of their chemically bound water simply because of the high vacuum in the sample chamber of the SEM (see Figures 6 and 7). The relatively smooth surface of the gypsum crystals is textured and through the micro crack formation the different crystal orientations become clearly visible.

Figure 4. microstructure of hardened cement paste with crack (width: 320 nm) in ESEM-wet mode at 50 % r. H.

Figure 5. Same sample area as in Figure 4 in low voltage mode: the original crack width has increased to 1130 nm due to high vacuum stressing in sample chamber

Figure 6. Gypsum crystals with relatively smooth crystal surface in ESEM-wet mode at 95 % r. H.

Figure 7. Same sample area as in Figure 6 after high vacuum stressing. Structuring of the surface through dehydration. (escape of crystal water)

The calcium silicate hydrate phases (C-S-H phases) being formed in the process of cement hardening show a very different picture when they are observed by means of conventional electron microscopy. The phases which are formed in the normal hardening process of cement are often described as gel-like, amorphous, tube-like, nap-like, blunt needle-like, and micro- or semi-crystalline with variable composition. Often blunt needle-like or nap-like C-S-H phases with a diameter of 100...130 nm can be observed as far as carbon coated samples are concerned. In contrast to this, the C-S-H phases observed by means of ESEM-wet mode or at a low stress in low-voltage mode appear in a long spiky form with the hydration time advancing.

The hydration progress can be seen mainly in the one-dimensional growth in which the C-S-H phases that are formed during the hydration of the clinker phase alite can reach a length of up to 1.5 µm at a constant diameter of 40 – 60 nm. A growing together of individual phases to form crystal aggregates can often be observed. The needle tips have a diameter of 5 nm and react extremely sensitively to thermal stress under high vacuum conditions. Through million fold interleaving of the nanocrystalline spiky C-S-H phases a solid structure is created.

To explain the observed discrepancy between the ESEM and the HV-SEM images, the influence of the coating and sputtering on the morphology was studied. For carbon coating a high vacuum vaporisation device according to Bredlay was used. The material was 1.13 nm tobermorite. Tobermorite is a calcium silicate hydrate phase which is formed during the autoclaved hardening of sand-lime brick. Tobermorite keeps its structure even under high vacuum conditions; this has been proven by comparative investigations with ESEM-wet. For this reason, changes of the preparation through thermal stress because of heat radiation during the coating process or because of the vaporisation layer itself (vaporisation artifacts) can be followed easily.

Figure 8. Tobermorite aggregate depicted by means of FE-SEM Sirion at ultra high resolution and very low accelerating voltage of 1 kV

The fine structure that is to be seen on uncoated preparations in low voltage mode at ultra high resolution is created by the directed aggregation of individual sword-like tobermorite crystals during the growth period.

Figure 9. Detail of tips of the „sword-like“ tobermorite crystals in low voltage mode at 2.5 kV

Figure 10. Same sample area as in Figure 9: deformed crystals coated with an approximately 30 nm carbon layer for the investigation in the HV-SEM (no structural stability)

This structuration is to be seen very clearly 200 nm underneath the crystal tips, which are 5 nm thick, at the “comb-like” end. (Figure 8)

The influence of the resistance vaporisation with a carbon coating on the morphology of tobermorite which is stable under high vacuum can be seen by comparing Figures 9 and 10 directly. Both figures show the same sample area. The thermal stress of the crystals which occurs under high vacuum during vaporisation leads to a melting and vaporising off of the crystal tips, which are only a few nm thick, or ball-like particles with a diameter of 60 nm are formed.

Through the evaporated carbon layer, which is approx. 30 nm thick, the crystal tips now appear as spheroides with a diameter of approx. 130 nm. Figure 9 also shows that the “gel-like” structure of the carbon coating is depicted and not the surface structure of the sample.

Through shading effects on the strongly structured sample we have different layer thicknesses of the evaporated carbon film. The observed bending of the approx. 20 nm thick crystals occurs because of water extraction as a consequence of heat radiation and because of the surface tension coming about through the cooling off of the carbon layer. When the sample is sputtered with a 10 nm thick Ag-layer instead, we can see in principle the same effects. However, the sputter-layer tends to form clusters interferes with high resolution.

Figure 11. C-S-H phases (C_3S -hydration) with needle-like structure before radiation damage by electron bombardment in high vacuum

Figure 12. Same sample area as in Figure 11: damaged C-S-H phases: vaporized and shrunk fibre tips in high vacuum

When you compare Figures 11 and 12 which were made with the FE-SEM Sirion, you can see that the C-S-H phases formed during the Portland cement hydration from alite and belite are damaged at much lower beam current at 10 pA in comparison with tobermorite in high vacuum. The excitation processes cause a melting and vaporisation of the fibre tips. This can be explained by the higher sensitivity of the phases to thermal stress, but mainly this is because of the much lower heat conductivity under high vacuum and because of the very unfavourable relation between length and diameter. Under direct electron-optical observation it is possible here to comprehend the process that takes place during the coating in high vacuum.

3.2. Electron Probe Microanalysis and Imaging at Low Beam Voltage and Current

Usually the analysis of most samples is performed at 15 – 20 kV. The X-ray and resolution will be reduced because of electron scattering. The electron scattering is dependent of the electron energy, the density of the sample, and the deviation from the normal incidence of the electron beam. To achieve a better resolution, a lower voltage should be used. This causes a reduced interactive volume within the sample compared to higher accelerating voltages. Figure 13 illustrates the stimulant single scattering volume of the electron beam as determined by Monte Carlo calculations of 4000 electron trajectories at 15 and 2.5 kV electron energy for a calcium silicate hydrate (1.13 nm tobermorite).

As we can see very clearly, the conventional microanalysis at high voltages means an excitation volume of the electrons of some μm^3 . Thus, not only one phase is analysed but a number of different ones. This applies especially for phases of low density (C-S-H phases have a density of approximately 2.2 g/cm^3) and a size of much less than $1 \mu\text{m}$. By comparison the low-voltage mode of 2.5 kV produces a high spatial resolution (between 50 and 100 nm) for X-ray microanalysis, which relates to the approximate thickness of an individual C-S-H phase (see Figure 13).

Figure 13. Monte Carlo calculations of 4000 electron trajectories at 15 kV (right) and 2.5 kV (left – the same scale) for a 1.13 nm tobermorite crystal

Figure 14. high resolution image at low accelerating voltage using the Hitachi FE-SEM S-5200 of C₃S, hydrated distilled water

Figure 15. the same sample as in Figure 14 but C₃S hydrated with pore solution pressed out of OPC with a high potassium content

An analysis of uncoated and non-conducting specimens at the nanometer scale can only be obtained when you work in a range of low accelerating voltages in combination with a sensitive, high resolution X-ray spectrometer.

There are further problems as to the microanalysis of cement-based material because we have water-containing nanophases and pore solution in the microstructure.

If one compares the images of the structure of uncoated C₃S in Figures 14 and 15 made by the Hitachi FE-SEM S-5200 at 1 – 1.5 kV, one can clearly see that the C-S-H phases are covered with pore solution (mainly with KOH). The dried pore solution sets up very thin films (thickness < 10 nm) around the C-S-H phases. An increasing of the accelerating voltage to > 2 kV leads to the loss of the surface information that is to be seen in the previous images. The thin films are then beamed so strongly that they are not visible anymore. It has also been shown that this fine structure can only be imaged by means of an FE-SEM with a cold field emission gun and not by means of a Schottky emitter as an electron source. The higher gun brightness of the Schottky emitter leads to damage of the sensitive phases due to electron beam (melting and thermal decomposition – see also Figure 12).

But micrometer-size, water-containing crystals like monosulfate or ettringite, can also be damaged in the uncoated state under high vacuum conditions, see Figures 16 and 17 (low thermal conductivity). The damage through the electron beam caused by the temperature rise at the point of impact of the beam leads to the loss of the chemically bound water. This loss of water expresses itself in a bubble formation on the otherwise relatively even crystal surface. This phenomenon will be even stronger when the beam scans over a small area for micro- or point-analysis.

Figure 16. uncoated monosulfate crystals before microanalysis at 5 kV beam energy

Figure 17. Same sample area as in Figure 16: analysed area exposed to 100 pA beam current (defects due to dehydration – bubbles)

3.3 Phase identification in nanometer range

To obtain further information by microbeam techniques the Electron Backscatter Diffraction (EBSD) can be deployed. EBSD is an accepted and important technique to obtain crystallographic information in the SEM or ESEM at sub-micron resolutions. EBSD is a powerful analytical tool which allows the rapid and accurate measurement of individual crystal orientations, with an accuracy of better than 1 %. It allows the interlinking between crystallography, morphology and chemistry at the same sample area.

Deploying an EBSD-system makes sense especially when you want to investigate crystals which have the same chemical composition but exist in various modifications. This is the case with the often occurring calcium carbonate with its three crystalline polymorphous modifications which are formed for example in the process of carbonation of the hydrated phases of lime mortar, on concrete surfaces or in the structure of deteriorated concrete. The modification change between them can very often not be followed morphologically since calcite is the richest mineral of all in form and surface.

Figures 18 – 21 show the phase identification of calcium carbonate (CaCO_3) by means of EBSD-pattern. Calcium carbonate always has the same chemical composition but various modifications (non-crystalline CaCO_3 , vaterite, aragonite, calcite). Although the patterns shown here were produced by means of HV-SEM which means that they are not optimal because of contamination and charging effects, you can nevertheless clearly distinguish the individual calcium carbonate modifications aragonite and calcite.

Another wide field of deploying an EBSD-system would be the distinction of phases which are chemically very similar but show clear distinctions as to their crystal lattice. (e. g. gypsum and semi-hydrate).

Figure 18. EBSD pattern of aragonite $[\text{CaCO}_3]$; taken in the TexSEM-Laboratories, Inc. USA of TSL with the DELPHY System

Figure 19. Indexed EBSD pattern of aragonite CaCO_3 , crystal lattice: rhombic

Figure 20. EBSD pattern of calcite $[\text{CaCO}_3]$; taken in the TexSEM-Laboratories, Inc. USA of TSL with the DELPHY System

Figure 21. Indexed EBSD pattern of calcite CaCO_3 , crystal lattice: trigonal

It should be possible, too, with the EBSD-system to identify phases on crystals which are only a few nm big, since the signal comes from a depth of 100 atom layers maximum. It would be interesting to see whether or not one gets pattern of the calcium silicate hydrate phases (C-S-H), which are formed during normal cement hydration respectively during the hydration of alite and belite, and if so, to which crystal structure they belong. These phases are generally seen as “amorphous to X-rays” because of their small crystal size and/or a strongly disturbed lattice, so they cannot be determined by means of XRD.

4. CONCLUSIONS

This article shows that it is possible by means of ESEM-FEG to carry out high resolution scanning electron optical and micro beam analysis investigations on sensitive water-containing building material samples in their original and unaltered state. The formation of the extremely sensitive hydrate phases which are only a few nanometers in size as well as the influence of concrete admixtures in the early hardening stage can only be followed close to reality by means of ESEM-FEG at present. The preparation time is also greatly reduced. Stopping the hydration process, drying and coating/sputtering of the surfaces are no longer necessary. This eliminates many potential artifact sources that in the past - by using the traditional high-vacuum electron microscopy (HV-SEM) - led to uncertainty in the evaluation of micro- and nanostructures and in some cases to incorrect interpretations.

By means of HV-SEM one reaches high resolution as to temperature- and vacuum-stable samples. But through the formation of a contamination layer in high-vacuum, fine object details may be covered and this decreases the resolution. Furthermore, insulating or poorly conductive specimens being charged on the surface by the electron beam in high-vacuum need a conductive coating/sputtering which covers the real structure, too. Both effects also influence the microanalysis negatively.

In ESEM mode, in contrast, the presence of positive ions in the irradiated gas in the sample chamber prevents the specimen from charging and reduces the contamination effect.

Since the ESEM-FEG can be used in different modes, i.e. ESEM, low- and high vacuum mode as well as low-voltage imaging mode, it is possible to investigate the same sample area under various modes chemically as well as optically. These capabilities were used to clarify object changes (artifacts) which occur when investigating and preparing some characteristic structure constituents by means of conventional methods.

Comparative investigations clearly showed that e.g. C-S-H phases which are formed in the normal hardening process of ordinary Portland cement, and which are often described as “gel-like” not only give up part of their water content in the high vacuum of the HV-SEM but they are severely damaged due to the temperature stress through heat- and electron radiation under vacuum conditions. Only the ESEM made it possible to illustrate the world of the C-S-H phases far more realistically.

The energy dispersive X-ray-spectroscopy offers advantages and capabilities compared with analysis by means of HV-SEM. For example the chemical determination of hydration-, dehydration-, carbonation-, and oxidation processes. The disadvantage of the ESEM mode, however, is the interaction between primary electrons and the emitted X-ray with the gas molecules. These effects can have influences as to the qualitative as well as the quantitative analysis.

By means of ESEM it could be shown that many decisive processes take place in a space of a few nanometers and that the formed phases themselves are only a few nanometers in size in some cases. Therefore, further investigations are important to get even deeper into the “nano-world”. This applies mainly for the capabilities of the chemical analysis and the phase identification. The latter can be carried out by means of Electron Backscatter Diffraction Pattern in the ESEM.

For the X-ray microanalysis of individual phases in the nanometer scale as well as for images of higher contrast, investigations must be carried out in the low-voltage mode. The reduction of the accelerating voltage means a small interactive volume. When an FE-SEM with cold cathode field emission is used it becomes possible to reduce the beam current in such a way that even sensitive phases, like C-S-H phases, are not damaged.

ABSTRACT

The way to reduce the amount of exhaust CO₂, a green house gas and how to use steelmaking slag, has been examined. Both of them are waste materials or by-products. We can solidify CO₂ gas by using the carbonation reaction of steelmaking slag, and we can easily obtain useful materials which have a compressive strength of several 10's of MPa. Here we discuss the reaction process between steelmaking slag and CO₂ gas, the benefits of this reaction and the properties of the hardened materials.

1. INTRODUCTION

The emission of carbon dioxide is a matter of worldwide concern because of the green house effect. According to the protocol of the Third Convention of Parties on Climate Change at Kyoto in 1997, Japan has a target of 6% reduction in CO₂ and other green house gas emissions. On the other hand, about 10 million tons of steelmaking slag is produced each year in Japan. Because the composition of the slag varies depending on the characteristics of steels being produced, they have not been used extensively except as gravel for roadbeds, and have otherwise been treated as industrial waste materials. Therefore, it is necessary to develop new techniques to use these slags. Fortunately, they contain much 2CaO·SiO₂(C₂S) and 3CaO·SiO₂(C₃S) and also free lime in some cases. These calcium silicates can react with carbon dioxide to make hardened materials [1, 2]. So, the slag has the potential to make useful materials by solidifying CO₂ gas.

In this study, the mechanism and the process of the carbonation reaction of steelmaking slag will be discussed. The effects of water content, temperature and CO₂ content of the reaction gas were assessed by measuring heat liberation, strength development, texture formation and so on.

Carbonation bricks have been manufactured from blast furnace slag in Germany as early as the 1900's [3] and LD slag has been used to make high strength materials by carbonation in Japan[4, 5]. The distinguish feature of this process is the reuse or recycling of waste materials such as steel making slag and exhaust CO₂ gas and the low energy consumption during the reuse or recycling of waste materials. The carbonation reaction is an exothermic reaction, so no energy is required for the reaction except for handling, grinding and/or transportation of materials. The carbonation products of calcium silicates are very stable in air or marine environments.

We will report the application of this process to make a large-scale block such as one cubic meter, porous blocks and also to make very small particles such as artificial sand. If one third of

steelmaking slag were used for this process in Japan, more than one million tons of carbon dioxide emission into the atmosphere would be saved every year.

Here we will report results obtained from several years' co-operative research between Yamaguchi University, Okayama University of Science and NKK Corporation.

2. PROBLEMS IN THE RECYCLING MATERIALS

Usually, we obtain many resources from the earth and we refine them, sometimes adding minor components to obtain highly functional materials. It means that we use pure materials which results in the production of contaminants. At the end of their life, they become waste materials, and are collected together with many contaminants, and then some are recycled as resources. There are 4 problems in material recycling. 1st, a useful material has been diluted as mentioned above. 2nd, sufficient amounts of material will not be supplied as resources, because waste material should not be generated to meet demand. 3rd, when the waste materials are used in existing processes many require high handling charges. The last problem is that more energy is required in the recycling process than that used with virgin materials. The recycling of materials saves resources, but it must be noted that every process uses energy, even the process of recycling.

The process proposed here has a very distinguishing feature – it products low emissions of CO₂ gas with especially low energy consumption except for handling, grinding and transportation of materials.

3. CHANGES IN THE CARBONATION PROCESS

3.1. Volume change

Many studies on the carbonation of calcium silicates have been done on the neutralization of concrete or concrete products, concerning with the durability of concrete. The solidification of slag by carbonation, proposed here, is also the same reaction, but it is used to make beneficial materials from waste materials. It does not need the texture formation by hydration reaction as does concrete. Consequently, through carbonation, calcium silicate will become calcium carbonate and silica gel, whether through hydration or not. At that time, the solid volume increases and fills the pore space to develop strength. The reaction equation is ;

When we assume the density of C₃S, β -, γ -C₂S, CaCO₃ and SiO₂ gel as 3.19, 3.28, 2.97, 2.71 and 2.22, respectively, the volume of carbonated C₃S, β -, and γ -C₂S will be 1.9 times, 1.9 times and 1.7 times, respectively. These increased volumes fill the pore space and combine the particles and develop the strength of the powder compacts.

3.2 Texture Formation

A small amount of water layer is important for the carbonation reaction, as it is the case for the carbonation of concrete. Under the condition of too little water, carbonation does not proceed because of the lack or very small space to react Ca²⁺ and CO₃²⁻, and also in the case of too much water, the reaction does not proceed, because the reaction proceeds only at the surface of the liquid, as shown in Figure 1. It is desirable that the water exists to make a meniscus between particles. Both Ca²⁺ and CO₂ gas must dissolve into the water layer. Then they meet to react and to produce calcium carbonate. When there is too much water, the precipitates will produce a film at the surface of water, far from the particle. These films do not work to bond the particles. When there is an appropriate water layer, calcium carbonate is produced between the particles and binds them to develop the strength. When the products fill up the space between the particles, there is no water

space, so the reaction stops and no expansion occurs through the carbonation reaction. In contrast, in the carbonation of concrete (hydrated cement body), sometimes shrinkage occurs. This should be due to the effect of silica gel.

Figure 2 shows cross sectional images of carbonated compacts of C_3S and $\gamma-C_2S$. Both of compacts initially have same porosity of ca 50%. C_3S gains almost same volume of solids by the carbonation reaction, so the surface of about 10 μm thickness is changed to a very dense carbonated layer after 10 days' carbonation and no further reaction occurred. On the other hand, in the case of $\gamma-C_2S$, the reaction proceeded more than 100 μm deep after 10 days' carbonation, because $\gamma-C_2S$ compacts with 50% porosity had not filled the pore space completely by the carbonation reaction. These compacts gained very high compressive strengths of more than 200 MPa [6].

In Figure 3, another cross sectional images of carbonated steelmaking slag compact with high porosity are shown. In these porous compacts, carbonated products existed homogeneously at the surface and interior of compacts. It is clearly observed that the carbonation products of $CaCO_3$ formed like a film, covering and connecting each particle of slag. Especially in the case using coarse powder, there was much unreacted material in the core of the particles. When these materials were autoclaved at 180°C for 64 h, no further hydration occurred [6]. The product layer is so dense that even water molecules cannot diffuse through the layer.

Figure 1. Illustration of carbonation process in the water layer.

Figure 2. SEM of the fractured surface of carbonated compacts of C_3S and $\gamma-C_2S$, both of which have an initial porosity of ca 50 vol%.

Figure 3. The cross sectional images of carbonated steelmaking slag compact.

3.3 Heat Evolution

The carbonation reaction mentioned as equation (1) and (2) is a neutralization reaction, so significant heat evolves. Here the enthalpy for the formation of γ - C_2S , $CO_2(g)$, $CaCO_3$ and SiO_2 (glass) (here we substitute silica glass for silica gel) is -551.73 、 -94.05 、 -288.45 and -215.48 $kcal \cdot g^{-1}$,

The heat of reaction of equation (3) is -52.54 $kcal \cdot mol^{-1}$ $-C_2S$. When we use a slag with a composition of CaO ;39.0, SiO_2 ;12.4, Al_2O_3 ;3.46, FeO ;13.5, total- Fe ;20.4 and MgO ;8.7 mass %, whose mineral composition is assumed as C_2S , C_2F , FeO and free CaO , the C_2S content was calculated as ca 35.5 mass%. When we assume that a mass of C_2S , which corresponds to 20% of total CaO , is carbonated, heat of reaction will liberate 3.66 kcal per 100 g of slag. This heat is able to increase the temperature up to $183^\circ C$ with an assumption of heat capacity of 0.2 $cal \cdot g^{-1} \cdot K^{-1}$, when it proceeds under adiabatic conditions. (100 g of slag with 5 g of water will be combined with 6.1 g of CO_2 .)

Figure 4 shows the temperature change during carbonation of the steel making slag bed. Where 10kg slag powder with ca 500g water were put into a column 50 cm high and 10 cm in diameter, and then pure CO_2 gas was introduced at a pressure of 0.2 MPa and a flow rate of 180 $ml \cdot min^{-1}$ at room temperature. 5 thermocouples were set at the point of 5 cm, 15 cm, 25 cm, 35 cm and 45 cm from the bottom of the bed (each position is expressed as 1 - 5 in Figure 4). This figure means that the reaction proceeded in laminar fashion from bottom to upper position. The lower part increased the temperature in a short time, then after the reaction proceeded at the next position. The lower part reached the higher temperature of ca $35^\circ C$ more than the upper part.

Figure 4. The temperature change during carbonation of steelmaking slag bed.

3.4 Development of Strength

In figure 5, the development of compressive strength for compacts of C_3S , and β -, γ - C_2S with carbonation time [6] are shown. The compacts had a dimension of 11 mm high and 8 mm in diameter contained 5 mass % of water and had initially 50 vol % porosity. They reacted with water vapor saturated with 5 % CO_2 gas. In the case of γ - C_2S , the compressive strength developed linearly with time to about 100 MPa at 96 h. In the case of C_3S , and β - C_2S , especially in C_3S , strength

developed faster than γ -C₂S in the early stages but did not reach as high a strength after a long time of reaction, giving 50-60 MPa at 96 h. This is owing to the formation of a dense layer at the surface of compacts as shown in Figure 2 and further reaction was hindered or stopped. The reaction should proceed faster with higher temperatures, but at more than 100°C it requires an autoclave because the reaction needs a liquid water layer.

Figure 5. Changes in compressive strength with carbonation time.

The changes in compressive strength with carbonation ratio for compacts of many kinds of slag carbonated at temperatures of 25°C and 50°C [6] are shown in Figure 6. There was not very much difference in the relationship between compressive strength and carbonation ratio for the samples carbonated at different temperatures. The strength of compacts reacted at 50°C were twice as strong as those reacted at 25 °C for the same reaction period.

Figure 6. The changes in compressive strength at temperatures of 25°C(hatched area) and 50°C(open circles).

The relationship between compressive strength and porosity can be expressed using the Ryshkewitch equation [4, 6], in which the logarithmic strength is linearly related to porosity. The results of compressive strength and porosity for carbonated slag compacts are shown in Figure 7. The compacts with porosity of about 20 % had strength of about 100 MPa. In the region of porosity of more than 40 %, strength decreased largely with porosity. In the figure, the relationship for hydrated materials is also presented as a dotted line. The dependency on porosity for carbonated materials is greater than that of hydrated materials. The strength of a carbonated matrix is lower than that of a hydrated one in the region with greater than 10 % porosity, but in the region lower than 10 %, the strength for the carbonated matrix is greater than that of the hydrated one. It will be expected as 350 MPa at porosity of zero.

Figure 7. The relationship between compressive strength and porosity.

3.5 Alkalinity and an Application

The alkalinity of carbonated compacts was in the range of pH 9 to 10, because most of the CaO or $\text{Ca}(\text{OH})_2$ converted to CaCO_3 . When glass fiber is used for reinforcement of these compacts as GRC, the durability of glass should be superior to cement hydrated compacts [7]. Here we show the results of durability tests of soda-lime glass in cement hydrated compact and carbonated cement compact. Belite clinker (clinker for belite rich and alite poor cement, as low heat cement) obtained from Ube Industries Co.Ltd., was used as cement. Plates of soda-lime glass were put into the compacts of 20 x 40 x 5 mm and they were carbonated or hydrated. Fibers of E-glass were also put into the paste. Then they were autoclaved at 180°C for up to 64 h. The surfaces of the glass plates were examined for Vickers hardness and observed by SEM. Changes in diameter of glass fiber by the reaction with alkali was also measured using SEM.

The results are shown in Figures 8, 9, and 10. Figure 8 shows the SEM images of the surfaces of soda-lime glass. Figure 9 shows the changes in hardness of the surfaces. Figure 10 shows the changes in the corroded thickness of the E-glass fiber. It was observed that a low degree of corrosion of glass occurred in carbonated matrix but very high in the hydrated matrix. When the E-glass was in hydrated matrix, it corroded 4 times faster than that of the carbonated matrix, as shown in Figure 10.

Glass fiber reinforced concrete is superior in tensile strength, anti-shock strength and toughness, but inferior in the durability of reinforced fiber. Many researchers have focusing on the upgrading of the fiber, for example, the improvement of its chemical composition and/or coating materials. Here we show another way to improve GFRC durability by changing the pH of the matrix, even when we use cheaper glass fiber.

Figure 8. SEM images of corroded surface of E-glass with hydrated slag and carbonated slag. a) the surface with carbonated matrix treated at 60°C for 1 week, b) that with hydrated matrix at 60°C for 1 week, c) autoclaved at 180°C for 1 h with hydrated matrix, d) autoclaved at 60°C for 64 h with carbonated matrix, and e) locally observed image for that autoclaved at 180°C for 16 h.

3.6 Other Applications

3.6.1 Small Particles as artificial aggregate

Artificial aggregate can be manufactured from steelmaking slag powder by pelletizing and carbonation [8]. In Figure 11, the particles of carbonated slag aggregates, which was granulated by pan type pelletized are shown. Most were spherical particles. In Figure 12, the tensile strength by compaction, water absorption ratio and porosity for aggregates, whose carbonation time was 96 h, are compared between pelletizing times of 30 min and 1 h. Aggregates with 18 MPa and water absorption ratio of 7 % were obtained. The tensile strength by compaction was calculated with an equation proposed by Hiramatsu et al [9],

$$S_t = 0.9 F_0 / d^2 \quad (4)$$

where S_t is tensile strength by compaction, F_0 is compressive stress for fracture of spherical particles and d is diameter of the sphere.

3.6.2 Large Scale Blocks

Large scale blocks with size of 1m x 1m x 1m were made successfully by Takahashi et al [5]. Slag was compacted in a mold after mixing with 5.3 mass% water. The porosity of

Figure 11. The particles of carbonated slag aggregates.

Figure 12. The tensile strength for carbonated slag aggregates by means of compaction.

the compacts was 28 %, and water saturated CO_2 was forcibly introduced into the mold at a pressure of 1.002 atm. through holes in the bottom. These blocks are using for seaweed beds and/or space for fish living, as shown in Figure 13. Blocks submerged in the sea have shown good durability for more than 4 years. No cracks or damage was observed. And surface floral changes by seaweeds like green algae are also observed.

Figure 13. Blocks with size of 1 m x 1 m x 0.5 m made by carbonation of slag.

4. CONCLUSIONS

By a trial calculation, nearly 200 kt of exhaust CO_2 can be beneficially utilised with this process, if it is assumed that 10 % of steel making slag produced is used and the 20% of CaO in the slag will be carbonated.

The process of producing functional materials from slag and carbon dioxide has many advantages. Firstly, we can make useful materials from steel making slag which is an unavoidable byproduct of the steel industry and CO_2 gas which is considered as an important factor for green house effect.

Secondly, in the recycling technology, it may be the lowest energy consumption technology where almost no energy is need for the process except for grinding and transportation. The CO₂ does not need to be generated as it is available from industrial exhausts. This process will be expected in near future, with taking care of the behavior of minor components.

ABSTRACT

Cement particles in suspension are agglomerated and form a three-dimension network. The water trapped between particles has no more lubricating action. Superplasticizers, which disperse agglomerates, free the entrapped water and thus improve the fluidity. It is shown how theories of interparticle forces developed for ceramic materials can be adapted to the more complex case of cement suspensions. In particular, how this allows the (semi-)quantitative evaluation of the yield stress of cement suspensions. The particle size distribution and the activity of ions of the pore solution are taken into account. The total interaction force allowing agglomeration of cement particles take into consideration the sum of dispersion, electrostatic and steric forces. The model is dependent on input parameters, like polymer adsorption, the plane of origin for the calculation of the electrostatic force, the Hamaker constant of cementitious phases, which need to be treated in more detail.

1. INTRODUCTION

Dispersion of agglomerated cement particles is a key point to improve the workability of concrete or to reduce the amount of mixing water. This is the role of superplasticizers or high range water reducers (HRWR). The development of new products, more efficient and tailored for specific applications, should be based on the knowledge of the mechanisms of their interaction with the cement.

Dispersion or London dispersion forces play an important role in the properties of numerous materials and in particular in cement suspensions. The Lifshitz's theory was a major advance and founded our current understanding of these forces [1, 2]. In the last fifty years, it was successfully applied to various practical problems [2]. The dispersion forces are essentially attractive in suspensions of one type of particle (i.e. the same phase).

The balance between these dispersion forces and repulsive forces from surface charge or adsorbed species governs the behaviour of particulate suspensions [3]. The DLVO theory takes into consideration the sum of these interparticle forces, and can be used to understand and predict suspension stability and rheology. This theory has been used to describe cementitious systems [4-6] despite the fact that cement suspensions are not really in the colloidal domain. These approaches have proven to be very useful in trying to understand the complex systems of cement suspensions with polymeric additives. However, the full complexity of such systems was generally not taken fully into consideration perhaps undermining some of the conclusions that may have been drawn from the approach. In more recent years attempts have been made to take into account the

complexity of the ionic medium of cement suspensions, the effects of their broad particle size distributions and their interaction with superplasticizers [5, 6]. Steric repulsion, which plays a key role in superplasticizers of the latest generation, can be taken into account. The key parameters, which govern the steric repulsion, i.e. the adsorption layer thickness and its conformation at the solid liquid interface are often difficult to quantify.

2. INTERPARTICLE FORCES

3.1 Dispersion forces

In the following developments, particles are spheres with un-equal diameters a_k and a_l .

The dispersion force can be written as the derivative of the interaction potential, Φ , with respect to the interparticle distance, h , (surface to surface):

$$F \cong \frac{d\Phi}{dh} = -A_{(h)} \frac{dH_{(a_k, a_l, h)}}{dh} \quad (1)$$

where A is the Hamaker constant and H a geometric factor [2]:

$$H_{(a_k, a_l, h)} = \frac{1}{6} \left(\frac{2a_k a_l}{2(a_k + a_l)h + h^2} + \frac{2a_k a_l}{4a_k a_l + 2(a_k + a_l)h + h^2} + \ln \left(\frac{2(a_k + a_l)h + h^2}{4a_k a_l + 2(a_k + a_l)h + h^2} \right) \right) \quad (2)$$

Also in the particle size range of interest for cement suspensions (0.4 μm to 50 μm) $a \gg h$ which reduces (2) to:

$$F_{(a_k, a_l, h)} = -\frac{A_{(h)}}{6} \left(\frac{-\bar{a}}{2h^2} + \frac{-1}{2\bar{a}} + \frac{1}{h} \right) \quad (3)$$

With $\bar{a} = \frac{2a_k a_l}{a_k + a_l}$

Further for small separations, this simplifies to :

$$F_{(a_k, a_l, h)} \cong -A_{(h)} \frac{\bar{a}}{12h^2} \quad (4)$$

Flatt [5] showed that the final approximation of equation 4 gives precision better than 20% if the maximum interparticle force is found at separation distances less than 45 nm.

Reliable Hamaker constants are essential if interparticle potentials are going to help us predict the yield stress or rheological behaviour of cement dispersions. The Hamaker constant used needs to be corrected for screening and retardation because of the high ionic concentration generally found in cement suspensions. Reliable dielectric data for cement components are not yet available although Sakai and Daimon [7] give a value of a non-retarded, non-screened Hamaker constant for tricalcium silicate, C_3S , a major component of Portland cements of 4.55×10^{-6} J/mol. This value was not obtained using recent dielectric data of water. In several studies on the evaluation of superplasticizer adsorption and dispersion, Flatt et al [8-10] have shown that MgO is a good model non-reactive substitute for Portland cement suspensions. Using the same dielectric data for water as Sakai and Daimon [7], they calculate for MgO a non-retarded and non-screened Hamaker constant of 4.2×10^{-6} J/mol. Since the values for MgO and C_3S are so close, MgO seems to be an acceptable model for calculating the retarded and screened dispersion forces. An effective Hamaker constant, which takes into consideration these effects, has been estimated by Flatt [5] and has been used in this work for Portland cement dispersions.

3.2 Electrostatic forces

The relative importance of the electrostatic contribution to cement dispersion is currently under much debate. One aspect of this topic recently explored by Flatt and Bowen [11] is how the non-ideal electrolyte found in cement suspensions affects the simplified Debye-Hückel approximation for evaluation of electrostatic repulsion. They show that the non-ideality of the cement pore solution can be taken into account based on solubility equilibria of the possible ionic species present in typical cement suspensions. By replacing the normally assumed symmetric electrolyte (1:1, 2:2, or 3:3) with a non-integer symmetric electrolyte, the simple Debye-Hückel approach has been shown to remain valid for negative potentials up to around -30 mV. The repulsive electrostatic force between spheres maintaining an identical and constant potential upon approach can therefore be written as:

$$F_{ES} \cong -2\pi\epsilon\epsilon_0\bar{a}\psi^2 \frac{\kappa e^{-\kappa h}}{(1 + e^{-\kappa h})} \quad (5)$$

With ϵ the relative dielectric constant for water, ϵ_0 the permittivity of vacuum, and κ^{-1} the Debye length, given by:

$$\kappa^{-1} = \sqrt{\frac{\epsilon\epsilon_0 k_B T}{2e^2 z_+^2 n_+^b}} \quad (6)$$

Where n_+^b is the concentration of species k in the bulk, z_+ the charge of the equivalent symmetric electrolyte, e the electronic charge, k_B is the Boltzmann constant and T the temperature in Kelvin.

One of the problems in calculating this force is the evaluation of the surface potential ψ . This is the potential at the outer boundary of the Stern layer, which is the layer in which ions are linked to the surface and not influenced by Brownian motion. Often, one uses the experimentally determined zeta potential, which is the potential at a shear plane. This plane is situated somewhat farther from the surface than the Stern plane. So, it leads to an under-evaluation of the electrostatic force. In this study, the charge is induced by adsorption of ionic polymers. Zeta potential measurements are based on relative motion between particles and the surrounding fluid. This motion may compress the layer of adsorbed polymers, thus modifying the distance at which the potential might be measured. De Gennes [12] states that the hydrodynamic layer thickness scales in the same way as the adsorbed layer thickness. He mentions that this is confirmed by experimental data, though in some cases the hydrodynamic layer might be even larger.

This results because only a couple protruding polymer chains suffice to strongly alter the hydrodynamic behaviour around the particle, but have much less impact on the average layer thickness that matters most as far as interparticle forces are concerned. Nevertheless, we will consider that during zeta potential measurements, hydrodynamic forces are not sufficient to significantly compress the adsorbed layer and the plane of origin of electrostatic forces can be placed at the surface of the adsorbed layer. The electrostatic force can then be represented by equation 7, integrating the adsorbed layer thickness L :

$$F_{ES} = -2\pi\epsilon\epsilon_0\bar{a}\psi^2 \frac{\kappa e^{-\kappa(h-2L)}}{(1 + e^{-\kappa(h-2L)})} \quad (7)$$

3.3 Steric force

The adsorption of superplasticizer at the cement particle-water interface not only induces a surface charge but gives an adsorbed polymer layer with a certain configuration, density and thickness. As particles in suspension approach one another a steric repulsive force acts as soon as the adsorbed layers begin to overlap. As the layers overlap they can be compressed and the repulsive force increases strongly and reaches infinity as the maximum compression is reached. The functionality of this increase is highly dependent on the adsorption conformation of the polymer. The adsorption configurations can be many and complex, but three modes useful for the evaluation of interparticle forces can be described as flat (pancake), intermediate (mushroom) and end-on (brush) [12]. Portland cements usually have a weakly positive surface charge whereas the superplasticizers used are negatively charged at the high pHs found in cement suspensions. Also the molar mass, M_w , are relatively high at around 25-40,000 g/mol it is unlikely that the molecules will adsorb in either the totally flat pancake or end-on brush-like mode. We consider that our suspensions will lead to a mushroom-type conformation. For such adsorption modes, the scaling theory developed by de Gennes [12] can be used to calculate the steric force [13] as follows:

$$F_{Ste} = \bar{a} \frac{6\pi k_B T}{5s^2} \left[\left(\frac{2L}{h} \right)^{5/3} - 1 \right] \quad (8)$$

Where s is the distance between the centres of two neighbouring mushrooms. L is the maximum length extending into the solvent.

3.4 Total interaction

The equations above indicate that at small separations, dispersion, electrostatic and steric forces are all proportional to the interaction radius \bar{a} for two dissimilar spheres. This can be written:

$$G = \frac{F}{\bar{a}} = \frac{F_{vdW} + F_{ES} + F_{Ste}}{\bar{a}} = -\frac{A_{eff}(h)}{12h^2} + 2\pi\epsilon\epsilon_0\kappa\psi^2 \frac{\kappa e^{-\kappa(h-2\lambda)}}{(1 + e^{-\kappa(h-2\lambda)})} + \frac{6\pi k_B T}{5s^2} \left[\left(\frac{2L}{h} \right)^{5/3} - 1 \right] \quad (9)$$

This is illustrated in Figure 1 and 2 for a model MgO powder with the key parameters being the adsorbed layer thickness and induced surface charge linked to the superplasticiser adsorption. The non-ideality of the pore solution is taken into account by the equivalent symmetric electrolyte. The positive values indicate repulsion and negative values attraction. In absence of electrostatic repulsion this maximum is reached for separations of about twice the maximum length of the layer extending from the surface into the solvent. When electrostatic effects come into play, the point of maximum repulsion is beyond this distance. There is a clear steric effect which can be significantly complemented by electrostatic repulsion, provided one can place the potential at the outer bound of the adsorbed layer [6].

The large sizes of cement particles (1 to 100 μm) means that shear forces largely dominate over Brownian motion, even at low shear rates. We therefore need to calculate the maximum attractive force between two particles in order to decide whether shear is capable of separating them.

4. YIELD STRESS EVALUATION

The evaluation of rheological properties with respect to interparticles forces of various ceramic systems shows, in general, only good qualitative agreement [4, 14]. This is partly because interparticle forces are a function of particle size and particle distribution. Most calculations are

limited to using some average diameter [4, 15]. The maximum solid loading of stable ceramic suspensions can approach the maximum packing fraction (65 % volume solids) while remaining a fluid suspension. Attractive non-flowing networks can be formed with cement pastes at much lower volume fractions, around 48 % solid loading ($w/c = 0.35$). It is why cement suspensions behave in general like a Bingham's fluid, i.e. with a yield stress. With superplasticizers, it is possible to suppress totally this yield stress and the paste behaves like a Newtonian fluid [16]. This is due to the fact that a fraction of water is trapped between agglomerated cement particles. So, a cement suspension is in fact like a cluster of agglomerates which have a higher effective volume than the real solid volume present in order to allow the cement suspension to flow. This effective volume has to be decreased by breaking apart a certain fraction of this attractive network.

Figure 1. Normalised interparticle force G as a function of separation for three different potentials and an adsorbed layer thickness of 1 nm. Positive values indicate repulsion and negative value attraction.

A strategy has been developed to evaluate what decrease in effective volume fraction of solids would be needed so that the attractive cement particle network begins to flow. It is based on considering all the interacting particles by pairs. Each pair is considered to contribute to an increase in effective volume fraction of solids in suspension, in a way that is directly related to the size of the interacting particles. At a specified shear only some of those pairs can be moved or broken apart and this again depends on the size of the particles. In fact for each class of sizes of interacting particles we calculate in the following section the probability of bond breaking.

The problem we face is to define what exactly is the increase in effective volume fraction that each interaction causes. We have chosen to use a truncated cone tangent to both spherical particles as indicated in Figure 3(a). The additional volume is denoted $\Delta V_{k,l}$. The dispersion of doublets with different individual particle sizes will not have the same effect on the rheology, as each individual pair will have different effective to real volumes (Figure 3(b)).

Figure 2. Normalised interparticle force G as a function of separation for three different potentials and an adsorbed layer thickness of 3 nm. Positive values indicate repulsion and negative value attraction.

Figure 3. (a) Truncated cone used to determine the effective volume change due to a doublet (b) different pairs of doublets illustrating the different effective volumes for different pairs.

This volume is given for two unequal spheres by:

$$\Delta V_{k,l} = \frac{2\pi}{3} \hat{a}^2 (4\hat{a} - \bar{a}) \quad (10)$$

The interparticle forces can be used with the effective volume freed on agglomerate disruption to predict a yield stress for the attractive network. A simple method would be to take the average coordination number, the average interparticle interaction force, using the mean harmonic diameter

$\langle \bar{a} \rangle$, then use the number of interactions per unit volume to calculate the force necessary to break the network, similarly to the approach proposed by Kapur et al [17]. This has been done for a gamma alumina suspension [18] and the average coordination number resulting from a numerical particle packing model using measured PSDs [19] gave very coherent results. Similar coordination numbers to those from the models of Goto, and Iwata & Homma, cited by Kapur et al [17] have been obtained. It would be interesting to take this approach further and perhaps use analytical models related to the particle size distribution to provide an average coordination number and harmonic average.

The approach we outline here follows that by Flatt [20]. It consists in carrying out a force balance between shear forces and interparticle forces to determine the fraction of unbroken doublets at a given shear τ .

$$f_{k,l}(G/\tau) = 1 - \frac{\int_0^{\pi/2} 2 \arctan \left\{ \left(\frac{G}{\tau} \right)^{-1} \frac{\pi(a_k^2 + a_l^2)}{3\bar{a}} \frac{1}{\cos \varphi} \right\} d\varphi}{\pi \int_0^{\pi/2} d\varphi} \quad (11)$$

where a_k and a_l are the radii of the pair of interacting particles, τ is the yield stress.

Summation over all the interacting particles allows calculation of the additional volume fraction due to particles that cannot be separated by the applied shear force:

$$\Delta\Theta = \frac{\sum_k \sum_{l \geq k} n_{k,l} f_{k,l} \Delta V_{k,l}}{d^3} \quad (12)$$

Where d is the size of the box in which a given number of particles was placed to determine the number contacts $n_{k,l}$ between particles of sizes a_k and a_l .

In Figure 4, we plot for the same cement and w/c, the expected yield stress versus the thickness of the adsorbed layer. This figure was constructed for a particular cement at a w/c of 0.35. For the particle size distribution of that cement, the loose packing volume fraction is 65%. Since the true volume fraction is 48%, the difference of 17% can be given from unbroken interparticle bonds and would give $G/\tau = 1.7 \mu\text{m}$. This additional volume fraction is plotted against the G/τ in Figure 5.

The sharp rise around 1.5 nm, corresponds to a layer thickness limit at the maximum attractive force at maximum compression of the adsorbed layers. The reason is that the combined effect of charge and steric hindrance as described in Eq. (8) are not sufficient to overcome van der Waals force and particles get pulled together until the layers cannot compress any further. In the case we are illustrating, it is obvious that a charge of +/- 10 mV at the exterior of an adsorbed layer will have important rheological consequences if that layer is smaller than 5 nm. Beyond that the effect is minor.

Figure 4. Expected yield stress of cement with specified PSD, for $w/c = 0.35$. The maximum compressibility is considered to be 0.7 nm.

Figure 5. Relation between the interparticle force parameter G normalised by shear stress and the additional volume fraction expected to result from unbroken interparticle bonds.

The approach we have presented bears the important limitation in the determination of number of contacts n_k , between particles of different sizes [20]. It also uses a semi-empirical approach to estimating the increase in volume fraction from non-dispersed particles. However, it leads to results that are coherent with the experimental observation that yield stresses of about 5-10 Pa are observed for polymers expected to have adsorbed layer thicknesses of the order of 2 nm for a 10 mV potential.

Future prospects would be to further investigate the various parameters, which are still uncertain to some degree, in the evaluation of the interparticle forces and need to be more accurately established. These include more reliable zeta potential measurements, maximum allowable effective volume fraction increase due to a non-dispersed doublet, the adsorbed polymer layer thickness, the plane of origin for electrostatic forces (placed at the surface of the adsorbed layer for the above calculations, but placed half way to the surface by Lewis et al. [4]), hydrodynamic forces which are expected to oppose dispersion, better Hamaker constants for the different cement phases (calculations done presently with MgO data, the fact that cement particles are multiphase and non-spherical).

5. CONCLUSIONS

It has been shown how colloidal theories can be applied to the very complex system of cement suspensions, though cement particles are not in the range of colloids. The interparticle forces, electrostatic, steric and dispersion, that act on cement particles were all found to scale on the harmonic diameter, $\bar{a} = \frac{2a_k a_l}{a_k + a_l}$, for un-equal spheres. Several parameters in the calculation of the interparticle force calculation have been reviewed and the importance of a small charge induced by superplasticiser adsorption shown to be important.

The particle size distribution can be taken into account by using a particle packing model which provides the harmonic diameter distribution of randomly packed cement particles. The possibility of taking into account the particle size distribution is an important step forward as it has often been cited as one of the stumbling blocks limiting the use of interparticle interaction energies for quantitative assessment of concentrated suspension rheology. The approach presented leads to reasonable coherence between molecular properties of dispersants, particle size distribution and measure yield stress. The limitations within this approach must be dealt with in the future to reach a fully consistent quantitative picture of how forces on the nano-level control in a predictable way the macroscopic rheological behaviour.

Robert J. Flatt

Robert Flatt received his diploma (1994) in chemical engineering and his PhD degree (1999) in materials science, both from the Swiss Federal Institute of Technology in Lausanne. He then spent 2.5 years as a research associate at Princeton University. Since May 2002, he is in charge of research on mineral/organic interactions at Sika A.G. in the division of Corporate Research and Analytics. His past research involved modelling the rheology of superplasticized cement suspensions, developing tailored mortars for the restoration of roman mosaics, identifying key factors in crystallization damage of porous materials and developing particle modified consolidants for the restoration of stone works.

THE DEVELOPMENT OF BLENDED SUPPLEMENTARY CEMENTING MATERIALS CONSISTING OF HIGH AND LOW CALCIUM FLY ASHES

ABSTRACT

For overcoming the problems associated with the use of each type of fly ash (high and low calcium) in cementitious systems (low early strength, insufficient chemical resistance, expansion, etc), a development of new supplementary cementing materials consisting of blends of high and low-calcium fly ashes in various proportions was examined. Developing such blended pozzolans will result in coping with the mechanical and durability problems arising from each of the two types when these are added separately into cementitious systems and concrete.

The blended pozzolans resulted from the mixing of a low calcium fly ash with a high calcium fly ash, both generated in great quantities in Greece. The fly ashes were selected to cover a range of active silica and calcium oxide contents. Various mix proportions were adopted in order to find an optimum composition for the new pozzolan. The efficacy of the new combined supplementary material was examined in terms of active silica content, compressive strength and efficiency factor from the mechanical properties perspective.

Identification of hydration products was based on XR Diffraction of the corresponding pastes, while microstructure development was monitored by means of a SEM. Comparison between the overall performance of the new combined fly ash systems and the initial fly ashes was attempted in order to explain individual contributions and detect possible synergistic effects related to the different fly ashes used.

1. INTRODUCTION

Acute environmental problems created by the irresponsible disposal of fly ash [1] and the anticipation that sustainability [2] in the construction sector can only be achieved via the increased utilization of such by-products, has led to an ongoing research for the full exploration of their properties. The majority of the fly ashes generated in Greece possess significant lime contents, being therefore characterized as high-calcium ashes. A respectable amount of low-lime fly ashes is also produced contributing to the great diversity of this material in the local scene.

Despite the fact that advantages of both types of fly ashes are fairly well established, certain shortfalls that accompany each of them, especially when these are used as cement replacements, contribute to the skepticism with which they are still being handled by a part of the industry. In recognition of the significant differences in behaviour of the two types of fly ashes, Canadian Standards Association (CSA) recently revised the specification for fly ashes categorization, dividing them into three classes depending on their calcium content [3]. This is a classification scheme that is expected to be implemented in the national standards of other countries producing different types of fly ashes during the forthcoming years.

In the literature there is plentiful information regarding the distinctions in the chemical and mineralogical composition between low and high calcium fly ashes and the effect that these factors have on their reactivity. It is low-calcium fly ashes for example that react slower, especially during the early stages of hardening, mainly due to the higher presence of crystalline phases, which are considered chemically inert in concrete [4]. High calcium fly ashes on the other hand provide better early age strengths as a result of the cementitious compounds they possess. It is believed [3] that calcium substitution in the glass phase is generally increasing the reactivity of high-lime fly ashes providing for the formation of the calcium-silicate and calcium-aluminate phases in the absence of an external source of lime. It should be however pointed out that class C fly ashes differ from the class F ashes not only in that they contain more lime, but also the lime depolymerized glass phase [5].

Despite their increased reactivity and lower sensitivity to inadequate curing [6], high-lime fly ashes are generally less efficient in suppressing expansion due to ASR [7] and sulphate attack [8]. On the other hand, ashes of lower lime contents provide better resistance to ASR and sulphate attack and furthermore they usually guarantee better long term performance. Concerning additional durability properties, such as carbonation and chloride penetration [9,10], both low and high calcium ashes seem to have a similar beneficial effect, with the latter presenting a slightly better resistance.

To deal with the mutual shortcomings of each type of fly ash, the majority of the researchers have attempted to produce ternary blends by introducing in the fly ash/cement matrix an additional highly reactive pozzolanic material, such as silica fume [11] and metakaolin [12]. These policies however in most cases result in substantial cost increases putting obstacles to their wider acceptance as a routine tactic in the concrete sector. Keeping this in perspective, and to additionally control the rate of the hydration reaction, Naik et al. [13] prepared several mixtures of blends of class F and class C ashes. The constructed blends, that occupied 40% of the total cementitious material, showed either comparable or better results (in terms of both mechanical and durability properties) than either the reference mixture or mixture containing the class C fly ash only.

In the present study, new supplementary cementing materials (SCM) were prepared by mixing two types of fly ashes in several proportions. The main objective was to demonstrate that contributions of each type of fly ash in concrete could compensate for the handicaps of the other, while maintaining the production cost at low levels. The efficiency of the new products was examined in comparison with both the control mixture and the corresponding mixtures containing each type of fly ash.

2. EXPERIMENTATION

2.1 Materials

Two different fly ashes, a high-calcium (designated as T_f) from Ptolemais region, and a low-calcium one (T_m) from Megalopolis, representing the diversity of fly ashes derived in Greek power plants were used in the present work. A normal setting Portland cement was used (CEM I 42.5N according to European Standard EN 197-1) during the construction of the mortar and paste specimens. The chemical composition both for the fly ashes and the cement used are given in Table 1.

2.2 Preparation of mortars and pastes

2.2.1 Mixing proportions and construction of new blends

Both fly ashes were ground prior to use in a lab ball mill in order to obtain ashes of similar fineness. The requirement set during grinding was that 80% of the particles passed through the 45 μm sieve. Grinding of T_m fly ash proved to be more energy demanding since it consisted of more coarse particles in the as-received form. Therefore prolonged grinding was implemented in that case.

When the ashes were brought to the required fineness, they were mixed in a rotating blender until homogeneity of the new blend was achieved. The blended fly ash mixtures were prepared by using various dosages of the high (T_f) and low (T_m) fly ashes. The proportions applied were 75% T_f and 25% T_m (blend designated as T_1), 50% T_f and 50% T_m (for blend T_2) and 25% T_f and 75% T_m for the mix designated as T_3 . The chemical composition of the new blends is given also in Table 1. An initial observation is that the blending procedure had a beneficial effect on the sulfate content of the blended fly ashes, as these either met the requirements stated in EN 450-1 ‘Fly ash for concrete’ [14], or in the worst case (T_1) approached conformation with those.

Table 1. Chemical composition of raw materials (mass %)

	SiO ₂	Si _{re} *	CaO	Al ₂ O ₃	Fe ₂ O ₃	MgO	SO ₃	Na ₂ O	K ₂ O
CEM I	20.28		65.01	4.75	3.76	1.61	2.55	0.17	0.35
T_f	36.92	29.13	29.79	13.50	7.06	2.69	5.10	0.92	0.5
T_m	51.36	31.36	13.80	16.73	8.75	2.26	1.49	0.77	1.52
T_1	40.38	29.60	24.89	14.65	7.50	2.56	4.02	0.88	0.75
T_2	44.08	30.36	21.50	15.70	8.75	2.45	3.18	0.81	0.93
T_3	48.00	32.02	17.96	15.92	8.92	2.36	2.39	0.78	1.26

* The method specified in European Standard EN 450-1 was followed for estimating the reactive silica content (Si_{re}) of fly ashes.

2.2.2 Curing procedures and compression test

In order to study the compressive strength, mortar mixes with the new blends were designed by adopting cementitious material-to-sand ratio of 1:3, water to binder ratio (w/b) of 0.5 and 10-30% by weight cement replacement. Keeping the w/b ratio constant, cement mortar without any fly ash or activator was prepared as the control one. Additionally, one mix with no fly ash addition (control specimen) and two mortars incorporating the two initial fly ashes (also replacing 10-30% by weight cement), were prepared for comparison purposes.

The dry mortars were mixed in a mixer machine and then water was added. After sufficient mixing, they were cast in 4x4x16 cm mortar prisms and vibrated for 20 sec on a vibration table. The molds were stripped after 24 h, and the specimens were immersed in lime-saturated water at 20°C, until testing. The testing ages were 2, 7, 28, and 90 days. For each age, two specimens of each mixture were tested for compressive strength and the mean value of these measurements is reported.

Pastes were prepared using a similar procedure, adopting a representative 20% cement replacement at the same w/b ratio and curing under water at 23°C, in order to monitor the hydration process of the constructed systems. At the dates of testing, the samples were fractured into pieces. The hydration was stopped with the addition of acetone and diethylethere followed by drying until constant weight in a vacuum pump. Finally, the specimens were placed into polypropylene bags and stored in a dryer until they were tested.

2.3 Efficiency factors

The concept of the efficiency factor (or *k-value* according to EN 206-1) has been introduced as a way to predict the effect of fly ashes (and other supplementary cementing materials) on the compressive strength of Portland cement systems that incorporate them. In other words, the efficiency factor is defined as the part of the fly ash, which can be considered as equivalent to Portland cement, having the same properties as the concrete without fly ash (obviously $k=1$ for Portland cement) [15]. In this work, the efficiency factors were determined in order to draw conclusions regarding the effectiveness of each new blended cementing material.

2.4 Evaluation of the Hydration Process

XRD patterns of the hydrated samples were recorded using a Siemens D 500 X-ray diffractometer (CuK_α radiation, 40KV, 30mA) in a scanning range of 5 to 65° in 2θ scale. The testing rate that was applied was $0.02^\circ/\text{min}$ for all specimens. The identification of the products was carried out by using a Diffrac-At Database. A XL 30 Philips ESEM equipped with an energy-dispersive X-ray analyzer (EDAX) was used both for the microstructure and quantitative elemental analysis of the hydration products.

3. RESULTS AND DISCUSSION

3.1 Compression test

The results of the compression test in the case of 20% cement replacement are presented in Figure 1. The compressive strength values for the control specimen and the mixtures incorporating the two initial ashes are plotted against the values of the blended fly ash specimens.

Figure 1. Compressive strengths with hydration age for 20% cement replacement

Figure 2. Compressive strengths with hydration age for 30% cement replacement

It is easily visible that during the first month of the hardening process, the control specimen (no fly ash addition) exhibited the highest value of almost all the mixtures tested. This is consistent with research establishments regarding the relatively slow evolution of the pozzolanic reaction, which mainly determines the strength development in fly ash-cement systems. The only mixture that presents higher strength value than the control after 4 weeks of hydration is T_2 , constructed with 50% of class C T_f and 50% of class F T_m ashes. Somewhat surprisingly at the same age the strength values of the ashes that participate in the blend are noticeably lower. This is clearly an indication that a synergistic effect between the two ashes has taken place leading to a quicker initiation of the pozzolanic action.

After 2 days of hydration it is high lime fly ash T_f that exhibits the lowest strength value. This was unexpected since generally high calcium ashes behave better at early ages as a result of the hydration of their cementitious compounds. On the other hand, despite its low reactivity at this stage, low-lime ash T_m contributes substantially to the strength of the T_2 blend. Since the initial ashes were both ground to obtain similar finenesses, the superior performance of T_m ash cannot be attributed to that factor. However, the beneficial action of the filler effect [16] cannot be excluded, especially when the grain size distribution of T_m ash is improved due to prolonged grinding. It is clear that a small replacement (25%) of T_f ash by T_m ash at this age (blend T_3) induces positive consequences for the mix. However, the most efficient mix (T_2) contains respectable amounts of high-lime ash indicating that the synergy between the two different ashes occurs even at early ages.

The hydration of the cementitious compounds of high-lime ash T_f seems to occur during the next 5 days, accounting for the remarkable strength gain evident after 7 days of hydration. At that stage, the contribution of T_f ash in the blends is critical, since those blends incorporating over 50% T_f (T_1 and T_2) outperformed the ones with a limited T_f participation (T_3).

At the end of the first month of the hardening process, T_2 blend has exceeded the strength values of both the control mixture and the individual ashes, whilst the other blended specimens are not gaining substantial strength, remaining lower than the individual ashes and the reference mixture. On the contrary, during the forthcoming months (at 90 days), the compression test results exhibited excellent strength values for all the blended fly ash specimens compared to the control specimen. The fact that at the same age the ashes that consist the blends are not performing evenly, provides a guidepost that at elevated ages even small contributions from each fly ash are effective in producing superior fly ash systems. The incorporation of a different type of fly ash in each constructed blend obviously did much to offset the synergetic effect that was also detected in previous hydration stages.

At increased cement replacement (Fig. 2) the situation differs substantially. Despite the fact that synergistic effects are still detected, it is clear that the individual ashes used as well as their intermixtures retard the strength development, especially during the early ages. This is mainly associated with the increased cement content substituted in that case and the well-established incompetence of fly ashes to act drastically from the beginning of the hydration period. The initial ashes (T_f and T_m) are presenting a similar behavior to the previous replacement dosage, but the most efficient blend is the one with substantial participation of low-lime T_m (blend T_3). It is possible that a small participation of high-lime ash T_f reduced the period before the onset of the pozzolanic reaction leading to a notable strength increase at 28 days.

After 3 months, a dramatic improvement in the strength performance of all the examined blends occurs. This is substantiated by the fact that T_3 blend outperforms the no-fly ash mixture at this age, whilst T_1 and T_2 blends only fall slightly short of the control specimen. Especially noticeable is the fact that in the systems with an appreciable cement replacement, the strength of the blended fly ash mixtures is proportional to their active silica content from 7 days forward. This becomes even more pronounced after the first month of hardening, where the noteworthy strength improvement of the T_3 blend over the control specimen is the result of its high active silica, which binds CH forming accessory pozzolanic C-S-H. This is in agreement with the findings of Antiohos et al. [17], who observed that the role of reactive silica in the strength development of fly ash-cement systems becomes predominant after the first month of the hydration process.

To sum up, it must be pointed out that none of the constructed blended fly ash systems at any age presented the worst behavior. Generally, it can be deduced that at moderate fly ash additions, the blend that incorporated equal amounts of two different fly ashes exhibited the best behavior at all ages of hydration. On the contrary, when the fly ash contribution became more substantial (30% by weight cement replacement), the role of soluble silica in each fly ash blend was highlighted, providing for the strength superiority of T_3 blend at the age of 28 days and beyond.

3.2 Efficiency factors

For estimating the k -values, the procedure described by Papadakis et al. [18] was followed. In the case of mortars and concrete that incorporate supplementary cementing materials, the k -value derives from the following expression for the compressive strength (f_c) measured for the constructed systems:

$$f_c = K \left(\frac{1}{W / (C + kP)} - a \right) \quad (1)$$

where K is a parameter depending on the cement type (here 38,8MPa), C and P are the cement and fly ash contents respectively in the mortar (kg/m^3), W is the water content (kg/m^3) kept constant in all the mixes and α a parameter depending mainly on time and curing. Using this equation, the measured values of the compressive strength given in Figures 1 and 2, the k -values for the new blended SCM of the present work were calculated and are presented in Table 2.

Table 2. Efficiency factors (k -values) for initial and blended fly ashes
 k -values

SCM dosage (% by cement weight)										
20						30				
Age (days)	T_f	T_m	T_1	T_2	T_3	T_f	T_m	T_1	T_2	T_3
2	0.67	0.81	0.72	0.82	0.80	0.63	0.71	0.65	0.71	0.70
7	0.92	0.72	0.89	0.94	0.84	0.73	0.65	0.72	0.76	0.78
28	0.92	0.88	0.75	1.09	0.85	0.76	0.78	0.76	0.85	0.92
90	0.99	0.97	1.12	1.15	1.06	0.99	0.82	0.91	0.95	1.03

In previous attempts [19] dealing with Greek fly ashes the reported k -values were around unity during the early ages and they progressively exceed it as the hydration procedure evolved. This means that up to a certain level, those fly ashes could easily substitute, equivalently, for Portland cement. However, those values were calculated for a moderate level of cement replacement (i.e. 20% by weight). For a similar pozzolan addition applied here, the results given in Table 2 verify the aforementioned conclusions. Both initial ashes (T_f and T_m) have a k -value less than 1 at 7 days, but afterwards as fly ash is involved in the pozzolanic reactions, they reach unity. The beneficial role of the intermixing procedure is again highlighted through the concept of the efficiency factor. None of the constructed fly ash blends presents the smallest value during the early stages of hydration. On the contrary, the blends present decent early-age k -values and at 90 days they all exceed the corresponding values of the initial ashes used. It is of special importance to note that the k -value of the blend consisting of equal amounts of the initial fly ashes (T_2) is very close to unity after only 7 days of hydration and has significantly exceeded unity 3 weeks later. Furthermore, a small incorporation of a class F fly ash in a matrix redundant with class C ash (case of T_1 blend) can assist the strength development of such a system especially after the first month of hydration. This is clear from the dramatic increase of the k -value of the aforementioned blend during the last two months of the procedure.

When the replacement dosage increases (i.e. 30%), the k -values of all systems are normally diminished. Co-operation between initial fly ashes in the blends is still efficacious, providing k -values that are comparable even with the ones that the initial ashes exhibited at a lower replacement level during the early stages of hydration. As the hydration progresses, the blends are tardily reaching unity due to pozzolanic reaction taking place. Blend T_3 (with surplus of low-lime T_m) takes over from T_2 and performs better especially after the first week, reaching an impressive 1.03 factor at the end of the hydration period. This manifests the ability of blended fly ash systems owing appropriate active silica contents to substitute equal amounts of Portland cement even at high cement replacements, providing final products of the same quality.

3.3 Identification of hydration products

For investigating the role of the newly formed hydration products in the performance of the constructed blends, their XRD patterns were examined in comparison with the corresponding ones of the initial ashes at the same testing ages. Indicative images for the early (7 days) and later (90 days) stages of hydration are given in Figures 3 and 4 respectively.

Figure 3. XRD patterns of hydrated pastes after 7 days of hydration.

The following notations were used for the various minerals identified: Et: ettringite, AF_m: monosulphate, P: portlandite, Br: Brownmillerite, Q: quartz, CAH: C₄AH₁₃, L: lime, c: calcite, G: gypsum, A: alite, B: belite.

Figure 3 shows the XRD patterns of the hardened fly ash-cement pastes at 7 days. Main hydration products observed for all specimens at this age were portlandite, AF_t, and AF_m. Especially for low-lime T_m ash and given that its SO₃ content is relatively low (1.49 percent), the unexpected intensification of the AF_m peaks can be attributed to the formation of C₄AH₁₃ instead of AF_m, because AF_m and C₄AH₁₃ have very similar diffraction peaks. Accessory differences between the initial fly ashes (such as variable intensity in the quartz and gypsum peaks) are mainly due to differences in their mineralogy. However, no other significant differences could be detected in the nature of the hydration products. The contribution of blended ashes seems to have no beneficial effect on the reaction rate of the minerals contained in the clinker. Moreover, portlandite is continuously produced in all samples, indicating the absence of pozzolanic reaction at such an early age. An important observation, that possibly denotes that synergetic action between the utilized ashes is not in full progress yet, is that the intensity of the various peaks is highly depended on the participating percentage of each ash in the blends. For example, when the contribution of T_f ash was increased in the blends (from 50% in T₂ to 75% in T₁ blend) an intensification of the AF_t and portlandite peaks was observed as a result of the excess of free lime and sulfur contained in this ash. In contrast, the intensity of crystalline silica (Quartz) diminished due to the limited T_m content in those blends.

Figure 4. XRD patterns of hydrated pastes after 90 days of hydration.

The following notations were used for the various minerals identified: Et: ettringite, AF_m : monosulphate,

P: portlandite, Q: quartz, Cc: $C_4A \underline{C} H_{11}$, c: calcite, A: alite, B: belite.

Three months after the start of the curing process, some changes in the XRD patterns of the specimens (Fig. 4) are easily detectable. The decrease of the portlandite peaks for instance, indicates the significant progress of the pozzolanic reaction mainly expressed as the consumption of crystalline CH by active silica of fly ashes. Carbonate hydrates are also appearing in both blended samples after 90 days. It is possible that a nontrivial part of CH was carbonated. Calcium silicate peaks are getting relatively smaller with hydration age, especially in the case of T_2 blend. However, the presence of alite and belite after 90 days indicates that the hydration of the two phases is not yet complete. Impressively, AF_t and AF_m peaks are not only increasingly generated, but contrary to what is stated in the literature [19] the AF_m peaks seem to grow independently of the AF_t ones. The fact that this phenomenon is more pronounced in the constructed blends constitutes an additional indication of the combined action of the initial ashes. The consistent production of pore-filling AF_t and AF_m phases, even at late stages, obviously contributes to the final strength of the blended systems.

3.4 ESEM and EDAX Examination

ESEM examination substantiated the results presented in the previous sections. Figures 5(a) and (b) depict the SEM images of the T_f and T_2 (the most effective) fly ash-cement systems respectively after 7 days curing. Despite the fact that some of the fly ash particles appear to be etched, or covered with hydration products, in both cases the majority retains its smooth shape indicating the absence of reaction. Voids visible in the images suggest that the systems are fairly porous.

When hydration progressed (28 days), the erosion of fly ash particles (fig. 5(c)) in T_2 blend has progressed dramatically, bringing about a breaking down of their glassy surface and release of additional active constituents inside the matrix. It is postulated that a substantial participation of a high-lime ash in the blend activated the ash particles in the matrix. A possible reason for that could be the high free lime contents of T_f ash that is easily dissolved from the outer shell of the glass, creating an excess of portlandite in the system.

Figure 5. ESEM images of initial and blended fly ash systems

The increase in the alkalinity of the system initiates the corrosion of the so far inert particles contained in the T_m ash [20]. Accordingly the period before the initiation of the pozzolanic reaction is notably diminished, leading with sufficient curing (at 90 days), to a more compact structure (fig. 5(d)). The evident decrease in the porosity of the system accounts for the strength superiority of the T_2 blend, especially after the first month of the hardening process.

4. CONCLUSIONS

The use of blends of high-calcium and low-calcium fly ash is an effective means for dealing with mutual shortcomings related to each type of fly ash. It was demonstrated that blends with equal contributions from each fly ash was found to be the most effective in terms of mechanical properties for moderate cement substitution, whilst at advanced replacements the intermixture possessing the highest active silica content shows supremacy at all hydration ages. The encouraging performance of the constructed supplementary cementing materials was mainly attributed to synergistic effects detected between the utilized ashes. While such composite cements are not a panacea for all concrete problems, they constitute a unique opportunity to produce concrete avoiding non environmental-friendly tactics with excessive cost.

ABSTRACT

A new kind of low-energy-belite cement has been synthesized by using, as raw material, two municipal solid waste incineration ashes (MSWIA). Mixtures were prepared in a proportion of 35.7% and 64.3% (by weight), respectively, to obtain a CaO/SiO₂ molar ratio of 2. To study the influence of temperature on the reactivity of cements, samples (synthesized from hydrothermal treatment, in water and KOH 0.5M, and then heated at 700, 800, 900 and 1000°C), were hydrated for 28 days at room temperature. During this hydration time, the combined water content was evaluated, from thermal analyses. The high reactivity was reached for the sample hydrothermally treated in KOH 0.5M and then heated at 800°C. This temperature is strongly lowered in comparison to 1450°C of traditional belite cement manufacture. The alkaline activation was corroborated from the mechanical strength results, which improved strongly in comparison to those obtained in samples hydrothermally treated in water.

1. INTRODUCTION

Among the reasons that are actually advancing the development of new materials, especially new kinds of cement, are their higher performances and the environmental restriction of their fabrication processes. In the case of Ordinary Portland Cement, the large amounts of CO₂ emission produced during its traditional fabrication, together with the large quantities of natural raw materials consumed, are stimulating investigations relating to new low-energy-belite cement, produced through environmentally friendly processes, which avoid or at least decrease the problems aforementioned.

The use of industrial waste and by-products as alternative secondary raw materials is increasing considerably. Numerous investigations are being carried out on the search for potential applications of MSWIR in the construction field. Nevertheless, expansion and high chloride contents are serious problems with these wastes, which must be treated prior to their incorporation into construction materials [1-3].

This paper is the continuation of an extensive investigation on the use of municipal solid waste incineration ash (MSWIA) as a raw material for synthesising reactive low energy cement [3-5]. The synthesis is based on previous studies, carried out in our laboratory, on the use of fly ash, from coal combustion, as raw materials for synthesising reactive belite cement [6-8]. The fabrication process is based on previous work by Jiang and Roy [9]. The process involves two sequential steps. The first step consists of the hydrothermal treatment of fly ash to form the hydrated precursors of the cement. Subsequent dehydration of these phases, by controlled heating, gives rise to the highly reactive belite phases. During the hydrothermal treatment (200°C for 4 hours and 1.24 MPa of

pressure) the fly ash pozzolanic reaction is strongly activated leading to hydraulic products: katoite ($\text{Ca}_3\text{Al}_2(\text{SiO}_4)(\text{OH})_8$) together with CSH gel ($\text{Ca}_{1.5}\text{SiO}_{3.5}\cdot x\text{H}_2\text{O}$) and $\alpha\text{-C}_2\text{SH}$, which are the precursors of the cement. In the second step the hydrates are calcined at 800°C .

In the present study, two types of municipal solid waste incineration ashes (MSWIA), one coming from fluidized bed combustion (called R1 in this paper) and the other from cleaning-gas devices (called R2 in this paper), were prepared in a proportion of 35.7% and 64.3% (by weight), respectively, to obtain a CaO/SiO_2 molar ratio of 2, similar to the Ca/Si molar ratio in low-energy-cement [6-8]. Cements were synthesised in a range of temperatures between 700°C and 900°C from the mixture of MSWIA aforementioned (R1+R2), which was previously activated by hydrothermal treatment at 200°C , in an alkaline KOH 0.5M solution.

To evaluate the effect of the alkaline solution, we compared the results with the behaviour of sample treated with water. An improvement in the value of compressive strength of the mixture with alkaline activation was observed. The precursor phases and the effect of alkaline activation were characterised, among others, by X-ray diffraction. The reactivity of cements was evaluated from their combined water contents (estimated from thermogravimetric curves (TG)) for a period of 28 days.

2. EXPERIMENTAL PROCEDURE

The chemical compositions of two municipal solid waste incineration ashes (MSWIA) (one coming from fluidized bed combustion (called R1) and the other from cleaning-gas devices (called R2)) are given in Table 1 and Figure 1.

Table 1. Chemical Composition of Original MSWIA (% by weight)

	R1	R2
CaO	21.9	44.9
SiO₂	34.1	11.4
Al₂O₃	19.3	11.3
Fe₂O₃	6.6	1.1
MgO	2.6	1.9
SO₃	3.3	3.9
Na₂O	2.1	2.1
K₂O	1.9	1.9
Cl⁻	3.6	13
Zn²⁺	0.41	0.36
Cd²⁺	0.0013	0.0017
Pb²⁺	0.13	0.38
LOI*	4.6	17.6
IR*	5.2	0.1
Density	2.59	2.55
Blaine (cm²/g)	2240	7275

* LOI= loss on ignition; IR= insoluble residue

The mixtures were prepared in a proportion of 35.7% and 64.3% (by weight), respectively, to obtain a CaO/SiO_2 molar ratio of 2.

The principal crystalline compounds detected in the starting MSWIA are: Halyte (NaCl), sylvite (KCl), $\text{CaCl}_2\cdot\text{Ca}(\text{OH})_2\cdot\text{H}_2\text{O}$ whose X-ray reflections are more intense for MSWIA coming from the cleaning-gas-device (R2) in comparison with those of R1; Portlandite ($\text{Ca}(\text{OH})_2$), anhydrite (CaSO_4), metallic aluminium and $\alpha\text{-SiO}_2$ are mainly detected in R1. Intense gehlenite (C_2AS) reflections appeared in both R1 and R2.

Figure 1. X-ray Diffraction Patterns of Original MSWIA: C calcite; Q α -quartz; P portlandite; G gehlenite; A Anhydrite; S sylvite; H hematite; Al metallic aluminium; H' halyte; \blacktriangle $\text{CaCl}_2 \cdot \text{Ca}(\text{OH})_2 \cdot \text{H}_2\text{O}$; \bullet C; $+$ Mg_2C_3

Alkaline solution (KOH 0.5M) and MSWIA (R1+R2) were mixed at an alkaline solution to R1+R2 ratio of 10. The mixture was maintained at room temperature for 24 hours to eliminate the H_2 gas, which is strongly formed from metallic aluminium dissolution. Thereafter, the alkaline mixture was hydrothermally treated at 200°C and 1.24 MPa steam-pressure for periods of 1h, 2h, 4h and 6h, where the precursors of cement were obtained. The dried solid was heated at a rate of 10°C/min. up to 600°C and at 5°C/min. from 600°C to 900°C.

Pastes of cements synthesised at 700°C, 800°C and 900°C were prepared at water to cement ratio of 0.8 to evaluate their hydraulic activity. The pastes were kept at >90% RH and 21°C \pm 2°C for a period of 28 days from mixing. The hydrothermal treatment was carried out with Parr Mod. 4522 pressure reactor equipment (1000 mL pump with split-ring closure and a PID Mod. 4842 temperature controller). The minor elements (Zn, Cd and Pb) were determined by Anodic Solution Voltamperometry (ASV) using a Mehtrom model 746.

The precursors and cement phases were characterised by X-ray diffraction (XRD), infrared spectroscopy (IR) and thermal analyses (TGA) [6]. X-ray diffraction (XRD) patterns were recorded with a diffractometer (Model PW-1730 Philips Research Laboratories, Eindhoven, The Netherlands) using a graphite monochromator and Cu $\text{K}\alpha_1$ radiation. IR study was carried out on a Perkin Elmer 783 instrument and KBr pellets containing 0.5% of sample. Thermal analyses were recorded with a Netzsch equipment with STA 409 simultaneous analysis system using 50 mg samples and a dynamic nitrogen stream (flow rate = 100 cm³/min) at a heating rate of 10°C/min.

For the mechanical study, several mortar samples of 5x5x5 cm were prepared using α -quartz. The sand-to-cement ratio was 3.0; the de-mineralized water-to-cement ratio was 0.9; 1 day after mixing, samples were demolded and stored at the temperature of 21 \pm 2°C and >90% rh for 28 days.

3. RESULTS AND DISCUSSION

3.1 Effect of Alkaline Activation and Hydrothermal Treatment

As was mentioned in previous work [6] after 1 hour to 6 hours of hydrothermal treatment no significant changes could be observed in the sample, independent of the medium: water or alkaline solution. In spite of this behaviour, significant differences could be observed in the sample treated at room temperature for 24h in KOH 0.5M solution (Figure 2):

Figure 2. Evolution of X-ray diffraction patterns of MSWIA mixture pre-treated with alkaline solution and with hydrothermal treatment: a) starting R1+R2; b) ambient (with 0.5M KOH) and c) after 1h 200°C (HT): K katoite; C calcite; ▼ $\text{CaCl}_2 \cdot \text{Ca}(\text{OH})_2 \cdot 2\text{H}_2\text{O}$; Q α -quartz; G gehlenite; A anhydrite; * $\text{Ca}_3\text{Al}_2(\text{SiO}_4, \text{CO}_3, \text{OH})_3$; Al metallic aluminium; S sylvite; H halite; E ettringite; F Friedel's salt

First, the original crystalline compounds disappeared, with the exception of portlandite and calcite, which increased owing to the alkaline solution decreasing the solubility of portlandite and favouring its carbonation; and, second, the formation of crystalline Friedel's salt ($\text{Ca}_4\text{Al}_2\text{O}_6\text{Cl}_2 \cdot 10\text{H}_2\text{O}$) and ettringite ($\text{Ca}_6\text{Al}_2(\text{SO}_4)_3(\text{OH})_{12} \cdot 26\text{H}_2\text{O}$) of the AFm and AFT structural families, respectively. These two compounds are formed from the dissolution metallic aluminium, which provides the aluminate ion together with the sulphate ion provided by anhydrite in the case of ettringite; and chloride ion provided by sylvite, halite and $\text{CaCl}_2 \cdot \text{Ca}(\text{OH})_2 \cdot \text{H}_2\text{O}$ in the case of Friedel's salt.

After 1h of hydrothermal treatment (Figure 2 (c)), ettringite, Friedel's salt and portlandite disappeared; and two types of katoites were formed: $\text{Ca}_3\text{Al}_2(\text{SiO}_4)(\text{OH})_8$ (C_3ASH_4) and $\text{Ca}_3\text{Al}_2(\text{SiO}_4, \text{CO}_3, \text{OH})_3$ ($\text{C}_3\text{AS}_3\text{c}_3\text{H}_{1.5}$). The presence of $\text{Ca}_{1.5}\text{SiO}_{3.5} \cdot x\text{H}_2\text{O}$ and $\alpha\text{-C}_2\text{SH}$ (their main X-ray reflections (at $2\theta = 29.4$) are overlapped with those of calcite), was confirmed from IR analyses by the strong absorption band at 950 cm^{-1} [6].

3.2 Evolution of Precursors with Heating Temperature

The dehydration of cement precursors appears in Figures 3 and 4 and was carried out by heating up to 900°C.

3.2.1 Samples Treated With Water

After HT (Figure 3(a)) intense X-ray reflections of katoite silication (C_3ASH_4) and $Ca_{1.5}SiO_{3.5}xH_2O$ (CSH gel) are formed. These phases have the property of incorporating a wide range of species via a solid solution mechanism, in the case of katoite silication, and via intercalation for CSH gel, providing, therefore, stabilisation mechanisms for minor toxic elements of MSWIA.

Figure 3. Evolution of Hydrated Precursors with Heating Temperature: K katoite; C calcite; M mayenite; \blacktriangle CaO; Q α -quartz; G gehlenite; α' - α'_L C_2S ; A anhydrite; g $Ca_{1.5}SiO_{3.5}.xH_2O$ (CSH gel).

Sample heated at 700°C (Figure 3(b)): the reflections of katoite: $Ca_3Al_2(SiO_4)(OH)_8$ and CSH gel disappeared, and those of calcite decreased. Gehlenite remains and new broad reflections began to be detected, which could be attributed to the α'_L - C_2S and mayenite ($C_{12}A_7$). At 800°C (Figure 3 (c)) the intensity of α'_L - C_2S and mayenite reflections increased; gehlenite reflections decrease; as expected by temperature, the calcite decreased significantly. After 900°C (Fig. 3(d)), reflections of α'_L - C_2S and mayenite were better defined, and gehlenite (C_2AS) increased; Calcium oxide is detected from 800°C.

The decrease of gehlenite reflections at 800°C together the amorphous halo observed between 31 and 34 of 2θ angular zone is, among others, the reason for the use of this sample as raw material for synthesising low-energy cement.

3.2.2 Samples Heated With Alkaline Solution

The evolution of samples heating from 700°C to 900°C (Figure 4), is very similar to the case of the sample with water. The principal differences are: (i) after hydrothermal treatment, two types of katoite: $Ca_3Al_2(SiO_4)(OH)_8$ and $Ca_3Al_2(SiO_4, CO_3, OH)_3$, are detected which disappeared with heating; (ii) after heating a new broad reflection began to be detected, which could be attributed to the α'_L - C_2S and mayenite ($C_{12}A_7$), (iii) a decrease of calcite reflections that disappeared totally after 700°C of heating. (iv) sample at 800°C presented an amorphous halo was between 31 and 34 of 2θ angular zone, higher than the case of water, which could be attributed to recently dehydrated phases and the intensity of α'_L - C_2S and mayenite reflections increased.

Figure 4. Evolution of Hydrated Precursors Activated with Heating Temperature: K katoite; C calcite; M mayenite; ▲ CaO; Q α -quartz; G gehlenite; α' - α' C_2S ; A anhydrite; * $Ca_3Al_2(SiO_4, CO_3, OH)_3$.

These results are very similar to those obtained when fly ash from coal combustion instead of MSWIA was used as raw material for synthesising fly ash belite cement (FABC) [7]. In that case, better hydraulic activity (estimated by the combined water content) and mechanical strength were found at the temperature of heating of 800°C. On the basis of those results, the authors applied the same methodology for the cements obtained here.

In both samples, the mayenite phase plays an important role, related to the hydration rate of cements.

3.3 Degree of hydraulicity of the New Cements

The degree of hydraulicity of cements obtained after hydrothermal treatment with water and KOH 0.5M of mixture R1+R2, was evaluated from the combined water content (evaluated from thermogravimetric curves). For this, pastes were prepared at a demineralized water to cement ratio of 0.8, which is similar to that used for fly-ash-belite-cement and municipal solid waste incineration ash cement in previous works [6, 9]. The pastes were maintained for 1, 7, 14 and 28 days from mixing of the cements obtained at 700°, 800° and 900°C, after hydrothermal treatment with water and KOH 0.5M. As can be seen in Fig. 5, the rate of hydration is markedly fast for alkaline activated cement.

Figure 5. Evolution of Combined Water versus Hydration Time: a) Water, b) 0.5M K(OH)

Thus, the combined water content of the cements reach the maximum value by 7 days, at 800°C, independent of the media. Nevertheless, the combined water content values of each cement at different temperatures is similar after 28 days of hydration.

This good behaviour of the cements obtained at 800°C, at early ages, was corroborated by the mechanical strength results.

3.4 Compressive Mechanical Strength

The compressive mechanical strength data are represented in Fig. 6. Each value representing the average of three measurements

Figure 6. Compressive Strength of the two kinds of cements

At any time of hydration, the cement synthesised with alkali activation presents higher strength values than cement synthesised with water, principally from 7 days. This cement reached, after 28 days of hydration, a value of 6 MPa, which is comparable to that β -C₂S variety substituted by alkalis (K/Na y Fe) [11] and obtained at 1520°C.

In this case, we obtained the cement with an important reduction of synthesis temperatures, that implies a considerable reduction of energy consumption.

This hydraulic activity could be attributed to the mayenite phase, besides, the α' -C₂S variety is not a pure phase, and, therefore, its reactivity will be higher in comparison to that of the pure phase obtained by traditional ways; together with the amorphous character of α' and β -C₂S phases in cement synthesised at 800°C as consequence of alkaline activation (see Fig.4).

4. CONCLUSIONS

- Chloride and metallic aluminium of MSWIA represent one of the main problems and from the point of view of its potential valorisation towards construction materials. The alkaline treatment of MSWIA avoids such problems and, in addition, the new hydraulic phases formed have the property of incorporating a wide range of species via solid solution or intercalation mechanisms, providing, therefore, stabilisation mechanisms for minor toxic elements of MSWIA or other toxic wastes.
- Treatment with KOH 5.0M is an important tool to strongly improve the mechanical strength of cements synthesized from these new raw materials.

ABSTRACT

The influence of the temperature of hydrothermal treatment in water of fly ash and bottom ash from incineration of municipal solid wastes is presented in this work. The evolution of the liquid phase was characterized by pH and electric conductivity measurements, and that of the solid phase was characterized by X ray diffraction (XRD), FT infrared (FTIR) spectroscopy and surface area (BET-N₂) analyses. The results showed, in the case of the bottom ash, the formation of ettringite, α -C₂SH and gel CSH at low temperatures (ambient and 50°C). Ettringite is converted to katoite after treatment at 100°C. A zeolite type scolecite is detected at 200°C. As a result, the surface area of the bottom ash increased. In the case of fly ash, Friedel's salt is massively formed at 100°C leading to an increase of 5 times the surface area. Hexagonal Friedel's salt converted to cubic katoite after treatment at 150°C, subsequently decreases its surface area. Gel CSH and C₂SH_{0.35} were also formed.

1. INTRODUCTION

The capacity for trapping ionic species in the lattice of the Portland clinker phases or forming solid solutions with phases of higher solubility during the hydration of Ordinary Portland Cement (OPC), is one of its more important properties, which constitutes the main mechanisms for immobilizing toxic and radioactive wastes. That is the case of CSH gel; AFm and AFt phases; katoites; tobermorites etc., which can trap a wide variety of ionic species owing to their microstructural characteristics.

These phases were synthesized in the past through the hydrothermal treatment of two type of wastes coming from two different combustion processes, such as, coal fly ash [1-5] and ash from incineration of municipal solid wastes [6, 7]. The experimental conditions of temperature and pressure, which are inherent in the hydrothermal conditions favour the thermodynamic evolution of any process through to the more stable state. In this way, it is possible to obtain similar phases from different materials such as the combustion wastes aforementioned.

On the basis of those works, an extensive research project is being undertaken in our laboratory on the hydrothermal treatment of different industrial wastes and characterization of their hydrated phases for immobilizing Pb, Cd, Cr and Cs. In the present work, the influence of the temperature of hydrothermal treatment in water of two type of ashes from incineration of municipal solid wastes: fly ash from cleaning-gas-devices and bottom ash, are presented. The liquid phase was characterized by pH and electric conductivity measurements, and the solid phase was characterized by X ray diffraction (XRD), FT infrared (FTIR) spectroscopy and surface area (BET-N₂) analyses.

The possibility for extending to these wastes the capacity for trapping toxic elements constitutes an important application of using a waste to immobilize other wastes.

2. EXPERIMENTAL

Two ashes from municipal solid waste incineration, one from fluidized bed combustion (bottom ash) and other from cleaning-gas-devices (fly ash), called R1 and R2, whose chemical compositions are given in Table 1, were hydrothermally treated (without stirring), in demineralized water at a water to solid ratio of 10, for 12 hours at the following temperatures: Ambient, 50°C, 100°C, 150°C and 200°C. The solid was filtered and dried to constant weight at 50°C.

The hydrothermal treatment was carried out without stirring with a Parr pressure reactor Model 4761, 300 mL bomb with split-ring closure and 4316 gage block assembly and a 4842 temperature controller. XRD patterns were recorded on a Philips PW 1730 diffractometer, graphite monochromator, Cu K α_1 radiation. FTIR study was carried out on a Atimattson Genesis FTIR TM instrument and KBr pellets containing 0.5% of sample. The surface area measurements were made by the BET method with a Micromeritics ASAP 2010 device; a previous sample degasification at 50°C during 24h up to 0.05 μ m Hg pressure, and N₂ gas 95N as absorbate.

Table 1. Chemical composition of untreated ashes (% by weight).

	LOI	IR	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	Na ₂ O	K ₂ O	Cl ⁻	Surface area (m ² /g)
R1	4.6	5.2	34.1	19.3	6.6	21.9	2.6	3.3	2.1	1.9	3.6	0.798
R2	17.6	0.1	11.4	11.3	1.1	45	1.9	3.9	2.1	1.9	13	7.84

3. RESULTS AND DISCUSSION

3.1 Bottom Ash from incineration of municipal solid waste (R1)

3.1.1 X-Ray Diffraction and BET-N₂ Analyses

The main crystalline compounds of untreated ash R1 (Figure 1 (a)) are the following: Ca₂Al₂SiO₇ (gehlenite), SiO₂ (α -quartz), γ -CaSO₄ (soluble anhydrite), NaCl (halite), KCl (sylvite), α' -L-Ca₂SiO₄, CaCO₃ (calcite) and metallic aluminium. The minority crystalline phases are: α -Fe₂O₃ (hematite), and probably Mg₂C₃.

After the treatment in water at room temperature and at 50°C (Figures 1 (b) (c)), the starting chloride-compounds and anhydrite disappeared; the intensity of reflections of metallic aluminum and gehlenite decreased. Ettringite (Ca₆Al₂(SO₄)₃(OH)₁₂.26H₂O) is obtained from anhydrite and dissolved metallic aluminium. In addition, α -Ca₂SiO₄.H₂O and C-S-H gel (Ca_{1.5}SiO_{3.5}.xH₂O) are formed from hydration of α' -L-Ca₂SiO₄. As a result of the treatment at room temperature, the specific surface area of the bottom ash increased 6 times (from 0.798 m²/g to 4.88 m²/g for the untreated R1 and after the treatment at room temperature, respectively). The amount of ettringite begins to decrease at 100°C (Figure 1 (d)) disappearing after 150°C of hydrothermal treatment (Figure 1 (e)). At this temperature, Katoite, silication (Ca₃Al₂(SiO₄)(OH)₈) appeared together with anhydrite, which reprecipitated from the sulfates liberated by decomposition of ettringite. At 200°C traces of CaAl₂Si₃O₁₀.3H₂O zeolite structure type scolecite is detected (Figure 1 (f)). The surface area remains more or less constant between room temperature and 100°C, increasing thereafter. So, after 150°C the surface area is 5.15 m²/g and 5.51 m²/g, after 200°C of treatment in water.

E ettringite; K katoite; G gehlenite; A anhydrite; S sylvite; H' halite; H hematite; C calcite; Al metallic aluminium; α α' -L-C₂S; * Mg₂C₃; Q α -quartz; \odot α -C₂SH; \bullet Ca_{1.5}SiO_{3.5}.xH₂O; S' scolecite.

Figure 1. Evolution of XRD Patterns of R1 with the Temperature of Hydrothermal Treatment in Water

3.1.2 FTIR Spectroscopy Analyses

The FTIR analyses corroborated the XRD conclusions. As can be seen in Figure 2, in the case of untreated R1 (Figure 2 (a)), the vibrations of lattice water produce the bands centered at 3450 cm⁻¹ and 1650 cm⁻¹; [CO₃]²⁻ group produces the bands centered at 1450 cm⁻¹ and 877 cm⁻¹; the wide band appeared between 1350 cm⁻¹ and 750 cm⁻¹ is due to the vibration of [SO₄]²⁻, [SiO₄]⁴⁻ and [AlO₂]⁻ groups.

Figure 2. Evolution of FTIR spectrum of R1 with the Temperature of Hydrothermal Treatment in Water.

After the treatment in water at ambient temperature, 50°C and 100°C (Figures 2 (b-d)) the OH⁻ groups from ettringite produce a band centered at 3644 cm⁻¹ and the band from [SO₄]²⁻ vibration is clearly detected at 1122 cm⁻¹. The main changes caused by the hydrothermal treatment at 150°C and 200°C (Figures 2 (e) and (f)) are the following: The band centered at 3644 cm⁻¹ disappeared and the wide band located between 1350 cm⁻¹ and 750 cm⁻¹ has a maximum at 1018 cm⁻¹, which could corresponds to [SiO₄]⁴⁻ from katoite, C-S-H gel and α-Ca₂SiO₄.H₂O.

3.1.3 Aqueous Phase Analyses

The evolution of the pH and conductivity is quite similar throughout the temperatures (Figure 3). After the treatment of the bottom ash R1 at the ambient temperature, the pH of the aqueous phase was 10.6, which at 50°C decreased to 9.8, due to the precipitation of ettringite. Thereafter, the pH varied to a value of 10.1 after 200°C. The conductivity reached a value of 9.7 mS, for the treatment at the ambient temperature, varying up to a value of 11.9 for 200°C of treatment.

Figure 3. Evolution of pH and conductivity of the aqueous phase of R1 with the Temperature of Hydrothermal Treatment in Water.

3.2 Fly ash from cleaning-gas-devices of municipal solid waste incineration (R2)

3.2.1 X-Ray Diffraction and BET-N₂ Analyses

The fly ash coming from the cleaning-gas-device has high Ca²⁺ content (from the CaO used as adsorbent), high chloride and high SO₃ content. The main crystalline compounds (Figure 4 (a)) are the following: NaCl (halite), KCl (sylvite), CaCl₂.Ca(OH)₂.H₂O, γ-CaSO₄ (soluble anhydrite), Ca(OH)₂ (portlandite), CaCO₃ (calcite), α'-L-Ca₂SiO₄, metallic Al and Ca₂Al₂SiO₇ (gehlenite). The minority crystalline phases are the following: α-Fe₂O₃ (hematite) and SiO₂ (α-quartz).

After the treatment in water at room temperature and at 50°C (Figures 4 (b) (c)), the starting chloride-compounds, metallic aluminium and anhydrite disappeared. Ettringite (Ca₆Al₂(SO₄)₃(OH)₁₂.26H₂O) and α-Friedel's salt (Ca₄Al₂O₆Cl₂.10H₂O) are formed from anhydrite; chloride-compounds and dissolved metallic aluminium. Besides, α-Ca₂SiO₄.0.35H₂O and Ca_{1.5}SiO_{3.5}.xH₂O are formed from hydration of α'-L-Ca₂SiO₄. As a result of the treatment at room temperature, the specific surface area of the fly ash R2 increased 3 times (from 7.84 m²/g to 24.9 m²/g for the untreated R2 and after the treatment at room temperature, respectively). The amount of Friedel's salt increased markedly at the temperature of 100°C (Figure 4 (d)), where the α to β Friedel's salt transformation is produced; portlandite disappeared. At this temperature, the specific surface area of the fly ash R2 increased 5 times (from 7.84 m²/g to 40.1 m²/g for the untreated R2 and after the treatment at 100°C temperature, respectively) The XRD profiles are quite different after 150°C and 200°C of hydrothermal treatment (Figures 4 (e) (f)), with the following changes: (i) ettringite, β-Friedel's salt and α-Ca₂SiO₄.0.35H₂O disappeared; (ii) katoite, silicaton (Ca₃Al₂(SiO₄)(OH)₈) is formed, together with traces of Ca₄Al₂O₆(CO₃)_{0.5}(OH).11.5H₂O. The presence of Ca_{1.5}SiO_{3.5}.xH₂O (its X-ray reflections are overlapped with those of calcite), was confirmed from IR analyses by the strong absorption band at 950 cm⁻¹ (Figures 5 (e) (f)).

Figure 4. Evolution of XRD Patterns of R2 with the Temperature of Hydrothermal Treatment in Water

The surface area of the fly ash R2 decreased strongly after the hydrothermal treatment at 150°C; 12.2 m²/g and 10.3 m²/g after the hydrothermal treatment at 200°C. This decrease is attributed to the conversion of hexagonal Friedel's salt to cubic katoite, which is produced at 150°C.

3.2.2 FTIR Spectroscopy Analyses

In the case of untreated R2 (Figure 5 (a)), the vibrations of lattice water produce the bands centered at 3477 cm⁻¹ and 1640 cm⁻¹; [CO₃]²⁻ group produces the bands centered at 1471 cm⁻¹ and 875 cm⁻¹; the wide band appeared between 1300 cm⁻¹ and 750 cm⁻¹ is due to the vibration of [SO₄]²⁻, [SiO₄]⁴⁻ and [AlO₂]⁻ groups. After the treatment in water at ambient temperature (Figure 5 (b)) the OH⁻ groups from ettringite and Friedel's salt produce a band centered at 3643 cm⁻¹ and the band from [SO₄]²⁻ vibration is clearly detected at 1132 cm⁻¹. The new bands at 800 cm⁻¹, 540 cm⁻¹ and 432 cm⁻¹ can be attributed to the vibration of AlO₂⁻ group from Friedel's salt. Their intensity increased with the heating temperature of hydrothermal treatment up to 100°C, disappearing after 150°C and 200°C of treatment (see Figures 5 (e) and (f)). At these temperatures, the band centered at 950 cm⁻¹ is clearly formed, which could corresponds to [SiO₄]⁴⁻ from katoite and C-S-H gel.

Figure 5. Evolution of FTIR spectrum of R2 with the Temperature of Hydrothermal Treatment in Water.

3.2.3 Aqueous Phase Analyses

As can be seen in Figure 6, there is no significant pH change of the aqueous phase of the fly ash R2 throughout the temperatures. After the ambient treatment the pH was 12.1 and the conductivity was 30 mS. At 50°C the conductivity decreased up to 25 mS, increasing thereafter progressively with the temperature up to reach a value of 35 mS, after the hydrothermal treatment at 200°C.

Figure 6. Evolution of pH and conductivity of the aqueous phase of R2 with the Temperature of Hydrothermal Treatment.

4. CONCLUSIONS

The hydrothermal treatment of these wastes caused the formation of phases with the property of incorporating ionic species in their structures. These phases were different for fly ash and bottom ash:

- Bottom ash: Ettringite, α -C₂SH and gel CSH are formed from the bottom ash at the lower temperatures: ambient and 50°C, leading to an increase of its surface area of 6 times. Ettringite converted in the more stable cubic katoite after 100°C of treatment. A zeolite type scolecite is detected at 200°C.
- Fly ash: Friedel's salt is massively formed at 100°C, in the case of fly ash, leading to an increase of 5 times of its surface area. Hexagonal Friedel's salt converted in cubic katoite after 150°C of treatment, decreasing consequently its surface area. Gel CSH and C₂SH_{0.35} were also formed.

BIODETERIORATIVE PROCESSES ON AIR-EXPOSED CEMENT MATERIALS

Kondratyeva I.A.¹, Gorbushina A.A.² and Boikova A.I.¹

Knowledge of the bioreceptivity of building materials for microbially induced decay processes has increased considerably in the last years. Indoor and outdoor atmosphere exposed building materials are widely recognized as a favorable environment for microbial biofilms in general and for microscopic fungi specifically.

An important role is played by the microscopic fungi in an atmosphere exposed environment. A series of experiments on industrial clinker samples were carried out to determine the behavior of cements under the influence of fungal growth in the air exposed environment.

The problem of increased durability of cement-based constructions can be solved only with a thorough understanding of the kinetics and microscopic mechanisms of deterioration. As it is known from other inorganic materials (stone, glass etc), special attention should be given to interactions of material with microorganisms and to the processes of their microbial degradation.

Interactions of cement-based materials with deteriorative microscopic fungi were investigated on samples of anhydrous industrial ordinary Portland cement clinkers and on hydrated cement samples (with and without SiO₂ sand) of varying chemical composition. Clinker samples of complex chemical composition included CaO, Al₂O₃, Fe₂O₃, SiO₂ as main components as well as Na, K, Mg, Ti, S as minor components.

These samples were inoculated with a number of microscopic fungal strains, commonly found on silicate rocks all over the world. For the experiment we selected a so-called ubiquitous isolate, the spores of which are frequently found in the air. Inoculation was done by the application of a fungal spore suspension on one side surface of cement cubes.

The samples were incubated at 70% relative humidity and room temperature. Incubation time has presently reached 1 year for anhydrous clinkers and 1.5 and 2.5 years for industrial hydrated cements. Short times of incubation (2-3 months) have shown no considerable material changes. Later, however, experimental growth was slightly accelerated by an addition of 50µl of organic nutrient medium per cement cube.

Scanning electron microscopy (SEM) and X-Ray powder diffraction were used in order to detect biodeteriorative processes on these building materials.

Figure 1.

Figure 2.

SEM demonstrates the growth of fungal mycelium on all inoculated cement blocks (Figure 1, 1.5 years exposure). Branching hyphae spread over the cement surface and frequently form very close contacts with the grains of material. Such contact might be important in the process of mechanical destruction and separation of cement grains. By the penetration of fungal structures between the grains, the crystals of the material can be diminished, which was additionally improved by the crystallographic analysis. Such mechanisms of mechanical destruction, which were previously also shown for marble and other mineral materials [1,2] could represent an important fact in changes of mechanical properties and cohesiveness of cement materials.

Figure 2 clearly demonstrates that fungi affect anhydrous minerals efficiently. It shows the border of the zones of ordinary clinker (upper part) and of clinker, which has been reacting with biological agents (1 year exposure). The differences in mineral composition of an intact clinker (alite, belite etc) and of the zone, which has reacted with microscopic fungi and their exudates (calcite) are extremely evident and were repeatedly demonstrated by both microscopic (SEM) and X-ray analysis. Previously Ribas Silva and Garcia indicated the following deteriorated compounds: calcium-based products - from cement, such as portlandite and calcium carbonate; siliceous products - from aggregates, such as quartz, feldspars, micas and other unidentified crystals.

While the direct products of the interaction between fungi and clinker phases (including their hydrates) remain currently unidentified, we hope to promote the respective study soon.

X-ray analysis of mineralogical changes has further demonstrated that hydration of cement phases was definitely stimulated by biological agents. During a short period of 1 year, anhydrous substances (clinkers) were hydrated and mineralogically changed by the presence of actively growing microscopic fungi. On the hydrated clinker cubes, the X-Ray analysis has demonstrated that chemical composition of the block surfaces has not been changed by microscopic fungi. However, the most important factor is the obvious decrease of intensities of maxima of all mineralogical phases on the cubes side interacting with growing micromycetes as well as broadening of all the reflections themselves.

Figures 3, 4 display the development of biofilms on the hydrated cement samples after 2.5 years exposure. Samples made from hydrated cements with SiO_2 sand are evidently (even by eye) more corroded by fungi than pure cement paste cubes. This difference can be ascribed to heterogeneity of sample texture provided by numerous pores in hydrated cements with SiO_2 sand. Several holes with a scale of about 1 mm are clearly visible in the surface of cement cubes (with SiO_2 sand) covered by fungi spores after 1.5 years exposure. Similar holes appear in hydrated cements without SiO_2 sand after longer exposure (2.5 years).

Microscopic fungi settle and grow on the surfaces of solid building materials, penetrate into the pores, interact with the minerals through production of organic acids or by a respiration process. Thus the growth of microscopic fungi on industrial Portland cement materials has been shown to represent a significant factor changing the mineral composition and mechanical properties of the material in question.

1. INTRODUCTION

Flue gas desulphurization wastes from wet methods are used nowadays as set controlling additives to cements, because of the high amount of CaSO₄·2H₂O, exceeding 95%, and stability of other properties. The proper amount of calcium sulphate controls the initial and final setting of cement, heat of hydration as well as strength development [1].

Application of semi-dry methods of desulphurization, especially for smaller plants results in the formation of CaSO₃·0.5H₂O in the products as well as the presence of a residual absorber (usually calcium hydroxide) and chloride salts. The main desulphurization product content depends on the method of desulphurization used (from several to several dozen percent in waste product). The proportions between calcium sulphite, calcium hydroxide and chlorides vary within a wide range even for the same installation. They depend on the type of coal used and boiler rating in electric or power plants.

Significant differences in various semi-dry methods of desulphurization and differences in chemical constitution of the wastes thus produced, cause many difficulties with waste disposal. It is connected particularly with high activity of all phases included in the wastes.

The main component of desulphurization product obtained in semi-dry process - calcium sulphite hemihydrate CaSO₃·0.5H₂O - is not without influence on cement setting [2-3, 7-11]. The results of setting time measurements of cements including CaSO₃·0.5H₂O show this very clearly. There are also some reports dealing with the effect of wastes obtained in semi-dry installations on cement properties [8]. A large number of tests were carried out for cements from group CEM I – without mineral additions. It has been found that the retarding influence of sulphite and wastes containing calcium sulphite is bound with different reaction mechanism than observed in the case of calcium sulphate (gypsum) added as set retarder.

The analysis of the published works and our studies indicate that there is no equivocal opinion about calcium sulphite effect on cement hydration. The authors assumed that addition of mineral admixtures to cement clinker could improve the properties of cements due to the lower amount of clinker and, consequently, lower amount of tricalcium aluminate in cement.

Our studies point out some differences in the properties of cement properties produced based on different clinkers, with high and low amounts of a C₃A phase [12]. Lower content of C₃A in cements affects water/cement ratio and increases plasticity of cement mortars.

This paper shows the results of the studies on the effect of desulphurization products from semi-dry installation and natural gypsum mixed at different ratios, added as a set controlling agent, on the

properties of cements with different clinker and slag contents, produced as CEM I, CEM IIB/S and EM III/A, according to European standards.

2. EXPERIMENTAL

The studies covered the determination of standard properties of cements made on the base of one clinker with C_3A content 9.3%. As a setting time controlling agent the gypsum in its natural form ($CaSO_4 \cdot 2H_2O = 95.5\%$), a waste product containing $CaSO_3 \cdot 0.5H_2O$ ($CaSO_3 \cdot 0.5H_2O = 61.4\%$) and the combination of these two materials in some different proportions were used. For preparing the cements from CEM II and CEM III groups granulated slag was used, added as 30 and 60% by weight of cement.

Cements were made with the following assumption: total content of sulphates or sulphites calculated as SO_3 was 3.5% of total weight of every cement. They were prepared from cements: type CEM I (containing gypsum), type CEM I (containing desulphurization product) – both prepared in laboratory, as well as ground slag, gypsum and desulphurization product in its natural form. The components for CEM I containing gypsum were pulverised in a laboratory ball mill to produce cement with specific surface of $330 \pm 5 \text{ m}^2/\text{kg}$, as measured by Blaine method. Time of grinding with addition of slag and different retarders was the same. Because desulphurization product from the semi-dry method and slag exhibit high specific surface, the specific surface of cement blends is higher. The composition of cements and their specific surface areas are presented in Table 4.

All cement samples were produced by homogenisation of ingredients in amounts given in Table 4. Gypsum and waste product was added when cements from group CEM II and CEM III were prepared.

The chemical components of the clinker and mineral composition calculated using Bogue's formulas, the chemical components of the slag and the chemical as well as mineral composition of the waste products are presented in Tables 1-3.

The water demand, initial and final setting times (Vicat method) and stability of volume were determined in the pastes prepared from cements. The determination of compressive and flexural strength of cement mortars, at w/c ratio = 0.5 was carried out on 4×4×16 cm standard bars stored in water, at 18 ± 2°C. The strength of those mortars was determined after one day and after 2, 7 and 28 days respectively. Moreover, the plasticity of mortars at the shaking table was determined just after their preparation.

Microcalorimetric measurements were carried out with help of Polish BMR differential microcalorimeter on cement pastes. The heat evolution curves were produced and total heat output was calculated.

3. RESULTS AND DISCUSSION

The stability of volume tests for all cements using the standard Le-Chatelier rings show the measured distance to be less than 2 mm (acceptable level is below 10 mm). The results of the determination of setting time and the water demand calculated as w/c ratio are shown in Figures 1 and 2.

The plasticity tests of mortars just after their preparation were carried out at 15 “jumps” of the shaking table by measuring the diameter of spilled mortar cake previously formed as a cut cone of footing diameter = 10 cm. The results of this test are shown in Figure 3.

Table 4. Composition of cements.

Type of cement	SO ₃ /SO ₂ (molar ratio)	Percentage of components [wt. %]					Specific surface area by Blaine [m ² /kg]
		CEM I (G)*	CEM I (W)**	Slag	Natural gypsum	Waste product	
CEM I / 1	100 / 0	100		-	-	-	325
CEM I / 2	70 / 30	70	30	-	-	-	335
CEM I / 3	50 / 50	50	50	-	-	-	340
CEM I / 4	0 / 100	-	100	-	-	-	350
CEM II / 1	100 / 0	67.4	-	30.0	2.6	-	360
CEM II / 2	70 / 30	47.2	20.1	30.0	1.8	0.9	370
CEM II / 3	50 / 50	33.7	33.5	30.0	1.3	1.5	375
CEM II / 4	0 / 100	-	67.1	30.0	-	2.9	385

CEM III / 3	50 / 50	17.4	17.1	60.0	2.6	2.9	410
CEM III / 4	0 / 100	-	37.1	60.0	-	5.8	425

*- CEM I (G): clinker 93.51%, natural gypsum 6.49%,

** - CEM I (W): clinker 92.71%, desulphurization product 7.29%.

Figure 1. Initial and final setting of cements.

Figure 2. Water/cement ratio of cement pastes.

Figure 3. Plasticity of cement mortars ($w/c = 0.5$; sand/cement ratio = 3).

Partial and total replacement of gypsum by the waste containing calcium sulphite hemihydrate (see Table 1), brings about the elongation of both initial and final setting of cement irrespective of slag content. Only in the case of CEM III can we observe shortening of the time gap between initial and final setting time. The retarding effect is growing with growing waste and slag content, something that was easy to predict.

The addition of the mixture containing desulphurization product (mainly $\text{CaSO}_3 \cdot 0.5\text{H}_2\text{O}$, $\text{Ca}(\text{OH})_2$ and CaCl_2) with calcium sulphate dihydrate influences the w/c ratio, especially for higher waste content. It can be also attributed to the higher specific surface area of those samples and C_3A reaction with other components of the waste product. Small additions of waste may even reduce w/c ratio (as for sample CEM II/2). Also the plasticity tests of the standard cement mortars (w/c=0.5, sand/cement=3) show slightly better results in the case of small additions of waste containing calcium sulphite. It is visible in case of CEM I as well as CEM III type cements.

Total replacement of gypsum with calcium sulphite containing waste affects negatively the properties of cement paste as well as the properties of ready mixed cement mortars. Only in the case of CEM III group the plasticity of mortar is slightly higher than in case of CEM II/1 containing pure gypsum. This change, observed for cements from group I and II containing waste material as retarder may be attributed to the higher specific surface of those cements and with – what we presented in our paper [12] - rapid C_3A hydration during the first minutes after mixing with water. The plasticity of cement mortars becomes lower and the water/cement ratio increases considerably. It is particularly visible for cements marked as CEM (I, II,) / 4.

The results of compressive and flexural strength of standard mortars are presented in figure 4 and 5. Initial strengths of mortars (after 1 day) strongly depend on the amount of gypsum replaced by the waste containing calcium sulphite hemihydrate. The strength development lowering is connected with the prolonged setting time of cements. After one day of hardening this strength is reduced from about 33 to 55% for the cements marked as CEM (I, II, III) /3 in relation to CEM (I, II, III) /1 corresponding to commercial cements. The strength differences observed in the first days of hardening are more pronounced when cements with gypsum are compared with cements containing the pure waste product as a retarder.

Figure 4. Compressive strength development of cements cements.

After two days of hardening we may observe not only the higher strength of cements containing additions of the waste (in contrast to cements containing pure gypsum as retarder) but also a significant acceleration of strength development. After 2 days of hydration the compressive strength may be higher in cements containing even 25% addition of waste. It means that the strength increase (especially compressive strength) between first and second day of hardening may be even 85% higher for cements containing mixtures of waste with gypsum.

Figure 5. Flexural strength development of cements.

In the case of cements containing high amounts of slag – CEM III (low amount of clinker) the influence of waste product from desulphurization process is not so visible as in case of CEM I and CEM II. We cannot observe such differences between the strength values after 1, 2, and 7 days and it is easy to find that addition of mixture of waste with gypsum or even neat waste product increases the compressive strength after 28 days of hardening. It may be caused by the presence of calcium hydroxide in the waste. Thus the slag hydration is strongly accelerated. However the flexural strength development is not observed.

Retardation of initial setting times and reduction of strength development during the first day of hydration in the presence of desulphurization by-product could be attributed not only to the effect of components included in it on C_3A hydration but also to the effect on the rate of alite (C_3S) hydration. As it is commonly known, strength development depends strongly on alite hydration in cements.

The slower strength development and prolonged setting time of cements containing lower and higher addition of desulphurisation waste material is correlated with smaller heat evolution rate. The microcalorimetric tests show significant differences in the extent of the so-called induction period in relation to cements containing pure gypsum as a retarder. It also influences the amount of heat produced during the first day.

A substantial strength increase observed between the 1-st and 2-nd day of hydration also complies well with differences between total heat output calculated after 3 days of hydration and heat output after 1 day.

Heat evolution curves of cements are presented in Figures 6-8. Heat-evolved values after 24 h and 72 h are illustrated in Figure 9.

Figure 6. Hydration kinetic curves for cements from group CEM I with different waste to gypsum ratio.

Figure 7. Heat evolution curves for CEM II B/S cements with different waste to gypsum ratio.

Figure 8. Heat evolution curves for CEM III A cements with different waste to gypsum ratio.

Figure 9. Heat output for cements after 24 and 72 hours of hydration.

Increased amounts of waste in cements brings about not only the elongation of the induction period during cement hydration, but also retards the reaction of the aluminate phase with water after consuming gypsum and /or calcium sulphite (the latter can be observed in case of CEM I cements). Addition of slag distinctly decreases the induction period, but only in the case of cements containing the mixture of gypsum with calcium sulphite containing waste. For cements CEM II/4 and CEM III/4 we observe longer induction periods. However, the total heat output shows no change after 3 days of hydration.

4. CONCLUSIONS

1. Total replacement of gypsum by calcium sulphite containing waste from semi-dry installation of desulphurization used as cement set controlling agent, results in prolonged setting time, considerably slower strength development during the first day of hardening, irrespective of slag content in cement.
2. After a longer period of time (28 days), we observe a decrease of flexural and an increase of compressive strength of cements as compared to cements prepared with pure gypsum as set retarder, irrespective of slag content.
3. Between 1-st and 2-nd day of hardening a substantial strength development in cement containing waste products is observed. Compressive strength after 2 days of hardening may be even 25% higher than in cement with gypsum. Such acceleration of strength development is observed in CEM III after a longer period of time (between 2-nd and 7-th days of reaction in water).
4. At lower content of waste in cements - 30%, calculated as calcium sulphite molar replacement of gypsum, the water to solid ratio and plasticity of cement mortars is affected only to a small extent; these properties seem to be even better than in the case of cement with gypsum. This is independent on slag content.
5. Prolonged setting time and lower strength within the first day of hydration are closely connected with elongation of induction period observed when calcium sulphite containing waste material is added.

ABSTRACT

Effect of PbO on hydration and hardening of different cements was tested by standard methods. As a first step the standard setting time and compressive tests were done, followed by calorimetric measurements. Substantial retardation of reaction with water at early stages with subsequent intensification of the process was firstly found. The studies in model systems, including pure clinker minerals and other retarding agent - ZnO were carried out to find the mechanism of delayed formation of products in post-induction period. PbO and ZnO added to cement paste or mortar as fine-grained solid additives retard setting proportionally to their content in hydrating materials.

Effect of retardation by PbO is different for different cements; but for PbO additive not exceeding 0,5 wt. % the setting parameters meet the European standard requirements. PbO does not affect such parameters of fresh paste as w/c or volume changes. PbO brings about a significant change of heat evolution kinetics – at 2 – 5% PbO the induction period becomes many times longer, but when reaction starts again it seems that there is no special modification of hydration mechanism and kinetics. The effect of PbO on heat evolution may differ significantly for different cements. PbO does not hinder the heat evolution process of alite while ZnO does. Finely ground PbO gives a significant growth of heat output on pure alite hydration – presumably it plays a role of nucleating agent.

1. INTRODUCTION

As was reported over 30 years ago, small amounts of PbO or ZnO retard strongly the hydration of Portland cement [1]. This effect has been attributed to the formation of an impermeable layer of products – heavy metal hydroxides or amphoteric salts produced in the reaction between the oxides and C₃S. The strength decrease at later ages was not observed in the case of PbO, though a significantly retarded setting was found. The calorimetric studies revealed a prolonged dormant period with many hours shift of the second heat evolution peak. The author did not find a full explanation for the effect of PbO on the hydration process.

Further the effect of heavy metals was studied from the point of view of their immobilisation in the hardened cement matrix [2,3]. The researchers focused on the studies of the stabilisation mechanism and leaching of heavy metals from different cement based materials [4, 5]. A very high degree of Pb or Zn immobilisation was found as well as the formation of highly disordered C-S-H in the presence of heavy metal compounds [6, 7]. The retarding effect of Pb or Zn compounds (salts) on cement hydration was also proved in some later works [8 -10].

2. EXPERIMENTAL

The experimental work was carried out step by step starting from the standard measurements on cements produced from commercial cement clinkers doped with PbO. Next, the calorimetric measurements were carried out, followed by some investigations using different methods to elucidate the mechanism of the retarding effect. Then the ZnO additive was introduced.

2.1 Materials

Two cements: “Cement 1” and “Cement 2” were produced in a laboratory ball mill from two clinkers from different cement plants in Poland. The clinkers were ground with gypsum (in proportions 95% clinker +5% gypsum) to the specific surface of $3000 \pm 50 \text{ cm}^2/\text{g}$ (Blaine). The characteristics of the cement clinkers is given in Table 1 (chemical composition and phase composition calculated using Bogue’s formulas). The analytical grade PbO or ZnO was used in cement paste (and mortar) preparation, added as 0,1%; 0,25%; 0,5%; 0,75%; 1%; 2% and 5% by weight of cement.

2.2 Methods

The following standard tests were carried out following the procedures given in European standards EN196-1 and EN 196-3:

- water demand of pastes with different PbO dosage
- setting time
- volume changes and consistency of pastes
- compressive strength
- flexural strength.

The compressive and flexural strength development was monitored during the 360 - day curing on small $2,5 \times 2,5 \times 10 \text{ cm}$ bars.

As a next step, the hydration kinetics was followed by microcalorimetry. Heat evolution measurements were carried out by the use of a differential microcalorimeter BMR (non-isothermal – non-adiabatic; constructed in the Institute of Physical Chemistry, Polish Academy of Science) on pastes produced at w/c ratio 0,5. The starting temperature was kept constant at 25°C .

Table 1. Chemical and phase composition of cement clinkers

Component	Content in wt. [%]	
	Cement clinker 1	Cement clinker 2
CaO	65,55	68,11
SiO ₂	21,33	22,57
Al ₂ O ₃	5,46	4,97
Fe ₂ O ₃	2,65	2,13
MgO	1,06	0,82
SO ₃	0,71	0,40
Alkalis	1,05	0,37
L.O.I		0,25
C ₃ S	64,2	68,05
C ₂ S	12,6	13,23
C ₃ A	9,9	6,79
C ₄ AF	8,1	7,28
CaO _{free}	1,2	0,68

2.3 Results

2.3.1 Standard tests

The results of standard tests are given in Tables 2 and 3 (w/c, Le Chatelier test, consistency of standard mortar), Figure 1 (setting data) and in Tables 4 – 7 (strength results). The strength tests were carried out with PbO additive up to 2%, because the samples with 5% PbO revealed no strength and very strong bleeding after 48 hours, so that the de-moulding of standard bars was not possible.

Figure 3. Heat evolution curves of Cement 2 doped with PbO.

2.4 Discussion

From the results from W/C and volume change determination, PbO gives neither the effect on water demand or consistency of mortar at the beginning of hydration produces expansive products (Le Chatelier test – see Table 1). The setting process is clearly disturbed with PbO additive; the pastes with up to 0,50% PbO meet the standard requirements. One can notice that initial and final setting, specially for higher PbO content, is less retarded in the case of Cement 2.

As the results from the compressive and flexural strength data show, PbO additive up to 0,5% gives generally no retarding effect on strength development. One can even notice a slight strength increase as compared to the control sample. At higher amounts a delayed hardening at early ages is observed at standard 2-day measurements. At 1% and more PbO, it is impossible to de-mould the standard bars after 24h. The samples with 5% PbO were completely destroyed – exfoliated. Up to 1% the strength results are almost on the same level. At 2% PbO the strength of mortar is less or more reduced within 360-day measurements; it relates particularly to cement 2 and its flexural strength. However it seems that the difference becomes higher not only at early ages but also after prolonged curing (180, 369 days).

The calorimetric studies prove the systematic retardation of cement hydration with time, documented as Figures 2 and 3.

The data showed above would indicate the formation of a physical “barrier” which is effective at an early age, augments with PbO additive and becomes withdrawn after a shorter or longer time, depending on PbO content.

This barrier (impermeable layer of Pb containing material?) is presumably thicker and more stable at higher PbO contents and really must be once destroyed; after this the formation of products takes place in such a way that the microstructure is almost the same, thus giving very similar strength results to the reference. This is compatible with calorimetric observations, where we can observe a shift of the main peak along the time axis, but the height and shape of peak remains little changed. A diffusion process through the layer surrounding the cement grains seem to be rather of less importance. (In these cases the peaks would be broader and lowered with PbO)

It seems reasonable that the Pb containing compounds, if they are formed have no special influence on the mechanism and rate of hydration after the initial prolonged dormant period, when they are present in the paste. The incorporation of some Pb ions to the structure of hydration products (C-S-H) is also possible. Taking into account the w/c data and shape of calorimetric curves one can find that the effect of PbO on ettringite formation should be rather excluded.

According to the suggestion given in one previous work [1] the retarding effect of PbO is attributed to the blocking up of the alite surface presumably by the formation of an impermeable layer of product. The retardation depends on the alite content. However it is difficult to adapt this explanation to the differences between the data for cement 1 and 2. The setting and hydration kinetics of cement 1, that is of lower alite content is more retarded. There must be other phenomena and processes involved. Anyway, the authors of this first study cited here [1] clearly point out that there is no satisfactory explanation dealing with PbO's influence on cement hydration and some points remain unclear (e.g. There is no defined product detected).

Let us discuss this taking into account our results:

PbO additive when retards alite hydration by formation of $\text{Pb}(\text{OH})_2$ or other amphoteric compounds, must dissolve at first.

It dissolves better, at a higher rate with higher alkali content in cement paste – more OH^- available! – such a situation is in Cement 1 (see Table 1). Thus it dissolves in cement paste from Cement 1 better. It means that it would dissolve in “normal” (not very low alkali) cement paste better than the low alkali one or in pure alite paste.

Additional possible reaction affecting PbO interaction with cement paste - gypsum dissolution at early stage of hydration - gives sulphate ions which combine with Pb and PbSO_4 precipitation takes place and Ca ions release to the solution (hypothetical formation of Ca salts with Pb in anion). But this effect of gypsum seems to be less important, otherwise calcium aluminate hydration in cement paste to form ettringite would not be balanced and false setting would be observed or water demand changed in some way.

2.5 Supplementary studies – results and discussion

To elucidate some aspect of the PbO retarding mechanism, the authors carried out some further experiments. The calorimetric measurements were done with ZnO, the effect of which is better documented and explained by the formation of well defined compounds [1]. A stronger but similar-in-shape retarding effect was observed. Therefore the calorimetric studies to follow the hydration of alite with ZnO and PbO were carried out as a next step. The calorimetric curves are given as Figures 4 and 5.

Figure 4. Calorimetric curves of alite with PbO.

Figure 5. Calorimetric curves of alite with ZnO.

As we can see the hydration of alite sample in the presence of alite is not retarded by PbO while in the presence of ZnO it is! Perhaps the formation of any Pb containing compound by a through solution mechanism is fairly slow and, what is more, the dissolution of PbO is much slower in alite paste than in cement paste, where there is always some concentration of easily soluble alkalis and other ions, which may strongly accelerate this process. It seems quite reasonable that in the case of pure alite PbO plays a role of nucleating agent prior to retarding the process. The results for alite hydrating in the presence of ZnO seem to prove that ZnO is more easily soluble in the alkaline liquid formed on alite hydration and that the calcium hydroxozicate does precipitate on the surface of hydrating grains and efficiently covers the surface to protect alite against attack of water. Another reason is that perhaps early Pb containing coating if it exists in pure alite system, is weak and its thickness is insufficient and permeable. Therefore, as a further step the interaction alite – PbO – CaSO_4 was taken into account. The calorimetric measurements were done and they demonstrate the retarding effect of the gypsum on alite + PbO hydrating mixture (Figure 6).

Figure 6. Calorimetric curves of alite with PbO and gypsum.

We can, therefore presume that the insoluble PbSO_4 layer can be formed; its thickness is a function of Pb content. After a time this layer collapses. Probably destroyed by osmotic pressure of hydrating silicate; Pb ions are partly consumed by poorly ordered C-S-H [11]. This layer is built up not only of sulphate; different energies of Pb bonds have been found in ESCA measurements in model systems [12], but PbSO_4 seem to be responsible for the retarding effect.

3. SUMMARY

The effect of PbO and ZnO interaction with cement pastes and mortars can be summarized as follows:

- PbO and ZnO added to cement paste or mortar as fine grained solid additives retard setting proportionally to their content in hydrating materials;
- effect of retardation by PbO is different for different cements; but for PbO additive not exceeding 0,5 wt. % the setting parameters meet the European standard requirements;
- PbO does not affect such parameters of fresh paste as w/c or volume changes;
- PbO brings about a significant change of heat evolution kinetics – at 2 – 5% PbO the induction period becomes many times longer, but when reaction starts again it seems that there is no special modification of hydration mechanism and kinetics;
- The effect of PbO on heat evolution may differ significantly for different cements;
- PbO does not hinder the heat evolution process of alite while ZnO does; PbO gives a significant growth of heat output – presumably it plays a role of nucleating agent.

- PbO hinders alite hydration in the presence of gypsum; PbSO_4 seems to be the main factor responsible for retarding effect.
- However, the retarding mechanism of PbO powder on cement hydration is complex. It seems that there is no one hypothesis which should be operative. This is not only the question of physical barrier on alite surface; the reason for this relates to the other components of cement paste.

ABSTRACT

The hydration process of cementitious mixtures with some finely ground and/or finely dispersed additives of different origins has been followed using calorimetry and other methods to evaluate the scope of cement replacement as well as the effect on strengthening of structure. The nucleating action and chemical modification of hydrating systems will be discussed. The hydration products will be characterised by means of thermogravimetry and microscopy.

The experimental work, which is a part of larger project, was carried out step by step starting, by using fly ash admixtures, then silica fume, calcined clay, limestone and finely grained siliceous glassy admixture.

Obviously, the heat evolved decreases with admixture content, however the heat calculated for 1g of cement in every initial, blended anhydrous sample becomes higher in case of silica fume, glassy admixture and metakaolin and this fact seems to prove that intensive hydration takes place. One can draw conclusions about the significant contribution of admixtures used in this study to setting and hardening. Relatively high heat calculated value for 50 % SF and glassy admixture can be attributed to wetting and (ad)sorption of process water with dissolved ions on the silica-rich developed surface of the admixture, followed by C-S-H formation. TG data show that small amounts of SF or MK favours $\text{Ca}(\text{OH})_2$ formation at an early age due to the nucleation effect and accelerated hydrolysis of silicates from cement. However, after 3 days the pozzolanic effect of calcium hydroxide consumption is evident in the case of silica fume but not yet in the case of metakaolin.

The differences between the particular admixtures are not only the question of specific surface development but also the active silica contribution to the C-S-H phase formation and role of alumina containing hydrates at later ages of hydration.

1. INTRODUCTION

The alumina and/or silica bearing admixtures of poorly ordered structure were used in ancient times to improve setting and hardening of mortars [1]. Nowadays, industrial by-products of different origins are used as admixtures, mainly slags and pulverised fuel ashes, but also silica fume and other artificial pozzolans [2].

Silica fume, delivered as a by-product in silicon alloy production, has been put into use in the seventies and is known as a very active pozzolanic admixture for high performance and self-compacting concrete [3].

Dehydrated clay, produced by heating at sufficiently low temperature, shows relatively high surface area and pozzolanic activity [4]. From the other side, the chemical composition of metakaolin is

very similar to the composition of many fly ashes. The dehydrated clay is not a component of standard pozzolanic cement itself, but its effect must be taken into account when we consider the use of some wastes containing the products of clayey mineral decomposition (e.g. coal shales, “mineral” part of the desulphurisation residue from some installations) [5].

Locally, some finely ground alumino-silicate materials are used as concrete admixtures, e.g. waste materials of zeolitic character or other vitrified substances [6].

The small particles of these admixtures are well distributed between the cement grains and easily absorb the calcium ions evolved on hydrolysis of silicate cement phases [7]. C-S-H phase produced as a result of pozzolanic reaction reveals a specific microstructure of initial amorphous component, very compact, “dense”, with no large pores. Calcium hydroxide is consumed with time in the pozzolanic reaction and enters the C-S-H structure, improving its resistance to chemical attack. In such a way a composite material of high strength and durability can be produced [8].

The interaction of admixtures with cement paste is very often of various character, particularly when they are built of amorphous, glassy or very disordered silica and alumina bearing substances. The physical, nucleating effect of small particles incorporated into cement paste should also be taken into account. The addition of finely dispersed limestone is a good example. Very fine powders are used in the production of some special high performance concretes [3].

2. EXPERIMENTAL

The experimental work, which is a part of larger project, was carried out step by step starting by using fly ash admixtures, then the silica fume, calcined clay, limestone and finely grained siliceous glassy admixture. As a first part of research programme the calorimetric measurements were carried out, followed by some investigations using different methods to elucidate the mechanism of accelerating/cement replacement effect.

2.1. Materials

The following materials were used in this study:

- standard cement “52.5R” with no other admixtures (CEM 52.5),
- silica fume of SiO_2 content $> 95\%$ and specific surface $> 15 \text{ m}^2/\text{g}$ (SF),
- pulverised fuel ash,
- siliceous admixture,
- metakaolin with $58.13\% \text{ SiO}_2$ and $38.12\% \text{ Al}_2\text{O}_3$ (MK)
- limestone (pure reagent grade).

The admixtures were used at 5 to 50% cement replacement (by weight) respectively. The pastes were produced at water to cement ratio = 0.5. The commonly known procedure was applied to stop the hydration as required (grinding or rinsing with acetone and drying).

2.2. Methods

The hydration kinetics was followed by microcalorimetry. Heat evolution measurements were carried out by use of differential microcalorimeter BMR (non-isothermal – non-adiabatic; constructed in the Institute of Physical Chemistry, Polish Academy of Science) on pastes produced at w/c ratio 0,5. The starting temperature was kept constant at 25°C . The selected samples were analysed using DTA-TG methods (differential thermoanalyser “Derivatograph Q 1500-C”) and observed under SEM (JEOL electron microscope with LINK-ISIS microanalyser).

2.3. Results

The results of calorimetric measurements are shown in Figures 1-5.

3. DISCUSSION

In this work the comparative studies of hydration process in cementitious systems with fly ash, calcined clay (metakaolin), silica fume, finely ground glassy siliceous admixture and calcium carbonate used as admixtures to cement were carried out. The details of hydration acceleration/retardation at early age have been clearly pointed out by microcalorimetry. The heat evolved values, calculated in relation to the “pure” cement content, show that at 20% admixture of siliceous admixtures or metakaolin, the accelerating effect on cement hydration, that is the shortening of induction period and shift of the main heat evolution peak is evident. Also the calcium carbonate fine grains, though almost non-reactive chemically, presumably play a role of nucleating agent; the effect of fly ash within the first 24h is similar.

Obviously, the heat evolved decreases with admixture content, however the heat calculated for 1g of cement in every initial, blended anhydrous sample becomes higher in case of silica fume, glassy admixture and metakaolin and this fact seems to prove that intensive hydration takes place. Though this simulation is based upon some simplified assumptions, one can draw conclusions about the significant contribution of admixtures used in this study on setting and hardening. The relatively high heat calculated value for 50 % SF and glassy admixture can be attributed to wetting and (ad)sorption of process water with dissolved ions on the silica-rich developed surface of admixture, followed by C-S-H formation. TG data show that small amount of SF or MK favours the Ca(OH)₂ formation at an early age due to the nucleation effect and accelerated hydrolysis of silicates from cement. However, after 3 days the pozzolanic effect of calcium hydroxide consumption is evident in case of silica fume but not yet in case of metakaolin. Metakaolin exhibits, in comparison with SF, more moderate action, as determined by several methods.

The differences between the particular admixtures are not only the question of specific surface development but also the active silica contribution to the C-S-H phase formation and role of alumina containing hydrates at later ages of hydration.

The SEM observations with EDS analysis are a good supplement to the calorimetric and TG measurements. In SF doped samples, C-S-H composed of small, spherical particles with Ca from hydrolysis of silicate phases is produced as a main component of paste (Figures 6-8) and shows a good adherence to cement grains, as can be seen in Figure 6. The metakaolin admixture is not so well dispersed in the paste. The plate-like metakaolin areas are however saturated with Ca and form Al containing C-S-H together with ettringite and calcium hydroxide. The particular phases can be distinguished only by means of EDS.

4. CONCLUSIONS

- Silica fume, metakaolin or every other aluminosilicate fine-grained admixture of disordered structure added to cement participates more or less actively in cement hydration as shown by the results of heat evolved calculated for 1 g of cement.
- The retarding effect of fly ash on heat evolution is similar to that of calcium carbonate, however the nucleating role of small particles is clearly seen at early age of hydration.
- The rate of calcium silicate hydration in pastes with silica fume or metakaolin increases, as shown by results from TG measurements showing the higher calcium hydroxide contents at an early age of hydration.
- The small particles of admixtures are dissolved and/or saturated with Ca (ad)sorbed from the liquid phase and C-S-H is thus formed as is documented in SEM+EDS studies.

ABSTRACT

The following report will mainly focus on the conditions of thaumasite formation in concrete and mortar. Until now there has been a predominant opinion that the destruction of concrete by sulphate ions is connected first of all with expansive ettringite and gypsum formation. The C_3A content in cement is the main parameter limiting the resistance of concrete to chemical corrosion. However, recent studies indicate that CSH undergoes also sulphate corrosion, especially in the presence of CO_2 and at lower temperatures. In this case thaumasite, which crystals are similar to those of ettringite, is produced. The formation of thaumasite also results in expansion followed by microcracks in concretes and mortars. In this work results of the experiments dealing with the influence of C/S ratio in CSH on the thaumasite formation are presented. The XRD, IR spectroscopy and SEM – EDS methods are used to characterize this phase.

1. INTRODUCTION

Concrete durability can be defined as a complex of concrete properties, which must be kept unchanged within the longest possible time of utilization [1,18].

There are a number of factors influencing concrete durability; among them are:

- Physical and chemical properties of components
- technology
- curing conditions
- mechanical load constant and/or variable
- aggressive environment
- maintenance / conservation.

In many cases the factors mentioned above interact to influence the concrete. Chemical corrosion belongs to the factors which change concrete durability in a significant way [1].

Concrete corrosion in sulphate environments is the most dangerous. As a result expansion with gypsum and ettringite formation takes place [1]. The amount of gypsum and ettringite depends mainly on the content of calcium hydroxide and hydrated calcium aluminate [2]. In the case of magnesium sulphate attack the most durable CSH phase also undergoes decomposition [2].

Another example of CSH destruction in concrete occurs when thaumasite is produced [5]. Thaumasite forms as a result of alkali sulphates and CO_2 attack on concrete at lower temperatures and in conditions of high humidity [5,6,7].

The influence of ammonium sulphate and magnesium sulphate can be considered even more destructive for concrete [3,4].

The investigations of many authors indicate that many concrete constructions may be deteriorated by thaumasite formation occurring as a result of sulphate attack.

Typical elements that may suffer from thaumasite sulphate attack are [5]:

- foundations, columns and pier bases
- ground slabs and buried pad foundation
- roads pavements
- trench fill and concrete drainage pipes
- concrete ground anchors
- tunnel linings

As a result of thaumasite sulphate attack on the elements mentioned above, potentially significant structural effects have been identified as [5]:

- loss of concrete cross-sectional area
- loss of cover concrete on the reinforcing bars
- loss of bond between reinforcement and concrete
- settlement, inducing structural damage
- loss of durability as a result of loss of protection against reinforcement corrosion.

Examples of the thaumasite sulphate attack mentioned above are widely described in literature.

The British authors point out numerous cases of the thaumasite sulphate attack phenomenon occurring mainly in concrete foundations of industrial buildings, flats, flyovers and bridges in Great Britain [5,6,7].

The damage caused by thaumasite formation have also been noticed in concrete surface and car and train tunnels in the Italian Alps [8]. Also very dangerous are the symptoms of thaumasite sulphate attack in concrete constructions in dams located in Italy [9]. There are also similar cases of sulphate attack on historical buildings in Greece and Turkey [10].

It seems reasonable that the thaumasite attack is more or less evident depending on the nature of base material exposed to low temperatures and corrosive media.

Thus the following report will present the preliminary results of research on the influence of C/S to CSH ratio on thaumasite formation.

2. EXPERIMENTAL

Concrete is produced from different cementitious materials. The differences may concern the mineral composition and mineral admixtures, such as slags, fly ashes and other pozzolans used.

As a result of cement hydration, CSH phase is formed with variable C/S ratio of 0,8 to 2,5. The lowest limit corresponds to the use of high volume silica bearing admixtures. Therefore in order to follow the C/S effect the CSH has been synthesized with C/S ratios of 0,8, 1,5, 2,0, 2,5 respectively.

2.1. CSH synthesis

The mechanism of calcium silicate hydrate synthesis has been studied by many authors [11,12,13,14,20].

This process includes the following stages:

- surface protonation of SiO_2 with OH^- formation
- slow migration of silicate anions into the solution
- reaction between Ca^{2+} from the solution and silicate ions with formation of a product rich in CaO (so-called CSH II of C/S ratio about 1,5 - 2,0)
- reaction of an initial product with SiO_2 dissolution product with CSH phase poorer in CaO synthesis (so-called CSH I of C/S ratio about 0,8 – 1,0)
- depending on the conditions of the synthesis and proportions between SiO_2 and CaO formation of more ordered phases.

The process of setting and hardening of the products containing calcium silicate can take place at normal temperature under atmospheric pressure or by using hydrothermal conditions, that is at temperatures above 100°C and saturated water vapour. The process can be considered as a hydration reaction “through solution” in which we can identify, in the most general case, dissolving substrates and precipitation of products.

As a result of the reaction in the reacting mixture we get the products in the form of calcium silicate hydrates, characterized by having different degrees of order.

In the following research a synthesis of CSH phases was carried out in hydrothermal conditions as well as at ambient temperature under atmospheric pressure. The materials were put together in the proportions expressed by C/S mole ratios, 0,8, 1,5, 2,0 and 2,5.

In the process of CSH phase synthesis amorphous silica and burnt lime were used, mixed in proper C/S proportions. Then the mixture was homogenized to produce a paste with water to solid ratio equal 1,5. The mixtures were then put into containers where they were heated at 50°C within 2 hours. After that they were subjected to the homogenization process again. The only variable parameter was C/S ratio. The samples prepared in such a way were subjected to thermal processing at 180°C under saturated steam pressure. The samples prepared at ambient temperature were shaken for 8 days.

2.2. Preparation of pastes

Fresh CSH produced as mentioned above was mixed with some additives, such as CaCO_3 , Ca(OH)_2 and $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, used in variable quantities in relation to CSH phase. Thus the series of doped C-S-H were produced; their composition is given in Table 1.

Table 1. Composition of pastes produced from CSH of variable C/S ratio, cured at normal temperature under atmospheric pressure for 8 days.

No	Sample code	Composition of samples						
		C/S ratio in CSH phase				CaCO ₃	Ca(OH) ₂	Na ₂ SO ₄ ·10H ₂ O
		0,8	1,5	2,0	2,5			
		weight [%]						
1	P/C/1D	75	-	-	-	10	5	10
2	P/C/2D	-	75	-	-	10	5	10
3	P/C/3D	-	-	75	-	10	5	10
4	P/C/4D	-	-	-	75	10	5	10
5	P/C/1	100	-	-	-	-	-	-
6	P/C/2	-	100	-	-	-	-	-
7	P/C/3	-	-	100	-	-	-	-
8	P/C/4	-	-	-	100	-	-	-

From the mixtures the 12 x 8 mm pastilles were made by pressing at a pressure of 1kN. The samples were exposed for sulphate attack.

Table 2. Composition of pastes produced from CSH of variable C/S ratio, cured in hydrothermal conditions within 24 hours of the autoclaved process.

No	Sample	Composition of samples						
	code	C/S ratio in CSH phase				CaCO ₃	Ca(OH) ₂	Na ₂ SO ₄ ·10H ₂ O
		0,8	1,5	2,0	2,5			
		weight [%]						
1	P/24/1D	75	-	-	-	10	5	10
2	P/24/2D	-	75	-	-	10	5	10
3	P/24/3D	-	-	75	-	10	5	10
4	P/24/4D	-	-	-	75	10	5	10
5	P/24/1	100	-	-	-	-	-	-
6	P/24/2	-	100	-	-	-	-	-
7	P/24/3	-	-	100	-	-	-	-
8	P/24/4	-	-	-	100	-	-	-

2.3. Conditions of curing

The CSH pastes doped with CaCO₃, Ca(OH)₂ and Na₂SO₄ were divided into two testing series and stored at two different temperature ranges [15,16,17]:

- I: $5 \pm 1^{\circ}\text{C}$ range
- II: $20 \pm 2^{\circ}\text{C}$ range.

The samples were stored in sealed containers at 95% RH. The testing took place after: 28, 90, 180, 270 and 360 days.

3. RESULTS

The effect of CaCO₃, Ca(OH)₂ and Na₂SO₄ additions used for preparation of CSH phases (with variable C/S ratio from 0,8 to 2,5) and conditions of curing (low temperature, autoclaving) on the formation of thaumasite were estimated based on the results produced by SEM – EDS, XRD and IR spectroscopy.

The results presented here show the effect of CaCO₃, Ca(OH)₂ and Na₂SO₄ additives, as well as curing temperature after 360 days storage. SEM observations reveal the crystallization of fibre – like form [Figures 1a, 2a] in samples doped with CaCO₃, Ca(OH)₂ and Na₂SO₄ with C/S ratio 1,5 and stored at temperature 5⁰C, regardless of the the origin of the CSH phase (produced at ambient temperature or by autoclaving) [19].

The crystallization takes place in the regions of cracks, gaps and voids. EDS analysis proves the thaumasite's character of these forms [Figures 1b, 2b].

a) Crystallization of fibre – like thaumasite forms

b) EDS analysis of thaumasite crystals (with incorporated Na from Na_2SO_4)

Figure 1. SEM-EDS. Sample (P/C/2D) - C/S ratio 1,5 doped with CaCO_3 , $\text{Ca}(\text{OH})_2$ and Na_2SO_4 , stored at 5°C , after 12 months curing.

a) Crystallization of fibre – like thaumasite forms

b) EDS analysis of thaumasite crystals

Figure 2. SEM-EDS. Sample (P/24/2D) - C/S ratio 1,5 doped with CaCO_3 , $\text{Ca}(\text{OH})_2$ and Na_2SO_4 , stored at 5°C , after 12 months curing.

Crystallization of similar product was observed in CSH samples with C/S ratio 2,0 doped with CaCO_3 , $\text{Ca}(\text{OH})_2$ and Na_2SO_4 and stored at 5°C [Figures 3a, 4a]. Also in this case, chemical analysis by EDS proved the thaumasite-like character of these forms [Figures 3b, 4b].

b) EDS analysis of thaumasite crystals

Figure 4. SEM-EDS. Sample (P/24/3D) - C/S ratio 2,0 doped with CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C , after 12 months curing.

Crystallization of fibre – like forms in samples produced at C/S ratio 2,5 with addition of CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at temperature 5°C shows the presence of better crystallized products [Figures 5a, 6a]. The EDS chemical analysis proves the thaumasite-like character of these forms in these samples [Figures 5b, 6b].

a) Formation of better crystallized products

b) EDS analysis of thaumasite crystals

Figure 5. SEM-EDS. Sample (P/C/4D) - C/S ratio 2,5 doped with CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C , after 12 months curing.

a) Formation of better crystallized products

b) EDS analysis of thaumasite crystals

Figure 6. SEM-EDS. Sample (P/24/4D) - C/S ratio 2,5 doped with CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C , after 12 months curing.

The crystallization of thaumasite-like forms took place in areas of voids, cracks and gaps. SEM observations of CSH samples (C/S ratio 0,8 with additions of CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C), in which fibre – like forms were not observed in cracks, gaps and voids, shows CSH phase and local crystallization of portlandite [Figures 7a, 8a], as identified by EDS [Figures 7b, 8b].

a) CSH phase without any crystallization

b) EDS analysis of these form

Figure 7. SEM-EDS. Sample (P/C/1D) - C/S ratio 0,8 doped with CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C , after 12 months curing.

a) Crystallization of portlandite

b) EDS analysis of these form

Figure 8. SEM-EDS. Sample (P/24/1D) - C/S ratio 0,8 doped with CaCO_3 , Ca(OH)_2 and Na_2SO_4 , stored at 5°C , after 12 months curing.

The XRD data for the samples cured for 360 days were compared to those for the samples cured at shorter times, 90 and 180 days respectively. The intensities of peaks decreased less or more, the peaks of Na_2SO_4 completely disappeared after 360 days storage at 5°C . Simultaneously an increase of $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ content with time was observed, for the samples with lower C/S ratio. In the samples produced at higher C/S ratio the portlandite residue was observed all the time, while in those with low C/S ratios calcium hydroxide was significantly consumed.

The XRD data in each case indicate the formation of thaumasite [19].

The IR spectroscopy results for the samples cured for 360 days, compared to the control samples, show the analogous changes in the intensity of bands attributed to SO_4^{2-} and OH^- groups from $\text{Ca}(\text{OH})_2$ structure as the XRD results.

4. CONCLUSIONS

The synthesised CSH phase, produced in this work was characterised by variable C/S ratio from 0,8 to 2,5. A variety of cements used in concrete production was a circumstance which decided about carrying out the research on the C-S-H of C/S variable in a wide range.

SEM observations confirm the presence of fibre – like forms in CSH of C/S ratio = 1,5; 2,0 and 2,5, doped with CaCO_3 , $\text{Ca}(\text{OH})_2$ and Na_2SO_4 and stored at 5°C . XRD and EDS analysis proves the thaumasite-like character of these products.

The SEM observations of C-S-H samples show also the consequences of volume changes - cracks and scratches in which thaumasite fibrous forms are deposited. The cracks and scratches appear in samples stored in 5°C .

The results of XRD analysis show also that in the samples containing CSH doped CaCO_3 , $\text{Ca}(\text{OH})_2$ and Na_2SO_4 and stored in 5°C the calcite, gypsum and portlandite are detectable apart from the thaumasite.

There are no differences between the two series of samples – one produced initially at ambient temperature and the second synthesized in hydrothermal conditions. Finally, the results presented above seem to indicate that the ettringite is not necessary for the formation of thaumasite.

ABSTRACT

In this study a radiotracer-based method is applied to follow the chloride transport in mortar and cement paste samples. Portland, blast furnace and limestone cements are used to cast prisms that, after curing, are sliced in 2.5 mm thick samples and then covered with a wax layer on all sides - except one. The samples are then put in contact with a ³⁶Cl-labelled NaCl solution. After a given time the samples are taken out of the solution and, after complete removal of the wax layer, placed on a beta particle sensitive film for the autoradiography. Densitometry, i.e. measurement of the degree of blackening of the film can provide qualitative and quantitative data on the two-dimensional diffusion profile attained.

1. INTRODUCTION

One of the problems affecting the durability of reinforced concrete structures is the corrosion of the steel bars. Normally these are protected from corrosion by a microscopic oxide layer which forms on the surface of the bars due to the high alkalinity (pH = 13) of concrete. The protecting layer can disappear due to the carbonation of the surrounding concrete, i.e. the reaction between Ca(OH)₂ and CO₂, which causes acidification. Another factor that contributes to the destruction of the film is the reaction with free chloride ions dissolved in the pore water. In the presence of water and oxygen this causes corrosion, due to electrochemical between iron ions, water and oxygen [1]. The source of chlorides in concrete may be internal or external. In the former and less common case, the chlorides are present from the moment of mixing. This is the case if chloride containing mixtures are added to the concrete (e.g. CaCl₂ is added to accelerate the setting and hardening), or if seawater or beach aggregates are used in the concrete. Nevertheless the most common source of chloride ions is external. This is in roads and highways in cold countries where de-icing salts are applied. Another situation where chloride ions are abundant is in the marine environment. Here the structures may be situated partly below the sea level and partly above it. The breaking of the waves and the periodic tides gives rise to a situation characterised by cycles of wetting (increasing the amount of the reactant water), and drying (increasing the amount of the reactant oxygen), that form an ideal environment for the corrosion of the steel bars [2][3].

In order to predict the durability of concrete structures it is helpful to evaluate the diffusion of chloride ions in such structures. This is normally done by sample destruction followed by chemical analysis of the portions of interest [4]. In this study a radiotracer-based method is applied to follow the chloride transport in mortar and cement paste samples.

2. EXPERIMENTAL

2.1 Materials and Specimens

2.1.1 Materials

Ordinary Portland Cement (CEM I 32.5 R), Blastfurnace Slag Cement (CEM III/B 42.5 LHHS) and Limestone Cement (CEM II/A-L 42.5 R) were used in making mortars and only Ordinary Portland Cement (CEM I 32.5) was used in making cement paste. The sand used in mortars was 2 mm maximum aggregate size standard sand according to the EN 196/1-ISO 679 norm and the mixing water was demineralized water. Cement, sand and mixing water were at laboratory temperature. The water/cement ratio was 0.5 and the aggregate /cement ratio was 3.

2.1.2 Test specimen preparation

The preparation of the mortars followed the EN 196/1-ISO 679 norm. The samples, cast in moulds soon after the preparation of the mortar and cement paste, were prisms having dimensions of 40mm x 40mm x 160mm. After 24 hours stored in a wet environment the prisms were demoulded and cured in water for 60 days. After curing, the prisms were sliced in 45mm x 40mm x 2.5mm specimens by means of a diamond saw cooled with water.

A total number of 30 test specimens were produced: 9 mortar specimens for each cement type and 3 cement paste specimens with Portland cement. The mortar and cement paste slices were then smoothed with water on a grinding machine in order to reach a constant thickness all along the specimen and then vacuum saturated with the same water in which they were cured. The specimens were kept under water until their sealing with wax. Each test specimen was coated by dipping for a few seconds in melted wax and then left in a controlled chamber at 20°C to let the coating become hard and not sticky any longer. Once the coating was hard enough the test specimens were taken out of the controlled chamber and the wax was removed from one of their sides by grinding it on sandpaper with water. The prepared specimens were then kept, till the beginning of the test, with the wax-free side in water to prevent evaporation.

2.1.3 Labelled solution preparation

The problem of diffusion of chloride ions arises mainly in structures exposed to saline environment therefore a sodium chloride solution was prepared by dissolving 3.5 g of analytical grade NaCl in 100 ml of distilled water to make up a solution that would produce an equivalent chloride ion concentration to that of sea water. The advantage over seawater is the absence of sulphates, which could react with the tri-calcium aluminates instead of chloride.

Once the sodium chloride solution 3.5% (w/w) was prepared, ^{36}Cl in negligible quantity (^{36}Cl = 0.08% of inactive NaCl) was added as the radioactive tracer. ^{36}Cl is a long-lived radioisotope ($T_{1/2}$ = $3.5 \cdot 10^5$ a) decaying by emitting β^- radiation with a maximal energy of 0.7 MeV. The activity (number of radioactive nuclei in a unit of time) of the solution was 11.5kBq/ml. For each experiment 10 ml of this solution were used, with a total activity of 115 kBq.

2.2 Techniques and procedures

2.2.1 Autoradiography method

Autoradiography is a radiochemical technique that is often applied to physiological and medical studies on living organisms. Nevertheless it also finds large application in non-living systems where a measure of the localisation of the radionuclide tracers is required. Autoradiography is based on the production of an image of the radioactive source on a photographic emulsion, which is a suspension of silver bromide crystals in gelatine. The interaction between the silver bromide and the nuclear radiation produces ionisation of the silver bromide crystals. This provides electrons that are free to travel from one ion to another until they are trapped at defects within the silver bromide crystal structure. At a structural defect a silver ion absorbs the electron and becomes a silver atom. The crystals containing silver atoms become visible after the application of the chemical developer. This reduces all the silver atoms formed to metallic silver, which is characterised by a black colouring. In contrast, the crystals that did not undergo the above-described modification are washed out of the emulsion by the chemical fixer solution. The whole process results in a black-coloured image of the radioactive source [5].

2.2.2 Test procedure

The experiments were performed in 10 glass boxes, each containing three specimens held by a PETG grid to keep the samples separated from each other and suspended vertically in the solution. The right volume (10 ml) of labelled solution was poured into the glass boxes in order to allow contact between the solution and the sample only at the lower side of the sample free of the wax layer. Each box was sealed with a glass cap and two foils of self-sealing Parafilm “M” laboratory film (American National Can) to prevent solution evaporation. Three contact times, during which the specimens were immersed in the labelled solution, were chosen: 14 days, 33 days and 55 days. For each contact time three mortar samples (one for each cement) and one cement paste sample were taken out of the solution and, after removal of the wax layer, placed on a photographic film for the autoradiography. The beta radiation emitted by Cl-36 close to the sample surface interacts with the film emulsion, giving rise to blackening of the film that becomes visible after its development. Darker parts of the image indicate higher Cl-36 i.e. chloride ion concentration in the layer adjacent to the sample surface (Figures 1-2).

Figure 1. Autoradiography of cement mortar after 14, 33 and 55 days in labelled solution

Figure 2. Autoradiography of cement paste after 14, 33 and 55 days in labelled solution

The images produced on the films were analysed as a grey scale using a computerised image process. Calibrating the grey level (degree of blackening) it would be possible to extract quantitative data on the amount of chloride that is diffused in the samples.

3. RESULTS AND DISCUSSION

3.1 Autoradiographic image analysis

By means of the autoradiography method 4 films were produced for each contact time, considering four different exposure time of the same set of samples to the beta particle sensitive film. Each film was scanned by means of a UMAX Mirage 2 scanner according to the scheme reported in Figure. 3.

Figure 3. Scheme of the 12 films produced by exposing three set of samples to beta particle sensitive film for four different exposure time

The films were analysed by means of an in-house developed software, that could acquire the autoradiographic images of the samples according to the scale of greys of different intensity and respectively associated to numerical values ranging between 1 and 256.

The images thus produced showed both the different intensity of grey corresponding to the different chloride activity and the penetration depth of the chloride front.

Once the images had been acquired in grey scale, there was the need to find a calibration curve that could associate a value of activity of the penetrated chlorine to each grey value. For this purpose the cement paste sample, immersed in solution for 55 days, was taken as a reference.

The 55 days of immersion in the labelled solution ensured the maximum value of activity (and then the maximum value of grey) reached, while the cement paste ensured a more precise calibration curve owing to the lack of aggregate.

3.2. Calibration curve

3.2.1 Theoretical basis

The grey values are a measure of the reaction (blackening) of the film to the energy absorbed by the film itself, namely the dose.

This energy absorbed by the film (i.e. dose) is proportional to the number of radioactive nuclei decaying in a unit of time (i.e. activity) and to the exposure time of the film to this activity (i.e. to the time that the film is exposed to the radioactive sample). Since the activity is directly proportional to the chloride concentration, it is clear that the dose is a direct measure of the chloride concentration itself. Note, then, that the relative dose is equivalent to the relative concentration. The calibration curve was obtained with a computer program on the following basis:

Given:

$G_{i,j}$ - grey values taken from the calibration images (four images of the cement paste CP sample with different photo exposure time and equal solution exposure i.e. the contact time, preferably the largest solution exposure time)

i - index of the given location (horizontal stripe of averaging) in the image (i.e. different i correspond to different dose rates)

j - index of the applied film exposure time ($j = [1..4]$)

t_j - film exposure time

Unknown:

d_i - dose rate at the given location of cement paste CP

$D_{i,j}$ - exposed dose at the location i of cement paste sample after the film exposure time t_j

For the dose holds:

$$D_{i,j} = t_j \cdot d_i \quad (1)$$

The dose should be a well-defined function of the grey value. Since we believe that a zero grey value corresponds to zero dose, we assume a polynomial:

$$D = \sum_{k=1}^{n_a} a_k \cdot G^k \quad (2)$$

To adapt the coefficients a_k we can use all available measuring information $G_{i,j}$ and t_i .

Unfortunately, D is unknown. For an optimal approximation we apply the "minimum of the sum of the error squares" criterion:

$$\sum_{i,j} \left(t_j \cdot d_i - \sum_{k=1}^{n_a} a_k G_{i,j}^k \right)^2 \rightarrow \min \quad (3)$$

Since d_i is unknown, we must treat these values as variables during the minimum search according to (3), i.e. they have the same quality as the coefficients a_k . To linearize (3), we must introduce a new function $T_{k,j}$:

$$T_{k,j} = \begin{cases} t_j & \text{if } k = i \\ 0 & \text{if } k \neq i \end{cases} \quad (4)$$

With this substitution, eq. (3) takes the form:

$$\Psi = \sum_{i,j} \left(\sum_{k=1}^{n_d} d_k \cdot T_{k,j} - \sum_{k=1}^{n_a} a_k G_{i,j}^k \right)^2 \rightarrow \min \quad (5)$$

To find the minimum, derivatives of eq. (5) have to be found:

$$\frac{\partial \Psi}{\partial d_m} = \sum_{i,j} T_{m,j} \cdot \left(\sum_{k=1}^{n_d} d_k \cdot T_{k,j} - \sum_{k=1}^{n_a} a_k G_{i,j}^k \right) = 0 \quad (6)$$

$$\frac{\partial \Psi}{\partial a_m} = \sum_{i,j} G_{i,j}^m \cdot \left(\sum_{k=1}^{n_d} d_k \cdot T_{k,j} - \sum_{k=1}^{n_a} a_k G_{i,j}^k \right) = 0 \quad (7)$$

After changing the order of the summations in (6) we get:

$$\frac{\partial \Psi}{\partial d_m} = \sum_{k=1}^{n_d} d_k \cdot \sum_j T_{m,j} \cdot T_{k,j} - \sum_{k=1}^{n_a} a_k \cdot \sum_{i,j} T_{m,j} \cdot G_{i,j}^k = 0 \quad (8)$$

Here, according to (4) all products of $T_{m,j} \cdot T_{k,j}$ for $k \neq m$ are equal zero. The same is true for $T_{m,j} \cdot G_{i,j}^k$, when $i \neq m$:

$$\frac{\partial \Psi}{\partial d_m} = d_m \sum_j t_j^2 - \sum_{k=1}^{n_a} a_k \cdot \sum_j t_j \cdot G_{m,j}^k = 0 \quad (9)$$

After changing the order of the summations in (7) we get:

$$\frac{\partial \Psi}{\partial a_m} = \sum_{k=1}^{n_d} d_k \sum_j G_{k,j}^m \cdot t_j - \sum_{k=1}^{n_a} a_k \sum_{i,j} G_{i,j}^m \cdot G_{i,j}^k = 0 \quad (10)$$

The linear system of equations to be solved looks like follows:

$$\begin{pmatrix} \sum_j t_j^2 & 0 & \dots & 0 & \sum_j t_j G_{1,j} & \sum_j t_j G_{1,j}^2 & \dots & \sum_j t_j G_{1,j}^{n_a} \\ 0 & \sum_j t_j^2 & \dots & 0 & \sum_j t_j G_{2,j} & \sum_j t_j G_{2,j}^2 & \dots & \sum_j t_j G_{2,j}^{n_a} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \sum_j t_j^2 & \sum_j t_j G_{n_d,j} & \sum_j t_j G_{n_d,j}^2 & \dots & \sum_j t_j G_{n_d,j}^{n_a} \\ \sum_j t_j G_{1,j} & \sum_j t_j G_{2,j} & \dots & \sum_j t_j G_{n_d,j} & \sum_{i,j} G_{i,j}^2 & \sum_{i,j} G_{i,j}^3 & \dots & \sum_{i,j} G_{i,j}^{n_a+1} \\ \sum_j t_j G_{1,j}^2 & \sum_j t_j G_{2,j}^2 & \dots & \sum_j t_j G_{n_d,j}^2 & \sum_{i,j} G_{i,j}^3 & \sum_{i,j} G_{i,j}^4 & \dots & \sum_{i,j} G_{i,j}^{n_a+2} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \sum_j t_j G_{1,j}^{n_a} & \sum_j t_j G_{2,j}^{n_a} & \dots & \sum_j t_j G_{n_d,j}^{n_a} & \sum_{i,j} G_{i,j}^{n_a+1} & \sum_{i,j} G_{i,j}^{n_a+2} & \dots & \sum_{i,j} G_{i,j}^{2n_a} \end{pmatrix} \cdot \begin{pmatrix} d_1 \\ d_2 \\ \vdots \\ d_{n_d} \\ a_1 \\ a_2 \\ \vdots \\ a_{n_a} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ 0 \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (11)$$

The determinant of the main matrix is zero. Since the constant vector is also zero, the system is underdetermined and one of the variables can be freely chosen. This reduces the order by 1. I choose $d_1 = 1$. This means that the result will be not the absolute dose but the dose relative to a chosen value (in our case to d_1). In this case, the system reduces to:

$$\begin{pmatrix} \sum_j t_j^2 & 0 & \dots & 0 & \sum_j t_j G_{2,j} & \sum_j t_j G_{2,j}^2 & \dots & \sum_j t_j G_{2,j}^{n_a} \\ 0 & \sum_j t_j^2 & \dots & \dots & \dots & \dots & \dots & \dots \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \sum_j t_j^2 & \sum_j t_j G_{n_d,j} & \sum_j t_j G_{n_d,j}^2 & \dots & \sum_j t_j G_{n_d,j}^{n_a} \\ \sum_j t_j G_{2,j} & \dots & \dots & \sum_j t_j G_{n_d,j} & \sum_j G_{i,j}^2 & \sum_j G_{i,j}^3 & \dots & \sum_j G_{i,j}^{n_a+1} \\ \sum_j t_j G_{2,j}^2 & \dots & \dots & \sum_j t_j G_{n_d,j}^2 & \sum_j G_{i,j}^3 & \sum_j G_{i,j}^4 & \dots & \sum_j G_{i,j}^{n_a+2} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \sum_j t_j G_{2,j}^{n_a} & \dots & \dots & \sum_j t_j G_{n_d,j}^{n_a} & \sum_j G_{i,j}^{n_a+1} & \sum_j G_{i,j}^{n_a+2} & \dots & \sum_j G_{i,j}^{2n_a} \end{pmatrix} \begin{pmatrix} d_2 \\ \vdots \\ d_{n_d} \\ a_1 \\ a_2 \\ \vdots \\ a_{n_a} \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ -\sum_j t_j G_{1,j} \\ -\sum_j t_j G_{1,j}^2 \\ \vdots \\ -\sum_j t_j G_{1,j}^{n_a} \end{pmatrix} \quad (12)$$

This system can be solved. In the result the relative dose rates $d_2 - d_{n_d}$ and the coefficients for the polynomial approximation are obtained. The dose rates are related to the arbitrarily chosen value for d_1 (i.e. $d = 1$).

3.2.2. Discussion

In the following graph the result of the polynomial approximation according eq. (2) for an order of 3 (three coefficients) is shown (Figure 4). From the image of sample CP, 125 successive pixel lines starting from line number 20 (maximum exposure) were evaluated. The points at the graph are products of relative dose rate multiplied by the photographic exposure time plotted over the corresponding grey value, i.e. $D_{i,j} = t_j \cdot d_i = f(G_{i,j})$, where d_i is a result of solving the system of eq. (12), and $d_1 = 1$.

Figure 4. Polynomial approximation for an order of three

The influence of the order is illustrated in the following figure:

Figure 5. Different influence of the order

Here, the points are taken from the result for fifth order, just the lines are corresponding to different orders. Since the correction of the dose rates for the individual points is done applying the calculated values of d_i , the location of the individual measuring points at the plot differs for different orders (Figure 6).

Figure 6. Comparison between order 1 and order 5

3.3 Results

The resulting relative dose curve (relative concentration curve) could be fitted with a polynomial of the 5th order. The equation obtained, linking the relative dose (or relative concentration) to the grey values, can be used now for all the other samples in order to get directly the relative concentration

curve, once the grey values are known by means of the software already mentioned. Therefore, for the cement paste sample taken as reference, the graph relating the relative dose to the penetration depth of the chloride can be seen in Figure 7.

Figure 7. Influence of exposure time on chloride ingress. The exposure time in days is marked on the curves

A diffusion coefficient of about $2 \cdot 10^{-12} \text{ m}^2/\text{s}$ corresponds to the curves represented in the above graph (Figure 7).

4. CONCLUSIONS

The use of a radioactive chloride isotope offers the possibility of performing non-destructive measurements of the evolving chloride distribution within the samples locally exposed to aqueous sodium chloride solution (3.5 % NaCl). The present method has a number of advantages if compared with the current methods for chloride analysis, namely (1) it is a non-destructive technique; (2) it provides two-dimensional chloride diffusion profiles; (3) the spatial resolution is less than 1 mm; (4) it offers the possibility of using small samples because of high spatial resolution i.e. short diffusion lengths are sufficient; (5) it is less labour intensive as compared with other methods; (6) the developed autoradiographic films remain available for further investigations and for placing on document files.

ABSTRACT

The demand for concrete that uses superplasticizer has increased in recent year, accompanying the diversification and the advances of concrete technology in the field of civil engineering. The most important superplasticizers are those that containing polycarboxylate-based dispersants (PCs) as their main component. The superplasticizers exhibit high dispersibility at low dosages and provide excellent slump retention. Much has been done on the adsorption and the dispersing properties of PC-based superplasticizers.

In this present paper, we studied 1) the relationship between the chemical structure of PC and dispersibility or dispersibility retention, and 2) the adsorption property of PC on inorganic fine particles such as cement particles. Furthermore, we describe some applications of PC-based superplasticizers.

1. INTRODUCTION

In recent years, with the expansion of the scale and application range of concrete construction, concomitantly new materials and new ways of execution have been developed. Therefore, features like high flowability, high strength, high durability, etc. were also required for performance. To satisfy such demands, chemical admixtures are essential. The importance of superplasticizers that have a high water reducing effect and good flowability retention is especially great

There are various types of dispersants such as β -naphthalene sulfonate formalin condensate (NS), melamine sulfonate formalin condensate (MS), aromatic aminosulfonic acid polymers (AS) and polycarboxylate-based polymers (PC), etc. as the main components of superplasticizers.

Especially, PCs draw attention as main components of superplasticizers, because they have high dispersibility at small dosage, and it is possible even to improve dispersibility and dispersibility retention by controlling the molecular structure.

In this paper, we focused on PCs as the main components of superplasticizers. We investigated the relationship between chemical structure and dispersibility or dispersibility retention. Furthermore, we studied the adsorption property of PC on inorganic fine particles.

2. EXPERIMENT

2.1 Materials

2.1.1 Dispersant

Polycarboxylate-based dispersants (acrylic acid-based: PC-1, 2, 3 and 4), a dispersing component in polycarboxylate-based superplasticizers, were used. Figure 1 shows the chemical structures and monomer ratio of PC polymers.

Figure 1. Chemical structure and monomer ratio of PC polymers

2.1.2 Inorganic fine particles

Ordinary Portland cement, two types of blast furnace slag (BF: specific surface area: 4000 and 10000 cm²/g) and three types of limestone powders (LS: specific surface area: 4700, 11000 and 20000 cm²/g) were used. Table 1 shows the chemical composition of the fine particles.

Table 1. Specific surface area and chemical components of fine particles

Fine Particles		Specific gravity	Specific surface area *	ig. loss	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	CaCO ₃
		g/cm ³	cm ² /g								
Mass %											
Cement	OPC	3.15	3160	0.6	21.6	5.3	2.3	64.5	2.1	1.8	-

* by Blaine method

2.2 Experimental method

2.2.1 Adsorbed amount

Paste with Water/Powder = 35% was mixed for 3 minutes with an ASTM mortar mixer. A suction filter filtered off the liquid phase. The organic carbon content in the filtrate was determined with a total organic carbon analyser (Shimadzu TOC 5000). The amount of dispersant adsorbed onto the fine particles (apparent adsorbed amount) was calculated by subtracting the dispersant amount calculated from the carbon content in the filtrate, from the dosage of dispersant.

The number of adsorbed PC molecules was estimated by calculating the adsorbed amount per unit area based on the BET specific surface area value, and subtracting the Avogadro number from the molecular weight of the dispersant polymer.

2.2.2 Measurement of root mean square radius (RMS radius)

RMS radius was measured by a light scattering instrument (DAWN-F; Wyatt Technology) connected to a GPC system. Tests were conducted in neutral and alkali (pH=11.0 by NaOH) environments.

2.2.3 Specific surface area

We produced plain paste and paste containing PC-3 at the dosage of 0.15% of powder weight, with W/C = 35%. Three minutes after the fine particles contacted the water, the paste was dispersed in acetone to stop further hydration. The liquid phase was filtered off with a suction filter and washed with acetone several times, then dried for 24 hours at 40°C to prepare specimens.

The specific surface area by the BET method was found for the processed specimens and non-hydrated fine particles from measurements with a gas-flow automatic specific surface area measuring device (Shimadzu Flowsorb 2300).

3. RESULTS AND DISCUSSIONS

3.1 Relation between chemical structure and dispersing effect

3.1.1 Adsorbed amount of PC polymers on the surface of OPC

The relation of dosage and adsorbed amount on the surface of OPC of PC polymers are shown in Figure 2. The adsorbed amount of PC-1 to 3 tended to increase as dosage of PC polymers increased. However, the adsorbed amount of PC-4 did not increase so much when dosage increased.

Figure 2. Relation between adsorbed amount and dosage

3.1.2 RMS radius of PC polymers

Figure 3 shows the RMS radius of PC polymers in neutral and alkali environments. In an alkali environment, the RMS radius of PC-2 and 3 which have low graft density increased compared with a neutral environment. However, in neutral and alkali environments, the RMS radius of PC-1 and PC-4 which have high graft density did not differ very much.

Figure 3. Cumulative RMS radius distribution

3.1.3 Dispersibility and dispersibility retention of PC polymers

Figure 4a) shows the relationship between the dosage and dispersibility in OPC mortar. In the figure, 100% on Y-axis indicates the flowability of plain mortar. The flowability of PC polymer modified mortar increased as the dosage increased. The flowability of PC-2 (long graft length, small number of grafts) increased most.

Figure 4b) shows the change in flowability over time. The flowability of mortar containing PC-4 does not change immediately after mixing and retains it at the age of 60 minutes. This is attributed to structural characteristics (long graft length, large number of grafts) of the PC polymer.

Figure 4. Dispersibility and dispersibility retention of PC polymers

3.1.4 Structural factors causing high dispersibility and long retention

Based on these results, Table 2 shows the structural factors of polymers in relation to dispersibility and dispersibility retention. In cases of low dispersibility and short dispersibility retention, the trunk polymer is long, the graft polymers are short, and the relative number of grafts is large. In the event of high dispersibility, the trunk polymer is short, the graft polymers are long, and the relative number of grafts is small. In cases of long dispersibility retention, the trunk polymer is even shorter, the graft polymers are long, and the relative number of grafts is large.

Table 2. Structural factors causing high and long dispersibility retention

Structural factor Dispersibility	Relative chain length of trunk polymer	Relative graft length	Relative number of grafts
Low dispersibility and short dispersibility retention	Long	short	Large
High dispersibility	Short	Long	Small
Long dispersibility retention	Shorter	Long	Large

As shown in Table 2, we can control dispersibility and its retention immediately after mixing by varying the balance of length of the trunk polymer and length of grafts with regard to their quantitative ratio.

3.2 Adsorption properties of PC polymers on inorganic fine particles

3.2.1 Molecular size of PC polymer

The size of the PC-3, which is the general type of PC polymers was calculated based on the chemical structure and molecular weight of the PC polymer. The length of C-C-C in the main chain was assumed to be 2.51 Å, which is the maximum stretched length of 3 carbon atoms according to the literature [4]. The length of an ethylene glycol side chain, according to the literature [4], is 19.5 Å for a 7-unit chain elongated in a stable conformation. The length of the trunk polymer when stretched to its maximum length was calculated to be 20 nm, with a side chain length of 7 nm (Figure 5 (a)) by Figure 1 ($n+m=70$).

Figure 5. Stable conformation and thermodynamic effective volume of PC-3

When PC-3 is adsorbed onto the particle surface of the cement material, most side chains face into the water. The size of the dispersant at that time is presumed to be as shown in Figure 5 (a). The volume occupied by the molecule when it freely moves is equivalent to a column 7 nm in thickness and 20 nm in diameter: the effective thermodynamical volume of the column is equivalent to the volume of a cylinder with a diameter of 20 nm and a height of 7 nm (Figure 5 (b)) [5]. Due to the size of the molecule stretched to its full length, based on the molecular weight of the polycarboxylate-based dispersant, it is considered that one dispersant polymer occupies the volume of a cylinder with 20 nm in diameter and 7 nm high, excluding other molecules. Thus, one adsorbed polymer occupies 314nm^2 and at saturation adsorption the density of adsorption is believed to be one molecule of dispersing polymer molecule, allowing for packing considerations, per 400 nm^2 of the binding material surface (Figure 5 (b))[6].

3.2.2 Specific surface area of various inorganic fine particles

Table 3 shows the results of specific surface area measurement of particles by the BET method after water contact. The specific surface area of OPC before water contact was $0.71\text{ m}^2/\text{g}$. However, three minutes after water contact, the specific surface area of plain OPC (without PC-3) increased to $1.04\text{ m}^2/\text{g}$, that is, 1.5 times; and that of OPC containing PC-3 increased up to $1.29\text{ m}^2/\text{g}$, that is, 1.8 times of that of non-hydrated OPC. On the other hand, the specific surface areas of less active BF and LS do not increase due to water contact.

Table 3. Specific surface area of several fine particles

Inorganic fine particles		Specific surface area		
		Before contact with water	3min. after from contact with water	
Cement	OPC	0.71	Without PC	With PC
			1.04	1.29
Blast furnace slag	BF-4000	0.87	0.89	0.90
	BF-10000	2.37	2.40	2.42
Lime-stone powder	LS-4700	1.03	1.04	1.03
	LS-11000	2.45	2.44	2.46
	LS-20000	4.06	4.07	4.08

3.2.3 Amount of PC-3 adsorbed on various inorganic fine particles

Table 4 shows the measurements of adsorption amount converted into unit weight and unit surface area, to various binding materials when the dosage of dispersing agent was fixed at 0.15% of the mass of binding material. In this paper, adsorption amount is related to the specific surface area after water contact when PC-3 was the fine powder.

3.2.4 Adsorbed number and occupied area of PC-3

Based on the adsorbed amount per unit surface area, and the molecular weight of the dispersant, a number of adsorbed PC-3 molecules per unit area of fine particles were calculated.

$$A = B / Mw \times N_A \quad (1)$$

Where A: adsorbed number of PC-3 per unit area

B: adsorbed amount of PC-3 per unit area

N_A : Avogadro number = 6.02×10^{23}

Mw: Weight-average molecular weight

Results are given in Table 4. The numbers of dispersant molecules adsorbed per unit area varied with the type of binding material. Adsorbed number on the unit surface area differs with the type of binding materials and the number of PC-3 per 100nm^2 surface area of OPC and BF are almost equal to 1.5, while that of LS is 0.8.

Table 4. Adsorbed amount of PC-3 on various fine particles

Inorganic fine particles		Adsorbed amount		Adsorbed ^{*1} number (N/100nm ²)	Area occupied per molecule (nm ²)
		per unit weight (mg/g)	per unit ^{*1} area (mg/cm ²)		
Cement	OPC	0.84	0.65	1.51	66.2
	Blast furnace slag	0.70	0.78	1.81	55.2
Limestone powder	BF-4000	1.25	0.52	1.21	82.6
	LS-4700	0.38	0.37	0.86	116.3
	LS-11000	0.91	0.37	0.86	116.3
	LS-20000	1.48	0.36	0.83	120.5

*1 Specific surface area of contact with water including PA

$$W=100/A$$

Where W: occupied area

A: adsorbed number of PC-3 per 100nm^2

Results are given in Table 4. In OPC and BF, occupied area per PC-3 molecule is approximately 70nm^2 but in LS, this area is approximately 120nm^2 .

3.2.5 Adsorbed conformation of PC-3 on the surface of various fine particles

When PC-3 extends to full length, the length of the main chain is approximately 20nm : one molecule of PC-3 therefore occupies an area of 314nm^2 . However, we presumed that real fine particles form fractal surface structures, and the adsorbing form of PC-3 cannot conform to it and consequently, requires a larger area.

On the contrary, the occupied area of one PC-3 molecule in the case of OPC and BF is approximately 70nm^2 , and in the case of LS is approximately 120nm^2 . If it is presumed that they

adsorb, the diameters of their thermodynamically effective volume are approximately 9nm and 12nm, respectively.

It was previously reported that the measurement results of the root mean square (RMS) radius of the molecule by a light scattering method indicates that the PC-3 polymer shrinks by about 60% as the sulfate ion concentration increases [7].

However, the length of PC-3 main chain is reduced by OPC and BF to 45% of its original length, and shrunk to 60% by LS, which does not contain sulfate ions. The reasons for the shrinkage of the polymer due to the effects of sulfate ions or other factors that reduce the thermo-mechanical effective volume are suggested, as follows:

- As seen in Figure 6 (b), the thermodynamically effective volumes of PC-3 overlap.
- As seen in Figure 6 (c), the thermodynamically effective volume of PC-3 is pressed, and PC-3 absorbs in an elongated form.

Figure 6. Various adsorbed configurations of PC-3

4. APPLICATIONS OF PC POLYMERS IN CONCRETE

Based on these mechanisms, we can control the dispersibility and dispersibility retention of concrete containing PC polymer based superplasticizers by controlling the balance of the length of the trunk polymer and the length of grafts.

We show two application examples of PC-based superplasticizer in concrete. One relates to high flowable concrete, using low heat Portland cement and limestone powder, another to ultra-high strength concrete using low heat Portland cement and silica fume.

4.1 High flowable concrete

Showing a demand performance and a mixing proportion in Table 5. To satisfy the demand performance, superplasticizer (SP-1) that combined PC-3 that shows high dispersion and PC-4 that has good dispersion maintenance was used.

Table 5. Demand performance and mixing proportion of high flowable concrete

Demand performance		Mixing proportion						
Slump Flow immediately after mixing	Slump flow after 90 min.	W/C (%)	s/a (%)	Unit weight (kg/m ³)				
				Water	Cement	Limestone powder	Sand	Coarse aggregate
65 ± 5 cm	65 ± 5 cm	45	49	165	367	150	821	853

The change of concrete flow with time is shown in Figure 7. It is clear from Figure 7 that it becomes possible to retain high dispersion for a long time by combining the dispersion ability of PC-3 and the dispersion maintenance ability of PC-4.

Figure 7. Change of slump flow

4.2 Ultra high strength concrete

Demand performance and mix proportions are shown in Table 6. In this study, to get ultra-high dispersibility, we used superplasticizer (SP-2) combined with PC-2 as they gave the highest dispersibility, and dispersibility improvement.

Table 6. Demand performance and mixing proportion of ultra-high strength concrete

Demand performance		Mixing proportion						
Slump Flow immediately after mixing	Compressive strength	W/C (%)	s/a (%)	Unit weight (kg/m ³)				
				Water	Cement	Silica fume	Sand	Coarse aggregate
65 ± 5 cm	> 130N/mm ² (91 days)	16	32.9	160	900	100	336	926

The concrete test results are shown in Figure 8. Based on these results, mixing of concrete with a very low water cement ratio, such as 16%, becomes possible by using a superplasticizer with a high

dispersing effect. As a result, the production of the ultra-high strength concrete with compressive strength exceeding 130 N/mm^2 at 91 days was possible.

Figure 8. Concrete test results of ultra-high strength concrete

5. CONCLUSIONS

The findings from our research are as follows:

- Varying the balance between length of trunk polymer and length of grafts of their quantitative ratio can control dispersibility and its retention immediately after mixing.
- The appropriate area of PC calculated from measured values is 1/3 to 1/5 of the value that is calculated from the value of the polymer in its fully extended configuration. Therefore PC polymer is considered to be adsorbed in contracted form. In addition, it is suggested that the contraction of polymer occurs due to effects other than sulfate ion, suggesting a decrease in thermo-mechanical effective volume that is not due to the contraction of the polymer.

ABSTRACT

In this study the influence of limestone addition on the length change and resonance frequency of mortars and paste samples was investigated under different curing conditions. The samples were prepared with a Portland cement, which resulted in significant expansion after heat curing in previous studies [1-3]. One part of the samples was cured for 4 hours at 95°C, the other part at 20°C until one day, and finally all samples were stored at 20°C and 5°C in water. The hydrated pastes and mortars were examined by means of x-ray diffraction and scanning electron microscopy. No ettringite was found after curing at 95°C. Only traces of AFm phases were identified as sulphate bearing phases. During the subsequent storage of these samples in water at 20°C and 5°C, expansion occurred. With increasing amounts of limestone in the cement the expansion effect was shifted to earlier times with decreasing maximum expansion values. Mortars showed higher expansions than pastes. The storage at 5°C in comparison with that at 20°C caused earlier expansion of the samples. The amount of ettringite determined by quantitative X-ray diffraction increased parallel to the expansion of the samples.

A fundamentally positive influence of an addition of limestone on the deleterious expansion of mortars and pastes after heat curing was not found. The mechanism of late ettringite formation in limestone cement is discussed.

1. INTRODUCTION

Delayed ettringite formation and the resulting structure changes in cement pastes and mortars is a very complex process. The expansion on the basis of delayed ettringite formation depends on several parameters, temperature of heat-treatment, chemical and mineralogical composition of the cement, storage conditions after heat-treatment, microstructure of mortar or paste etc.

Preliminary studies on the soundness of heat-treated Portland limestone cement (4h, 95°C) followed by 7 years storage under water at room temperature showed almost no length change [1]. One hypothesis for this phenomenon is based on the observation of stable ettringite formation caused by a parallel reaction of carbonate and sulphate with aluminate [2]. Therefore minor potential for delayed ettringite formation had been expected. On the other hand thaumasite can be formed at low temperatures during the hydration of heat-treated Portland limestone cements, whereby CSH phases act as a source of sulphate.

The aim of this research was to clarify the influence of limestone additions on the delayed ettringite formation and expansion in the mortars and neat pastes at 20°C and 5°C and to characterize the mechanisms of this influence.

2. MATERIALS AND METHODS OF TESTING

In the experiments a cement, type CEM I 42,5 R and its mixes with 15 and 30 wt-% limestone from Jurassic limestone (Jurakalk) was used. The limestone was milled to a degree of fineness similar to that of limestone in an industrial Portland-limestone cement according to own investigations (94% < 63 µm). The particle size of the original materials was characterised using air jet screening. The density was determined with a Helium pycnometer, the specific area was measured according to the Blaine method. The results are shown in Table 1.

The chemical analysis of the original materials was determined by x-ray fluorescence analysis after the samples had been ignited at 1000°C. The Na₂O, K₂O, SO₃ and Cl contents were determined according to DIN/EN 196, part 2 and part 21. The content of CO₂ was measured volumetrically. For the calculation of clinker-phases according to Bogue, it was supposed that all of the SO₃-content was bound as CaSO₄ and all of the CO₂ content was bound as CaCO₃. The results are shown in Table 2.

Powder XRD analysis showed the presence of the anhydrous phases in the cement: C₃S, β-C₂S, C₃A, periclase (MgO), anhydrite (CaSO₄), calcite (CaCO₃) and brownmillerite (C₂(A,F)). In addition to calcite, a small amount of dolomite, quartz, mica and illite was identified in the limestone. The mortars were prepared according to DIN/EN 196 part 1. The pastes were prepared in accordance to DIN/EN 196, part 3 with a water/cement ratio of 0.5.

For the investigations flat prisms (measuring: 1x4x16 cm) with gauge studs were cast using pure cement and mixes with 15 and 30% of limestone. Part of these samples were stored for 2 hours and then treated in water at 95°C for 4 hours. The rest of the samples were first stored for up to 24 hours in an environment of 20°C and 95% relative humidity. All the samples were then stored in water at 5°C and 20°C.

Table 1. Particle size distribution (air-jet screening), density and specific surface of cement limestone

3. RESULTS OF INVESTIGATIONS

3.1 Strength, length change and resonance frequency of the samples

As expected the strength of mortar prisms decreases with increasing limestone addition (Table 3). Therefore the mortars without any limestone addition and with 15 wt.-% of limestone addition still belong to the range of the strength class 42.5 R. However, in case of the 30 wt.-% addition limestone only 32.5 R equivalent is reached.

The length change and resonance frequency of the heat-treated samples were measured after different periods of hydration (Figures 1 to 4).

Table 2. Chemical composition of cement and limestone

15	5.5	7.4	29.6	46.7
30	4.4	6.6	22.5	36.0

Figure 1. Length change and resonance frequency of mortars without heat-treatment.
(KS = limestone)

After 720 days mortar samples without heat-treatment showed a low expansion of 0.20 mm/m at 20°C storage temperature and small shrinkage of 0.02 mm/m at 5°C. The expansion decreased with the limestone content. After increasing during the first 6 months, the resonance frequency remained almost constant for the following 18 months. The resonance frequency decreased as the limestone content increased.

Heat-treated mortar samples showed a high expansion of up to 11.3 mm/m during the time of examination. The evolution of the expansion depends on the amount of limestone and on storage conditions. An earlier commencement of the expansion was observed with an increasing amount of limestone and/or a decrease in storage temperature. The addition of limestone led to earlier termination of the main expansion phases and to slighter expansion after 720 days.

Figure 2. Length change and resonance frequency of mortars with heat-treatment (KS = limestone)

The resonance frequency decreased during the expansion period. Afterwards the resonance frequency remained constant or increased slightly. Cracks occurred in all the samples stored for longer than six months at 20°C.

For up to 720 days of storage, paste samples without heat-treatment showed higher rates of expansion than the mortar samples. Similarly to the mortar prisms, the expansion increased at lower limestone contents or higher temperature of storage. The resonance frequency increased for the first 180 days and then remained almost constant.

Figure 3. Length change and resonance frequency of pastes without heat-treatment (KS = limestone)

It was observed that after one year, in contrast to samples not subjected to heat-treatment, the heat-treated samples exhibited higher expansion rates with an increasing amount of limestone. For example samples with 30% of limestone expanded by 1.17 mm/m at 20°C and 0.90 mm/m at 5°C after one year. In the second year of storage at 20°C the samples with limestone showed distinct expansion. At 5°C the expansion remained at a low level. The resonance frequencies showed no significant decrease during that period.

Figure 4. Length change and resonance frequency of pastes with heat-treatment (KS = limestone)

3.2 Mineralogical analyses

The hydrates formed in the aged samples were examined by X-ray diffraction analysis (XRD), scanning electron microscopy (SEM) and X-ray microanalysis. The content of ettringite in the hydrated samples was detected by using the method of internal standards. Calcium sulphate hemihydrate ($\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$) was used as the internal standard (3). For the XRD and X-ray microanalysis, fragments of the mortar and paste samples were sputtered with carbon.

Some results of the analyses are presented in Figures 5 to 9 and in Table 4.

Table 4. Amount of ettringite in the mortars and pastes (XRD determination)

n.d.- not determined; n.m.- not measurable

After two hours of hydration of pastes, only ettringite was identified as a hydrated phase of cement. During storage of mortars and pastes without heat-treatment at 20°C and 5°C monocarboaluminate hydrate and ettringite were observed after 28 days. The concentration of monocarboaluminate hydrate was found to increase with an increase of calciumcarbonate and with higher storage temperature (20°C). After 360 days the influence of the storage temperature (5°C or 20°C) for $C_3A \cdot CaCO_3 \cdot 11H_2O$ formation was no longer detectable. No monosulphoaluminate hydrate and thaumasite was identified for mortar and paste samples stored at 5°C and 20°C during the observation time.

Only traces of monosulphoaluminate hydrate were found in mortar and paste samples immediately after heat-treatment. Ettringite and monosulphoaluminate hydrates were formed during 28 days storage at 20°C and 5°C. Generally the amount of ettringite increased with increasing amount of carbonate in cement and is substantially lower in the samples without heat-treatment. The effect of

storage temperature is distinct only for mortar and paste samples with 30% limestone – with decreasing temperature the amount of ettringite increases. No monocarboaluminate hydrate was identified in heat-treated pastes and mortars after 28 days storage at 20°C and 5°C

Compared to the samples without heat-treatment a higher amount of ettringite and lower amount of monocarboaluminate was found in the heat-treated mortar samples after 360 days.

Monosulphoaluminate hydrate and a small amount of ettringite were identified in pastes containing no limestone and stored at 5°C and 20°C. The same hydrates were found in the pastes prepared with 15% limestone stored at 20°C. A higher amount of ettringite was identified in the paste prepared with 15% limestone and stored at 5°C. The same was found for the paste prepared with 30% limestone and stored at 5°C and 20°C. The amount of monocarboaluminate hydrate increases with increasing CaCO_3 content in the samples. The mortar samples contain substantially more ettringite in the paste (without sand) as the paste samples.

Figure 5. Correlation between expansion and ettringite amount in the cement paste

The expansion of mortar and paste samples correlated with the amount of ettringite in the cement matrix. Usually, with an increasing amount of ettringite, expansion of the samples increase (Figure 5). The results of SEM- and X-ray microanalysis of 360 days aged samples of mortars and pastes containing 30% of limestone, stored at 5°C are presented in the Figures 6 to 9.

Although particles with chemical composition high in sulphate were identified, no needle-like crystals of ettringite were found in the non heat-treated mortar samples. The irregular shaped particles found with an increased amount of sulphate are ettringite-like phases, mixed with calcium silicate hydrates, as is indicated by the chemical composition (Figure 6).

Given the low Al_2O_3 and Fe_2O_3 content, the high sulphate content, of the area marked by “1” (Figure 6) can not only be attributed to the presence of calcium sulphate-aluminate or ferrite phases. This may be a mixture of calcium silicate hydrate and thaumasite-like phases.

In the mortar samples treated at 95°C, needle-like crystals of ettringite could be identified. The chemical composition of these crystals showed only slight deviation from the theoretical composition. Based on the present results it cannot be stated whether the presence of SiO_2 and excess of CaO are due to traces of calcium silicate hydrates, calcite or portlandite respectively or a matter of accommodation of SiO_2 in the crystal structure of ettringite. In the same sample only one composition with SiO_2 and a higher molar $\text{SO}_3/\text{Al}_2\text{O}_3$ ratio (of 3.6) than expected for ettringite was found. The identified irregularly formed particle, which is rich in sulphate, is a mixture of ettringite, CSH-phases and possibly calcite or portlandite.

There are also irregularly formed particles in the non heat-treated paste samples. They are rich in sulphate and as well as the components typical for AFT-phases (CaO , Al_2O_3 and Fe_2O_3) they contain MgO and SiO_2 . In the pore, needle-like ettringite crystals are apparent. The $\text{SO}_3/\text{Al}_2\text{O}_3$ ratio

was found to be lower than the theoretical value typical for ettringite. Furthermore, no SiO_2 was detected (Figure 7).

Figure 7. SEM and X-ray microanalysis of cement paste with 30% limestone in cement after 360 days storage at 5°C

No needle-like ettringite crystals appeared in the heat-treated paste samples. It was shown by X-ray microanalysis that areas rich in sulphate contain mainly mixes of different phases (Figures 8 and 9). The chemical composition at mark 1 (Figure 8) shows a much higher $\text{SO}_3/\text{Al}_2\text{O}_3$ -molar ratio (of 4.22) than for ettringite which might indicate the presence of thaumasite or ettringite-thaumasite solid solutions.

4. DISCUSSION AND CONCLUSIONS

Delayed ettringite formation and the resulting structure changes in cement pastes and mortars is a very complex process. The expansion on the basis of delayed ettringite formation depends on several parameters, i.e. the temperature of heat-treatment, chemical and mineralogical composition of cement, storage conditions after heat-treatment and the microstructure of mortar or paste [4].

In the present work the effect of limestone addition on the soundness of cement pastes and mortars with and without heat-treatment was investigated.

The effects of the limestone during cement hydration are partly physical and partly chemical. Chemically it reacts with aluminate phase producing $C_3A \cdot CaCO_3 \cdot 11H_2O$ thus competing with the gypsum. Furthermore monocarboaluminate hydrate is formed because the dissolution of $CaCO_3$ takes place slowly in comparison with the ettringite formation. In the pastes and mortars monocarboaluminate hydrate was found at ages over 28 days. After 1 day of hydration this phase was not present. As expected, no monocarboaluminate hydrate phases were found in mortar and paste samples after heat-treatment. This corresponds with results of Ghorab et. al. [5] who found decomposition of $C_3A \cdot CaCO_3 \cdot 11H_2O$ at higher temperatures. In heat-treated samples reactions may occur as follows (in simplified form):

During the storage of cured samples the reactions 2 and 3 are normally expected. With this reactions a better crystallization of monosulfoaluminate hydrate during 28 days of hydration was observed. Until 28 days of hydration no reaction between aluminate hydrates and calcite was observed. The result of the competing reaction between carbonate and aluminate phases (reaction 4) was observed only between 28 and 360 days of hydration. Delayed ettringite formation was accelerated by lower temperature and $CaCO_3$ addition. Although $CaCO_3$ and sulphate compete to react with tricalciumaluminate hydrate after 28 days of hydration, a higher amount of ettringite was found as was expected. This phenomenon can presumably be attributed to differences of microstructure and strength characteristics of specimens with and without limestone addition. According to Taylor et al. [4] anything that weakens the material will lower its ability to resist expansion. More investigation is needed to identify and explain the latter reaction path.

Mortar samples showed higher rate and extent of expansion in comparison with neat paste samples. This corresponds with the observations of Yang et al. [6]. According to Taylor et al. [4] the paste material is strong enough to resist the stresses caused by ettringite formation to an extent that greatly retards the reaction and the resulting expansion. A weaker bond between aggregate and paste allows the reaction and expansion to proceed more quickly.

Some weakening in the structure of pastes and mortars can occur due thaumasite formation at $5^\circ C$. The formation of thaumasite in mortars and concretes is usually dependant on a surplus of sulphate-ions, the existence of $CaCO_3$ and humid storage conditions at low temperatures. If mortars are heat-treated (at $95^\circ C$), part of the sulphate-ions are accumulated in the CSH-phases. The presence of $CaCO_3$ in combination with low temperature storage may theoretically also lead to formation of thaumasite. This, in particular, is happening in micro-areas where CSH-phases rich in sulphate have close contact to $CaCO_3$ or it is due to carbonation of the CSH-phases. The investigations showed that crystal-mixes appeared in micro-areas of pastes with 30% (wt.) of limestone filler which were heat-treated and stored at $5^\circ C$. The amount of thaumasite or ettringite-thaumasite mixed crystals is so small that they could not be identified by XRD. Sulphate from the CSH-phases and

CaCO_3 which are both part of the cement in first place, react with calcium-aluminate-hydrate and form monocarboaluminatehydrate ($\text{C}_3\text{A} \cdot \text{CaCO}_3 \cdot 11\text{H}_2\text{O}$) and ettringite ($\text{C}_3\text{A} \cdot 3\text{CaSO}_4 \cdot 32\text{H}_2\text{O}$).

The investigations showed that after heat-treatment the addition of fine limestone led to:

- an accelerated ettringite formation and expansion of the mortars and pastes
- a decrease in expansion of mortar
- a higher initial rate of expansion reactions of mortar samples during subsequent water storage at 5°C in comparison with that at 20°C

INFLUENCE OF LIMESTONE AND FLY ASH ADDITIONS TO CEMENT THAT CAUSED EXPANSION OF HEAT-TREATED MORTAR DUE TO DEF

Wiesław Kurdowski and Sylwester Duszak

University of Mining and Metallurgy, Cracow, Poland.

ABSTRACT

Ground limestone and fly ash were added to cement which showed a DEF expansion after thermal treatment of the mortar. The fifteen per cent addition decreased, but did not eliminate the expansion. However, the samples to which potassium hydroxide was also added revealed a distinctly lower expansion. The higher content of additions, namely 30%, was sufficient to practically eliminate DEF. However, when SO_3 content in blended cements was completed by gypsum addition close to 4%, i.e. to the content in pure Portland cement, the expansion is practically eliminated. The comparison of mortar expansion with XRD ettringite is discussed.

Keywords: DEF, Portland cement, fly ash, limestone, expansion

1. INTRODUCTION

Delayed ettringite formation (DEF) is a very stimulating topic and many problems remain unsolved especially the mechanism of expansion [1-4].

It is well known that the replacement of 30% of cement by fly ash and 50% by slag is very effective in elimination of the expansion caused by DEF [5-7]. However, only a few papers are devoted to the influence of limestone and Kelham [8], among others, examined this addition, but no comments have been given in his paper. Summarising one can conclude that the influence of limestone is relatively less familiar.

The principal goal of this investigation is the examination of the influence of limestone on the DEF and consequently on the expansion of the mortars. For the sake of comparison the same quantity of low lime fly ash was used.

The paper presents the results of the investigation of these additions on the expansion of mortars after heat treatment. Also the composition of the paste in these mortars was followed by the X-ray method.

2. MATERIALS AND METHODS

Portland cement clinker of composition presented in Table 1 was used. This clinker was ground with addition of gypsum giving 4% SO_3 in cement. The mortar of this cement after heat treatment at 90°C (Figure 1) presented an expansion of about 6 mm/m [9].

Figure 1. Programme of heat treatment

Fifteen and 30% of very pure limestone (L) and of fly ash (V) were added to this cement (for example 15L and 30L). The second series of cements containing 15% of addition was obtained by adding 0.22% KOH and 0.9% of gypsum to these cements (15LKG and 15 VKG). On the other hand to the cements containing 30% of addition 1.8% of gypsum was added (30LG or 30VG). Thus 8 cements were obtained, the ninth being the standard cement without addition.

In Table 1 chemical compositions of all materials used are presented and in Table 2 the contents of SO_3 and Na_2O_e in all cements are given.

30LG	3.51	4.33	0.68	0.67
30VG	3.51	4.55	0.68	1.82

The solubility of alkalis of fly ash is very limited because not more than 5% is dissolved after 24 hours [10]. Therefore the content of soluble alkalis in cements containing fly ash will be practically the same as for the cements with limestone addition.

The mortars were prepared from these cements according to EN196-1 (one part of cement, three parts of sand). For all mortars, after different periods of water curing, the expansion was measured with the Graf-Kaufmann apparatus. [11]. For these measurements the mortar prisms of 4x4x16 cm were provided with two bolts, each one on the opposite longer end of the prism. The phase composition of the samples was followed by X-ray. For some samples porosity was measured using MIP.

3. RESULTS

The expansion of all mortars is presented in Figure 2. The highest expansion was found in the case of Portland cement. The mortar of cement with 15% of fly ash (15V) attained less than a half of the value for Portland cement and with 15% of limestone less than for 15V. The mortars of cements containing a small additional addition of gypsum and KOH (15LKG and 15VKG) presented a very small expansion.

Figure 2. Expansion of the mortars after different times of water curing

Practically no expansion of mortars was observed in case of cements with a 30% addition without and with additional gypsum.

The changes in the phase composition of the samples were determined by the X-ray diffraction analysis. The mortars obtained from cements with the addition of fly ash (15V) give the following results:

After 7 days monosulfate prevails and its quantity decreases slightly for 200 days. Simultaneously, a small quantity of ettringite is formed in the mortar after 28 days of water curing and increases for 200 days (Figure 3).

Figure 3. Section of X-ray pattern of the mortars after water curing

The content of ettringite is evidently higher already after 7 days of water curing and the intensity of its line on X-ray pattern increases from 7 days for 90 days in the mortar of cement containing an addition of fly ash together with KOH and an additional portion of gypsum (15VKG). Then, after 200 days, the ettringite content is a little smaller.

In the mortars prepared from cement with limestone, the content of ettringite is drastically higher in the case of cement 15LKG (Figure 3), and similarly to cement 15 VKG, its content is high already after 7 days of water curing. In the mortar of cement 15L the content of ettringite is much lower, but after 7 days of water curing the line of monosulfate appears on the X-ray pattern (Figure 3). Its intensity decreases after 28 days and disappears after 90 days. The content of ettringite increases noticeably between 7 and 28 days.

In all mortars of cement with the limestone addition the content of calcite is high in all periods of curing and the intensity of its line on the X-ray pattern remains practically constant.

The X-ray examination of the mortars of cements with 30% of fly ash and limestone showed a similar behaviour. In the pastes containing limestone intensity of ettringite line is noticeably higher than in case of cements with fly ash. However, in the sample 30L, and especially 30LG, the line of gypsum is strong after 180 days of water curing (Figure 4). Probably it is due to the tricalcium aluminate reaction with calcite, but no carboaluminate line can be found in the X-ray examination. In samples with fly ash, namely 30V and 30VG, the strong line of monosulfate is visible after 180 days of water curing of mortars. In the mortar 30VG the content of ettringite was already high after 7 days of water curing.

The porosity of two mortars, namely of cements 15V and 15VKG, was measured after 450 days of water curing. The porosity of both mortars is low and essentially the same: for 15V it is equal to 8.37%, for 15VKG 8.45%. However, the content of capillary pores in the range 0.1 to 1 μm is higher in the case of mortar of cement 15VKG (Figure 5).

Figure 4. Section of X-ray pattern of mortars 30L and 30LG after 180 days

Figure 5. Cumulative porosity of mortars of cements 15V (1) and 15VKG (2)

4. DISCUSSION

In the light of results obtained it is clear that the addition of fly ash and limestone decreases or even eliminates the expansion of heat treated mortar after long water curing. In case of 15% addition the decrease of expansion is larger than 50%. From the content of monosulfate and ettringite found in X-ray patterns (Figure 3) it is evident that in the samples with the addition of KOH and gypsum (series 15LKG and 15VKG) ettringite is stable during heat treatment and its increase during longer water curing is small. It is in good correlation with the lack of expansion of these specimens. However, in the mortars of cements 15L and 15V after thermal treatment and water curing for 7

days, the monosulfate prevails and is progressively transformed into ettringite thus causing expansion. The reason for stability of ettringite in specimens 15LKG and 15VKG is not clear and the explanation of this phenomenon needs further study.

Also the content of capillary pores are higher in the mortars of cements with addition of KOH. The comparison of alkali content (Table 2) shows that it is also higher in the mortar presenting lower expansion (cements 15LKG and 15VKG).

The addition of 30% of fly ash or limestone essentially eliminates expansion and the quantity of gypsum has no evident influence on the behaviour of mortars. On the other hand, the paste composition is different for limestone and fly ash, which means that the chemical reactions of aluminates are different. In the case of cement 30V monosulfate prevails for 180 days. In contrast to this, in a mortar of cement 30L and 30LG, there are relatively high concentrations of ettringite. However, the remaining gypsum in the mortars of cement with limestone, especially 30L, presents a serious hazard and gives the potential for ettringite formation at later ages.

5. CONCLUSIONS

From the results of the investigation, the following conclusions can be drawn:

1. The addition of 15% limestone decreases the expansion of mortars to a larger degree than the low lime fly ash.
2. The addition of 30% of limestone and low lime fly ash practically eliminates the expansion of mortars.
3. The addition of a small quantity of potassium hydroxide solution (0.2% of KOH) and gypsum (0.9%) to cements with 15% of fly ash or limestone has a very pronounced effect on expansion but the explanation of this phenomenon needs further study.
4. The determination of the liquid phase composition in the mortar should give more information about the influence of the addition of KOH and gypsum to the system.
5. In case of cement 30L the high content of gypsum remains in the mortar after 180 days of water curing.
6. More light on the problem of gypsum in case of the limestone addition should give examination of the SO_4^{2-} concentration in the liquid phase of the mortar as well as following the paste composition over longer curing times.

MICROSTRUCTURE OF HAC PASTE AFTER FIFTEEN YEARS OF IMMERSION IN STRONG CHLORIDE SOLUTION

Wiesław Kurdowski¹, Sylwester Duszak¹ and Francois Sorrentino²

¹University of Mining and Metallurgy, Cracow, Poland

²Lafarge, France

ABSTRACT

Bars of HAC paste showed high strength after fifteen years of immersion in a strong chloride solution. No evident trace of corrosion was seen. On the surface of the bars a skin was found which was detached in several places. The cross section of the bar revealed three zones: the superficial and intermediate layers of total thickness of about 3 mm and the “unchanged” interior of the paste. The superficial layer has a much higher porosity than the intermediate layer, but lower than the interior of the sample. The intermediate layer has the lowest porosity and seems to play a role of a diffusion barrier. The chloride ion content is the highest in superficial layer, but the differences are not very pronounced. Also the phase composition of all three zones of the sample is very similar and the main components are Friedel’s salt, gibbsite and hydrogarnet. The composition of the skin is totally different and contains brucite and aragonite. The transformation of hexagonal aluminates to cubic had no negative influence on strength. Also the results of experiments clearly show that the formation of Friedel’s salt has no destructive effect on cement paste. HAC paste is extremely durable in strong chloride solution.

Keywords: aragonite, basic calcium chloride, calcite, chloride corrosion, Friedel’s salt, hydrogarnet, gibbsite, High Alumina Cement,

1. INTRODUCTION

During their hydration high aluminate cements (HAC) develop hexagonal crystals CAH_{10} , C_2AH_8 which transform to cubic hydrogarnet C_3AH_6 . The ability of these hydrates to trap chloride ions (1) mainly as chloroaluminate $\text{C}_3\text{A} \times \text{CaCl}_2 \times 10 \text{ H}_2\text{O}$ (Friedel’s salt) has led to several applications of this type of cement such as concreting in marine [2,3] or chemically severe environments [4,5] or stabilisation of waste [6,7] .

Another area of interest concerns the ability of HAC to prevent the corrosion of concrete reinforcement [8,9].

The good performance of HAC in a corrosive environment is mainly due to the development of a special microstructure [10]. Nevertheless, the problem relevant to the durability of the structures i.e. the formation and the stability of the Friedel’s salt, deserves a definite answer.

Most of the studies which have been done in the past [2-11] have used a calcium aluminate cement produced by a smelting process. In the present study, we use a calcium aluminate produced by sintering

In 1990 during the HAC Conference in London the results of the investigations of corrosion of HAC paste immersed in strong chloride solution were presented [12]. The main conclusions of these investigations were that the good durability of the paste was caused by very low porosity. The only new phase formation found in the core of the paste was Friedel's salt.

After a further 12 years of immersion of the bars of HAC past, the samples were once more examined. The results of this examination are presented in this paper.

2. MATERIAL

The samples were the bars of HAC paste made in 1987 and immersed in strong chloride solution whose composition is presented in Table1 [12]. The solution was the mine water from the salt mine Kłodawa in north Poland. The dimension of bars was 4 x 4 x 16 cm and w/c ratio of the paste was 0.4.

Table 1. Chemical composition of chloride solution

Component	Concentration, g/l
NaCl	240
MgCl ₂	65
KCl	15

The HAC cement used was Górkal 70 from the Polish plant and was produced by the sintering method. Its main mineralogical phases were CA and CA₂ and α A added during grinding. In very small amounts, gehlenite was also present.

In the bars crushed during compressive strength measurement, several layers can be distinguished even with naked eye. Thus the bars were cut in such a manner to obtain a sample including all layers formed in the bar during immersion in chloride solution. Simultaneously each layer was separated and constituted individual samples.

From all samples, polished sections were prepared for SEM examination. Independently, crushed pieces of the bar were also examined under SEM.

3. METHODS

Phase composition of the samples was determined by XRD which was the basic method.

The XRD results were supported by SEM examination connected with chemical analysis using EDAX.

For porosity measurements the Mercury Intrusion Porosimetry method was used.

4. EXPERIMENTAL RESULTS

The bars are in a very good state with no trace of destruction, even of surface corrosion.

The confirmation of this good state of samples was their high strength. The strength was as follows:

compressive strength 69.1 MPa
bending strength 17.3 MPa

On the surface of the bars a brighter skin deposited (Figure 1). This skin is very unstable and is detached in several places.

Under the skin there is a dark external layer about 2 - 3 mm thick. Then there is a bright transitional layer about 1 mm thick. This bright layer surrounds the “unchanged” core of the sample (Figure 2)

MIP shows that the porosity of the bright transitional layer is very low, much lower than the core. However, the average pore radius is the highest in this zone and drastically lower in the core. The results of the MIP measurements are presented in Table 2.

Figure 1. General view of the cut bar with partially detached skin

Figure 2. The section of the bar; the dark, the bright layers and the core are clearly visible

Table 2. Porosity of three zones of the bar

Layer	Total pore volume, mm^3/g	Porosity, %	Average pore radius, μm ,
Core	3.00	0.66	0.016
Transitional	0.73	0.16	0.44
External	2.14	0.45	0.23

The chemical composition of the three zones of the bar was determined by EDAX. The results (Figure 3) show that the differences are very limited. It is seen that the content of three elements in question i.e. Ca, Al and Cl is practically the same in the transitional layer and in the core.

Figure 3. Content of three elements in different zones of the sample.

The X-ray examination of the skin shows that it is composed principally of brucite and aragonite. Two additional phases are calcite and Friedel's salt (Figure 4), but their content is drastically lower. A trace of halite is also found.

A – Aragonite, B – Brucite, C – Calcite, F – Friedel's salt, H – Halite

Figure 4. X-ray of skin

The phase composition of three other samples i.e. two layers and the core differ significantly from each other (Figure 5). The external layer contains low quantity of Friedel's salt but high content of calcite. The content of gibbsite is relatively high. These remaining phases are aragonite and CA_2 .

Figure 5. Phase composition of two layers and a core

The transitional layer is much richer in Friedel's salt. Also the X-ray lines of hydrogarnet have a high intensity. Gibbsite concentration is considerable.

The content of CA_2 seems to be on the same level in all three sample. Small quantities of calcite are to be noted.

The core is very rich in three phases namely: Friedel's salt, gibbsite and hydrogarnet.

The phase composition is summarised in Table 3.

Table 3. Phase composition of different zones of the bar

Layer	Main phases	Minor phaes
Skin	Aragonite, Brucite	Calcite, Friedel's salt, Halite
External layer	Calcite, Friedel's salt, Gibbsite	CA_2 , Corundum, Brucite, Aragonite
Transitional layer	Friedel's salt, Gibbsite, Hydrogarnet	CA_2 , Corundum,
Core	Friedel's salt, Gibbsite, Hydrogarnet	CA_2 , Corundum,

SEM observation supported but also enriched the results of XRD analysis. This observation shows that in the skin the basic calcium and magnesium chlorides are present (Figure 6).

Figure 6. SEM image of the skin and two layers

These chlorides form very compact gel and it is the reason of inefficiency of XRD (Figure 7).

Figure 7. Compact layer of basic chlorides

The two remaining phases are aragonite and brucite (Figure 8).

CA₂ forms frequently forms large grains of about 100 μm (Figure 9) but can also be found in beautiful crystals.

Figure 8. The composition of the skin under SEM, low layer – brucite, middle layer aragonite laths

Figure 9. SEM picture of CA_2 big grain

The results of careful X-ray microanalysis give some interesting data. The layer of hydrates which surrounds the unhydrated cement grain which represents the Friedel's salt of low chloride content. One can suppose that there is a solid solution series $C_3A \times CaCl_2 \times 10H_2O - C_4AH_{13}$ [13]. The particles in this layer represents the content of chloride in the level 4.5 - 10.4% (Figure 10). It seems that this layer represents so called inner hydrate.

The process of transformation of cement grains into the Friedel's salt hydrate is shown in Figure 11. The central part of transformed grains is composed of particles of Friedel's salt but near the two ends the brighter relicts of unhydrated cement are clearly seen (Figure 11).

Figure 10. Solid solution Friedel's salt - C_4AH_{13} around the unhydrated cement grain (inner hydrate)

Figure 11. Transformation of unhydrated cement (1-8) in Friedel's salt (3-6), 2 and 7 represent a solid solution of Friedel's salt and calcium aluminate hydrates

In Table 4, some examples of typical analysis of different phases are shown.

Table 4. Typical analysis of different phases

Component	Kind of phase					
	cement	Friedel's salt	solid* solution	Alumina	Gehlenite	CA ₂
	content, mass %					
CaO	36.3	57.5	59.3	3.5	41.9	18.4
SiO ₂	0.3	0.3	0	1.0	20.0	1.2
Al ₂ O ₃	62.9	25.6	34.5	93.7	37.6	72
Fe ₂ O ₃	0.3	0	0.5	0	0	0
MgO	0	0	0	0	0	0
Cl ₂	0	15.5	5.5	0.3	0.2	8.1

* solid solution Friedel's salt - C_4AH_{13}

The minor phase which is gehlenite contains practically no chloride and the same is valid for alumina. Contrary to this in CA_2 the content of chloride is relatively high. This is probably the beginning of the transformation of this phase into Friedel's salts.

5. DISCUSSION

The results of examinations show that the HAC paste is very durable when immersed in strong chloride solution. On the superficial zone of the bars the transitional layer is formed which is very dense and hinders the diffusion of chloride ions in the deeper part of the bar. The concentration of chloride ions in this transitional layer is significantly lower than in the external layer and is the same as in the core. Also the mineralogical composition of the transition zone is almost identical to that of the core and differs drastically from the external layer.

Contrary to this the skin is not very stable and seems to play a minor role as a corrosion barrier. Also its mineralogical composition changed significantly during the long period of aggressive action of the chloride solution. Previously the main constituents were basic chlorides and amorphous brucite [12]. Now under influence of atmosphere which enriched the solution in CO_2 aragonite prevails but also a crystalline brucite is in high concentration. The trace of halite can be caused by different nest formations under the skin which were found in our first study [12].

In the external layer no basic chlorides were found and the main corrosion products are calcite and Friedel's salt.

Also in the core of the sample Friedel's salt is formed preferentially on the surface of cement grains and frequently forms a solid solution with C_4AH_{13} and thus has a lower chloride concentration.

Results show that the HAC paste is very durable in chloride environments and the main corrosion product is Friedel's salt. Simultaneously the paste composition is changed from CAH_{10} hydrogarnet which became the main hydration phase. Also alumine hydroxide gel is transformed into gibbsite.

Despite the relatively high content of Friedel's salt in the core of the sample the porosity of this part of the bar is very low (Table 2). Without doubt it is the main reason for the very good durability of the paste [14]. It is also evident that the formation of Friedel's salt is not accompanied by crystallisation pressure and porosity increase. Average pore radius in the core is about 16 nm which means that the pores belong to the very small capillary pores. Because of the low porosity of the paste its strength is high, even after 12 years of immersion in chloride solution.

6. CONCLUSIONS

From the experimental results the following conclusions can be drawn:

1. HAC paste is very durable in chloride solution,
2. The main corrosion product in the bar, except in the superficial layer, is the Friedel's salt after 12 years corrosive action of chloride solution,
3. The formation of Friedel's salt does not cause an increase of porosity and the strength of cement paste remains high,
4. The hydration products underwent transformation i.e. the $Al(OH)_3$ gel formed gibbsite and the hexagonal hydrates were transformed into hydrogarnet.

EARLY-AGE HEAT EVOLUTION CHARACTERISTICS OF SOUTH AFRICAN CEMENTS IN RELATION TO CLINKER CHEMISTRY AND CRYSTALLOGRAPHY

Graham, P.C. and Ballim, Y.

School of Civil and Environmental Engineering, University of the Witwatersrand, Johannesburg, South Africa; E-mail: peterg@civil.wits.ac.za; ballim@civil.wits.ac.za

ABSTRACT

This paper presents the results of a test programme, which was undertaken to quantify and compare the heat characteristics of cement clinker obtained from most of the cement manufacturing facilities in South Africa. The clinkers were all ground to a uniform fineness, blended with a uniform gypsum and, using a uniform concrete mixture, were tested in an adiabatic calorimeter to determine the amount of heat and the rate of heat evolution during the early period of hydration. Cements obtained from the same manufacturing plants were also tested to separately indicate the effects of the actual manufacturing process on the heat characteristics of the cements. The heat results are also assessed in relation to the results of chemical analyses and optical microscopy of the clinkers.

The results show that the nine clinkers assessed can be categorised into low, medium and high heat clinkers. Also, for a given cement clinker, the heat characteristics of the manufactured cement appear to be related to a combination of fineness of grinding, amount of SO_3 and type of gypsum or additives used in the manufacturing process.

1. INTRODUCTION

The thermal response of concrete due to hydration of cement is a predominant factor in the potential for early-age cracking of large concrete elements. An analysis of this cracking potential requires an ability to quantify both the amount of heat that is evolved by the cement as well as the rate at which this heat is evolved [1]. Both these parameters are strongly influenced by the chemical and mineralogical composition of the cement, insofar as it affects the kinetics of the hydration reactions of cement. Furthermore, clinker morphology has been shown [2] to influence the compressive strength and, by inference, the hydration development of cement. Clearly, an ability to estimate the thermal response of cement in concrete, based on a knowledge of clinker characteristics would be of assistance to mass concrete designers and cement manufacturers seeking to control temperature development in such structures.

As a contribution to understanding the relationship between clinker characteristics and heat evolution, this paper presents the results of adiabatic calorimeter tests aimed at assessing the thermal response of a range of South African cements, nominally of the same quality and standard but drawn from different manufacturing facilities across the country. Nine clinker samples were obtained and a cement was produced from each clinker by grinding with a controlled amount of a uniform gypsum (laboratory cement). The laboratory cements were prepared in this manner (uniform specific surface area and SO_3 content) in order to render them as comparable as possible with respect to the thermal responses of the clinkers. Manufactured cement was also obtained from the same cement plants (factory cement) to provide a basis for determining the effects of the manufacturing process on the heat characteristics of the cement, as distinct from the clinker

chemistry. The chemical composition of the clinkers and the gypsum was determined using X-ray fluorescence (XRF) and samples of the raw clinkers were mounted, polished and etched for optical microscope study. These results were then used to characterise the crystallographic and chemical properties of the cements.

Each of the laboratory and factory cements was used to prepare a concrete with fixed mixture proportions and aggregate type. The concretes were tested in an adiabatic calorimeter in order to determine the rate and amount of heat evolved by the cements. Comparisons of the heat properties of the different cements were made on the basis of a maturity function rather than clock time.

2. CEMENT AND CLINKER SAMPLING AND PREPARATION

2.1 Sample Collection

Cement and clinker samples were drawn from nine production plants belonging to three cement companies operating in South Africa. Each of these production plants manufactures Type 1 cement that satisfies the requirements of the local standard specification, SABS EN 197-1 [3]. To ensure that the samples were representative of current production, the clinker was drawn from the moving stock just before entry into the grinding mill. Approximately 4 kg of clinker was drawn from each plant and 500 g of each sample was reserved for microscopy and chemical analysis. The remaining 3.5 kg was used to manufacture cement in the laboratory. At each factory, a 4 kg sample of manufactured cement was drawn from the exit end of the grinding mill approximately 20 minutes after the clinker sample was drawn. This ensured that, within reason, the clinker sample and the clinker component of the cement sample drawn from a production facility were of the same chemical composition.

2.2 Gypsum for Manufacturing the Laboratory Cements

In order to manufacture the cements in the laboratory, a sample of gypsum, with chemical composition as shown in Table 1, was obtained from one of the production plants.

Table 1. XRF analysis of the chemical composition of the gypsum used in the cements and the amount of gypsum added to each clinker

	% by Mass	Clinker Identification	% Gypsum added (by mass)
CaO	30.20	A	3.683
SiO ₂	6.90	B	4.910
Fe ₂ O ₃	0.44	C	5.031
Al ₂ O ₃	0.60	D	5.010
MgO	0.80	E	5.147
TiO ₂	0.04	F	4.490
Mn ₂ O ₃	0.02	G	4.984
K ₂ O	0.19	H	5.120
Na ₂ O	0.25	K	4.490
SO ₃	41.00		
P ₂ O ₅	0.00		
LOI	18.25		

Based on this chemical analysis, the amount of gypsum added to each of the clinkers was adjusted so that each cement had an SO₃ content of 2.3%. Table 1 also shows the proportion of gypsum added to each of the cement clinkers. The SO₃ contents of the factory cements, determined from XRF analyses, are shown in Table 2.

2.3 Grinding and Fineness of the Cements

In manufacturing the laboratory cements, each clinker with the appropriate amount of gypsum was ground in a laboratory ball mill. The mill was periodically stopped and the specific area of the sample was determined using the Blaine test [4]. Grinding was stopped when the measured specific surface area of the sample was $3200 \pm 50 \text{ cm}^2/\text{g}$. Using this procedure, the average fineness measured for the nine samples was $3198 \text{ cm}^2/\text{g}$ with a standard deviation of $24 \text{ cm}^2/\text{g}$. The fineness of the factory cements was determined using the Blaine test and the results obtained are shown in Table 2.

Table 2. Fineness and SO_3 contents of the nine factory cements sampled

Clinker	A	B	C	D	E	F	G	H	K
Fineness (cm^2/g)	2956	3528	3197	3528	3756	2886	3650	3702	3573
SO_3 (%)	2.36	2.00	1.35	1.61	2.11	2.23	1.67	1.97	2.00

3. TEST METHODS

3.1 X-ray Fluorescence

XRF was used to determine the chemical compound composition of the clinkers. The analyses were conducted using ground clinker samples and these results were also used to determine the required amount of gypsum for each cement. This analysis was conducted in the laboratory of one of the cement producers, where XRF is used for routine quality control purposes. The instrument is regularly calibrated and checked for operational accuracy. The samples used in this project were placed in the automatic feed system of the instrument alongside the routine production sample analyses.

3.2 Optical Microscopy

A geological polarising microscope with reflected light capability, was used to assess the structure and morphology of polished and etched samples of each of the clinkers. The clinker samples were lightly crushed using a steel pestle and the -2.36 to $+1.18 \text{ mm}$ fraction was used to prepare the polished sections. The fragments were encapsulated in epoxy and one surface was polished, initially with 600 grit carborundum paper, followed by progressively finer abrasion systems, until a final polish with 0.25 mm diamond paste, on a lapping disk with a non-aqueous lubricant.

The polished samples were then etched using a procedure recommended by St John, et al [5] in order to differentiate the alite, belite and interstitial aluminate phases in the clinker. Digital photomicrographs were then obtained of the etched surfaces and an image analysis system was used to measure crystal sizes and to provide a qualitative description of the clinker morphology.

3.3 Adiabatic Calorimetry

3.3.1 Expressions for the rate of heat evolution

The adiabatic calorimeter proposed by Gibbon, et al [6] was used to determine the amount and rate of heat evolved by each of the laboratory cement samples. In essence, the calorimeter uses a one-litre sample of concrete in a bath of water but separated from direct contact with the water by a 40 mm thick air space. A temperature probe in the concrete sample is monitored by a personal computer fitted with an analogue-to-digital input/output card. A heater element in the concrete bath is then turned on or off in response to the concrete temperature to maintain the water bath at the same temperature as that of the concrete. The concrete temperature is then monitored over time and the amount of heat per unit mass of cement (q_t) is determined from:

$$q_t = C_p \cdot (T_t - T_o) \cdot \frac{m_s}{m_c} \quad (1)$$

where C_p is the specific heat capacity of the concrete, determined as the mass weighted average of the specific heat capacities of the concrete components and is assumed to be constant throughout the test [6]; T_t is the temperature of the concrete sample at time t during the adiabatic test and T_o is the sample temperature at the beginning of the test; m_s is the mass of the concrete test sample and m_c is the mass of cementitious binder in the sample.

The heat rate is conventionally determined by differentiating Equation 1 with respect to time, so that:

$$\dot{q}_t = \frac{dq_t}{dt} \quad (2)$$

The time basis of Equation 2 presents a problem because of the circular relationship between the rate of heat evolution, the extent of hydration, time and the temperature at which the hydration reactions take place. This is generally addressed by expressing the heat rate (as in Equation 2) as a function of maturity [7,8], rather than time. Hence, the heat rate applicable to a particular point in a structure at a given time is determined by the maturity (or time-temperature history) at that point. Stated differently, at a given point in time, the heat rate will vary across a concrete section in accordance with the variation in maturity across the section.

In order to normalise the heat curves to an equivalent degree of advance of hydration, the time axis is expressed in terms of Arrhenius maturity development [9], which, in its relative form, is written as:

$$t_{20} = \sum_{i=1}^{i=n} \exp \left[\left(\frac{E}{R} \right) \left(\frac{1}{293} - \frac{1}{273 + 0.5(T_i + T_{i-1})} \right) \right] \cdot (t_i - t_{i-1}) \quad (3)$$

The reference temperature in Equation 3 is taken as 20 °C and t_{20} is the equivalent maturity time (in hours); E is the activation energy parameter (33.5 kJ/mol, taken as constant [10]); R is the universal gas constant (8.314 J/mol.°C); T_i is the temperature (°C) at the end of the i^{th} time interval, t_i .

Noting that the rate of hydration and therefore, the rate of heat evolution, is dependent on the absolute temperature, Ballim and Graham [11] have shown that, since Equation 1 accounts only for temperature differences, the rate of heat evolution determined from an adiabatic calorimeter test should be normalised with respect to maturity, rather than time. This means that, rather than the form shown in Equation 2, the heat rate should be expressed as:

$$\dot{q}_M = \frac{dq_t}{dM} \quad (4)$$

Expressing the maturity heat rate (Equation 4) as a function of the cumulative maturity, allows the heat rate curve to be normalised so as to be independent of the starting temperatures in the adiabatic test.

3.3.2 Sample preparation and testing

The nine laboratory cements were each used to make a concrete sample with the mixture composition as shown in Table 2. All the mixture components, including the water, were stored in the same room as the calorimeter at least 24 hours before mixing. This allowed the temperature of the materials to equilibrate to the room temperature, which was controlled at 19±1 °C. A 1.2 litre sample of each concrete was prepared by manual mixing in a steel bowl and the adiabatic test was started within 15 minutes after the water was added to the mixture. All the tests were started at

temperatures between 18 and 20 °C and temperature measurement in the calorimeter was continued for approximately 4 days. The silica sand used in the concretes was obtained in four size fractions and these were recombined as needed for the mixing operation to ensure a uniform sand grading for each concrete.

Table 2. Mixture composition of the concrete used for the adiabatic calorimeter tests

Cement	350 kg/m ³
9.5 mm washed silica stone	850 kg/m ³
graded, washed silica sand	885 kg/m ³
Water	233 L/m ³

4. RESULTS AND DISCUSSION

4.1 XRF Analysis

Table 3 shows the results of the XRF analyses of each of the clinker samples. The table also shows the calculated proportions of the four main cement mineral phases in each clinker based on the Bogue analysis [12]. It was not thought necessary to apply the modifications to the Bogue analysis as proposed by Taylor [13] since the analysis was conducted on clinker samples. In this case, the error incurred in the analysis would not be significantly improved for rapidly cooled clinkers such as those tested in this investigation. Table 3 also shows the calculated values of the alumina and silica ratios as defined in reference 12.

The following points are noted from the results presented in Table 3:

- The chemical compound analysis of the clinkers generally lies within the limits proposed by Addis [14] for South African cements. This means that the nine clinker samples selected can be considered typical of South African clinkers intended for cement manufacture.
- Clinker E shows an unusually high content of Fe₂O₃ which explains the high calculated C₄AF content of this clinker.
- Clinker K is unusual in the group because of the significantly higher MgO content as well as the higher Al₂O₃ content.
- Accepting that the Bogue analysis indicates likely or potential compound development, the results indicate that the higher alite content of clinkers B, C, E and F is likely to result in relatively high early age heat results because of the strong influence of this compound on heat liberation during early hydration [13].
- The relatively high C₃A content of clinker K is also likely to add significantly to the early heat evolution of this clinker.
- With the exception of the cements from clinker A, all of the cements can be classed as low alkali [14]. The sodium equivalent values for clinkers B and C are however lower than the minimums cited by Addis [14] for South African cements.

Table 3. Results of XRF analysis of the clinker samples and Bogue calculation of crystalline phase composition.

	% Composition of clinker								
	A	B	C	D	E	F	G	H	K
CaO	66.50	68.16	66.50	65.57	68.40	67.60	67.60	65.06	65.6
SiO ₂	22.30	23.03	21.20	22.15	22.10	22.20	22.80	22.26	21.90

4.2 Optical Microscopy

Table 4 presents a summary of the observations made during the microscopic assessment of the clinkers.

4.3 Adiabatic Calorimetry

Figure 1(a) shows the calculated heat rates for the nine laboratory cements using the maturity heat rate form as described by Equation 4. The units of the heat rate in this figure are unconventional and are best described as “maturity watts” per kg of cement (J/maturity second per kg). This figure shows considerable overlap of the heat rate curves and only the clearly discernable curves are identified. Expressed in this form, clinker cement K stands out in the brief but significantly larger heat rate at between 15 and 20 maturity hours. The curves also show that, after 200 maturity hours, most of the maturity heat rates have reduced to less than 0.1 J/maturity second/kg.

Based on the heat rate curves shown in Figure 1(a), the laboratory cements fall into three distinct groups in terms of the maximum heat rate as follows:

- High heat – clinker cement K
- Medium heat – clinker cements A, B, E and F
- Low heat – clinker cements C, D, G and H

For clarity, representative curves of each of these three groups are extracted from Figure 1(a) and shown in Figure 1(b). Figure 2 shows the measured heat rates of the laboratory and factory cements made with clinker D as an example of the effect of the downstream production process on heat rate.

Figure 1. Measured heat rates of the nine laboratory cements showing (a) all the curves and (b) three curves representative of the three heat rate categories.

Figure 2. Measured heat rates of the laboratory and factory cements made with clinker D

Table 4. Summary of observations made during the microscopic examination of the clinker samples

Clinker	Alite	Belite	Interstitial phase
A	Angular, euhedral crystal shape, generally hexagonal; crystal size from 20 to 60 Φm	Well distributed with occasional nests; rounded, oval or pear-shaped crystals; crystal size in the range 15 to 55 Φm	Generally thinly distributed, especially in areas where C_3S and C_2S are tightly packed.
B	Angular, euhedral crystal shape, generally hexagonal; crystal size from 20 to 60 Φm ; most crystals have C_2S inclusions	Well distributed with occasional nests; rounded shapes with ragged edges; crystal size in the range 20 to 50 Φm	Well distributed matrix with approximately equal aluminate and ferrite phases;
C	Dominant crystal form; many crystals have joined but retain the angular structure; crystal size from 10 to 50 Φm	Sparse distribution; individual crystals rare and mainly occurs as flows between the C_3S crystals; crystal size from 3 to 15 Φm	Well distributed matrix; aluminate clearly discernable and appears as localised patches or concentrated spots
D	Crystals usually angular with common pseudo-hexagonal shapes; crystal size from 10 to 50 Φm ; some large inclusions	Well distributed in small nests; rounded, oval or pear-shaped crystals; crystal size in range 10 to 30 Φm ; narrow rims on C_3S crystal edges	Well distributed throughout; poor distinction between phases; aluminates appear present as localised patches
E	Dominant crystal form; angular with pseudo-hexagonal shapes; crystal size from 10 to 55 Φm ; C_2S inclusions common	Well distributed in small nests; rounded to oval-shaped crystals; crystal size in range 10 to 35 Φm ; distinct lamellar structure	Good distribution with occasional abutting C_3S grains; aluminate in the form of narrow streaks – possibly dendritic
F	Tightly packed with much joining while retaining angular shape; small inclusions which are not common;	Well distributed in small nests; rounded to oval-shaped crystals; crystal size in range 20 to 30 Φm ; distinct lamellar structure	Good distribution; aluminate in the form of small patches and narrow streaks – possibly dendritic
G	Relatively small grains: 5 to 35 Φm ; angular with pseudo-hexagonal shapes; inclusions common	Rounded to oval; small crystals: 5 to 40 Φm ; thin zones on edges of C_3S .	Aluminate phase prevalent; large patches with small ferrite areas.
H	Tightly packed grains; joined to form subhedral shapes; 10 to 50 Φm ; some inclusions	Well distributed in small and large nests; rounded to pear shaped; 10 to 30 Φm	Aluminate phase in dendritic form
K	Crystals angular euhedral; often joined; 10 to 40 Φm ; inclusions small and rare	Individual crystals rare; generally occurs in the matrix in dendritic crystals or as rims on C_3S grains	Well distributed and rich in aluminate; small amounts of periclase visible.

In general the difference between the heat rates of the laboratory and factory cements was in the peak heat rate obtained, with the ascending and descending limbs of the heat rate curves showing significant overlap. Hence, as a basis for comparison, Table 5 shows the maximum heat rate obtained for the laboratory cements and the corresponding factory cements.

Given the methods of sample preparation used in this project, the main production factors that are likely to differentiate the heat characteristics of the factory cements are the fineness and SO₃ content (shown in Table 2) and the additives (if any) added at the grinding stage in the factory. The extent and nature of any extraneous materials added at the grinding stage were not identified or quantified in this project nor was the actual gypsum used at each factory analysed to assess variations in the chemical compositions.

Table 5. Peak maturity heat rates measured for the laboratory and factory cements

Cement Type:	Peak heat rate (Watts/kg) using clinker:								
	A	B	C	D	E	F	G	H	K
Laboratory	2.75	2.85	2.44	2.26	2.91	3.00	2.50	2.34	4.58
Factory	2.56	2.55	3.00	2.72	3.45	2.69	2.93	1.52	6.72

Considering the results shown in Table 5 together with the measured fineness and SO₃ contents of the factory cements as shown in Table 2, it appears that, in general, a higher fineness and a lower SO₃ content results in higher peak heat rates. However, this observation is not valid for clinkers B and H. In particular, clinker H has a fineness of 3702 cm²/g (compared to 3200 cm²/g for the laboratory cement) and an SO₃ content of 1.97% (compared to 2.3% for the laboratory cement), yet the peak heat rate of the factory cement is 35% lower than that of the laboratory cement. The reason for this is likely to lie in the type of gypsum or the effects of possible additives used in the manufacture of this cement.

4.4 Relating heat rates to physico-chemical characteristics of the clinker

Considering the results of the XRF analysis presented in Table 3, the qualitative description of the clinker morphology characteristics presented in Table 4 and the heat rate classifications presented above, the following points are noted:

- The high heat rate performance of clinker K seems to be related to the high C₃A content, which is also reflected in a high alumina ratio. While working with significantly different cements at the time, Lerch [15] noted similar “spikes” in the rate of heat evolution of cements with high C₃A contents. He also noted that the magnitude of the heat rate “spike” decreased and the time of its occurrence increased as the SO₃ content of the cement increased. Macphee and Lachowski [16] note that the presence of periclase has the effect of reducing the hydration kinetics of the cement. However, in the case of clinker K, it appears that the effect of the relatively high MgO content and the resulting presence of periclase is overshadowed by the effect of the high C₃A content. Furthermore, the dendritic form of the belite in this clinker, may also encourage earlier hydration of this phase.
- There are very few common chemical or morphological characteristics between clinkers A, B, E, F and H to indicate that they should belong in a joint heat rate category as measured in the adiabatic calorimeter tests. This is particularly so when considering the clinkers that have been categorised as low-heat clinkers (C, D, G and H). These two groups of clinker are not distinguishable on the bases of the chemical analysis or the morphological descriptions.
- This point is further emphasised by the apparently anomalous peak heat rate performance of the factory cement produced with clinker H in comparison with the corresponding laboratory cement. This indicates that the nature of the gypsum and the possible effects of the additives used in the manufacture of the cement can have a larger influence than the (relatively small) variations in cement fineness and chemical/mineralogical composition of the clinker.
- Because of the relatively high alite contents, none of the clinkers assessed conform to the description of a “low-heat” cement as described by Jackson [17].

5. CONCLUSIONS

- 1 Considering the maturity rate of heat evolution, the nine clinker cements tested can be categorised into high, medium and low heat cements based on the maximum measured heat rate. The average maximum heat rates obtained in each of these categories were: 2.5 J/maturity second/kg, 3.0 J/maturity second/kg and 4.6 J/maturity second/kg respectively.
- 2 Within this categorisation, only clinker cement K was placed in the high heat category, clinker cements A, B, E and F were categorised as medium heat cements and clinker cements C, D, G and H were considered as low heat cements.
- 3 XRF analysis for chemical composition and qualitative microscopy for morphological characterisation of cement clinker, in themselves, do not provide sufficient information to allow a heat-rate characterisation of the cement derived from such a clinker. It is suggested that this information should be combined with further analysis of the clinker involving a thorough characterisation of the crystallographic forms and an assessment of the phase distribution in different size fractions of the ground cement.
- 4 Comparing the performance of the factory and corresponding laboratory cements, it appears that, in general, the peak value of the heat rate is strongly influenced by the fineness of grinding and amount of SO_3 in the cement. However, it is possible that factors such as the type of gypsum used and the effects of additives introduced at the grinding stage could have a larger effect than fineness and SO_3 content. This aspect requires further investigation.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the kind assistance of the three cement companies, PPC Co. (Pty) Ltd, Alpha (Pty) Ltd and Lafarge Cement (Pty) Ltd who provided the cement and clinker samples that were used in the tests.

ABSTRACT

In the paper some results of investigations of the processes of binding and solidification of the various kinds of both liquid and solid radwaste in cement paste by using a hot pressing method are presented. The efficiency of both various binding systems and hot pressing conditions has been discussed. The compositions of hydrated new-formations and properties of solidified cement paste (porosity, water-resistance, leach rate, etc.) have been investigated. The high efficiency of the use of hot pressing technology for radioactive waste solidification (in comparison with the traditional technology of radwaste cementation) has been demonstrated.

1. INTRODUCTION

The employment of effective technologies of manufacturing cement-based construction articles is increasing in the field of radioactive and other hazardous waste management. Current developments in the field of hot pressing were used to develop a new technology of immobilizing some low and middle level radioactive waste. According to that technology, both high temperature (100-200 °C) and pressure (25-50 MPa) have an influence on the mix of cementitious binder and radwaste (at the same time) during certain time (30-45 minutes). Products obtained are characterized by decreased porosity (<10 %), increased strength (30-100 MPa) and low level of cesium-137 leach rate (<10⁻⁵ g/cm²·day). Some natural materials (e.g. clinoptilolite, bentonite, etc.), which have advanced surface and developed pore structure and hence have good sorption properties, can be used for the absorption of various toxic and radioactive substances. Their use as modifying admixtures for cementitious matrices also has been investigated.

2. EXPERIMENTAL PROCEDURE

The following radwastes were investigated: salt concentrate of the Chernobyl nuclear power plant (Chernobyl NPP), spent radioactive cation exchanger KU-2-8, and the bottom silt of Pripjat's creek (the Chernobyl Exclusion Zone). Because of the danger of working with radwaste in the laboratory, non-reactive components were made with the same chemical composition as the wastes to be investigated.

The salt concentrate of Chernobyl NPP is related to middle level active waste. The chemical composition of the salt concentrate after it was steamed is shown in Table 1. The simulator of the radioactive cation exchanger was prepared. Exception was made for the ground sediment (bottom silt) of Pripjat's creek: it was sampled from a place with very low activity but its average chemical composition was similar to that around the cistern.

Table 1. Mean chemical composition of an evaporated concentrate of Chernobyl NPP

Chemical compound	Concentration in a solution, g/L	Amount, mass %
NaNO ₃	660-720	55-60
Na ₂ SO ₄	96-120	8-10
NaCl	48-60	4-5
NaOH	120-180	10-15

For the investigations of the cesium leaching the composites, which simulate the radwaste, the non-active CsOH was added in the calculated quantity: for composites imitated low-level waste (silt and cation exchanger) — $5 \cdot 10^{-7}$ g/kg (calculated from the average activity $1 \cdot 10^{-5}$ Ci/kg according to the proportion $1 \text{ Ci}^{Cs-137} = 1.26532344318937 \cdot 10^{-2} \text{ g Cs-137}$ [1]), for middle-active waste (salt concentrate) — $1 \cdot 10^{-4}$ g/kg (calculated from $2.5 \cdot 10^{-7}$ Ci/L)

The chemical composition of binder components is shown in Table 2. The composites of cement matrices for binding and solidifying waste are shown in Table 3.

Table 2. Chemical compositions of the binder components for preparation of the immobilization matrices

Component	Quantity of main oxides, mass %			
	CaO	Al ₂ O ₃	SiO ₂	Fe ₂ O ₃
Blast Furnace Slag	41	11	36	2
Bentonite	10	14	46	2

Specimens for hot pressing, after cement binder and waste were mixed thoroughly, were placed in the hot pressing device (Figure 1). To prepare specimens the following optimized regime of hot pressing was used: the temperature of isothermal curing of 150 °C, pressure of 25 MPa, total time of hot pressing - 45 min. After hot pressing is finished, the specimens were being extracted out of the device and then placed in a desiccator with distilled water. The samples of water solution, taken at 1, 7 and 28 day, were investigated by the atomic-absorption method (device AAS-30) for cesium concentration determination.

The obtained results of cesium leach rate determination show a decreasing outflow of this element out off the cementing matrix. It completely co-ordinates with the results of the determination of cesium leach rate. It is necessary to take into account that the real area of the leaching surface of cement specimens is much bigger that the one determined by usual geometric measurement due to the presence of the developed pore structure. In this case the specific cesium leach rate is even less.

The use of the atomic-absorbing method of analysis was dictated by following reason. The results, determined by direct measurement of the activity of a solution, did not mirror the real chemical concentration of cesium in this solution. That discrepancy is predetermined by the inequality of the left and right parts in the equation of the determination of leaching radioactive substances by the method of ISO 6961 [3]:

$$R_n^i = \frac{a_n^i}{A_0^i \times F \times t_n},$$

where R_n^i is the increment of the level of leach rate for i-th component, kg/m²·day; a_n^i – radioactivity per second or weight (kg) of each component leached during each time interval; A_0^i – specific radioactivity or mass concentration of each component in the initial specimen, kg·day; F – area of specimen surface, m²; t_n – duration of n-th period of leaching, day; n – time increment; A_0 and a_n are corrected according to the half-value period.

Increased physical-mechanical properties and low level of substances' leaching for the composites with the additives of bentonite and BFS could be explained by the formation of the additional products of hardening due to interaction between these components and the alkalis of salt waste. As a result zeolite-like new-formations are formed. Both increased temperature (150 °C) and pressure (25 MPa) promote these processes. On the x-ray diagrams of specimens obtained the gismondite-like zeolite Na-P can be noticed. Its internal volume is enough for disposal of the molecules of some substances (like sodium nitrate) inside it. Those compositions could be called "clathrate"-like [4]. However, this question needs further investigation. Determination of calcium leach rate showed the heterogeneity of the process of leaching of this element from cementitious matrices. Obviously, that behavior is predetermined by solubilization of calcium hydrosilicates, which is initiated after the pH level has decreased enough owing to calcium hydroxide leaching. The comparison of the determined values of calcium and cesium solubilities (see Table 4) shows that in all the cases leach rate of calcium is much less then relates as to its initial concentration and the high level of sorption of cesium on the active centers of new-formations of hydrosilicates' during the full process of hot pressing [5,6].

4. CONCLUSIONS

The use of cementitious compositions on the basis of OPC clinker, BFS and bentonite as the immobilizing matrices producers composites which contain the new-formations of hydrosilicates with included salt waste as in chemical compounds as by the "clathrate" principle.

The study of leaching cesium and calcium from cementitious specimens (with radwaste) by atomic-absorption method allowed us to determine that the values of leaching of these elements into environment are low enough and mainly satisfy the requirements for immobilizing matrices. The use of hot pressing decreased these negative indications that shows the important prospects of applying this method for immobilization various hazardous waste.

VALERIY V. CHISTYAKOV

Valeriy V. Chistyakov was born February 11, 1949 in Ukraine.

His M.Sc. Degree (building materials technology) he received at the Kiev Civil Engineering Institute (since 1995 – Kiev National University of Construction and Architecture), 1979.

His Ph.D. Degree (the technology of silicates and the refractory of nonmetallic materials) he received at the Kiev Polytechnic Institute (now National Technical University of Ukraine), 1986.

His Dr. Sc. Degree (Technical) he received in 1994. The title of his thesis was: “Physical-chemical aspects of intensification of hydrate- and structure-formation processes in mineral cementitious systems”.

Since 1980 has worked as a staff member of the Department on Concrete and Reinforced Technology at the Kiev Civil Engineering Institute.

Since 1983 he worked as the chief scientist of the Department of Chemical Technology of Binding Substances at the Kiev Polytechnic Institute.

Since 1995 he is Professor of Department of Building Materials of Kiev National University of Construction and Architecture.

Professor Chistyakov contributed/published over 180 scientific articles, papers in various national and international journals, proceedings, seminar/congress volumes and 2 monographs. He granted 20 certificates of authorship. In 1994 he was a recipient J. Soros Grant No. K2X100, project “Physical-chemical bases for synthesis of analogues of natural minerals in the systems $\text{Me}_2\text{O}-\text{Me}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$ and $\text{Me}_2\text{O}-\text{MeO}-\text{Me}_2\text{O}_3-\text{SiO}_2-\text{H}_2\text{O}$ ”.

Specialization:

1. Main field: inorganic chemistry of cementitious systems.
2. Other fields: radioactive and toxic waste management.
3. Current research interests: cement and mineral systems; cement composites and concrete; admixtures for cement systems; new cements; processes of hydrate- and structure-formations; high pressure and temperature reactions; nuclear and chemical waste management; chemically bonded ceramics; materials and technologies for producing the containers for synthesis of artificial diamonds.

ESTIMATION OF THE CAPACITY OF SOUTH AFRICAN COAL FLY ASH FOR PHOSPHATE ION REMOVAL FROM AQUEOUS SOLUTION

ABSTRACT

Phosphate ions have been removed from aqueous solution by fly ash. Better removal was obtained at higher solute concentration, acidic pH and higher temperature. The effect of particle size and the speed of mixing were found not to be significant. A first-order kinetic model was used to obtain values for overall sorption rate constants and intra-particle diffusion constants. The Frumkin isotherm was found to be the appropriate equation for modelling isotherms from the experimental adsorption data, and values have been obtained for the isotherm constants. A 400 mg/l PO_4^{3-} (as P) solution was fed at a steady velocity of 2.0 cm/min through a 2.0 cm fixed-bed column (at pH 9.0 and 25°C), and breakthrough curves were constructed to obtain an estimated adsorption capacity value of 32 mg PO_4^{3-} /g fly ash.

1. INTRODUCTION

Environmental and economic concerns have led to an on-going search to find novel and effective ways to utilise the huge amounts of fly ash that is land-filled or stockpiled. In the year 2000, only 18 out of the over 56 million metric tons of fly ash generated in the U.S.A. were utilised [1], mostly in the cement and concrete industry. For South Africa the fractional utilisation was even lower, at 1.2 out of 25 million metric tons production [2].

Eutrophication, the gradual increase in the levels of nutrients such as phosphorous in an ageing ecosystem such as a lake, leads to an explosion in algae growth, which eventually results in a lack of light penetration and oxygen absorption that is necessary for underwater life. Cultural or man-made eutrophication, resulting from runoff containing excessive amounts of nutrients in the form of sewage, detergents, and fertilisers, is a well-known environmental concern. The most widely used method for phosphate removal from aqueous solution, namely, precipitation with lime, is expensive due to the high doses of lime required [3].

Due to the high percentages of alumina and silica, fly ash is a good candidate for use as an economic adsorbent for large-scale use. It has been found to remove F^- [4,5], Cr^{3+} [6], Cu^{2+} , Pb^{2+} , Cd^{2+} [7] ions as well as phenolic compounds [8,9] from aqueous solution. The study was used to investigate the feasibility of using fly ash, a by-product of coal combustion for electric power generation, to remove phosphate ions from aqueous solution, as a possible technique for wastewater treatment.

An earlier study on the removal of phosphate ion from aqueous solution by fly ash and slag [10] suggested that the Frumkin isotherm (1) [11] is the appropriate equation for modelling the experimental adsorption data:

$$v = \log (\beta/55.55) + 2\alpha\Phi/2.303 \quad (1)$$

where $v = \log [\Phi/(1-\Phi)c]$, c = concentration of the solute that is in equilibrium with the adsorbent, $\Phi = M/M_{ads}$, M = mass of solute adsorbed at equilibrium, M_{ads} = the maximum mass of solute adsorbed at equilibrium, α = the lateral interaction coefficient, and β = a constant which describes the adsorption equilibrium ($\beta = \exp(-\Delta G_{ads}^0/RT)$, where ΔG_{ads}^0 represents the standard free energy of adsorption). This equation is a useful isotherm for fitting non-ideal adsorption systems, and can be arrived at theoretically in terms of surface heterogeneity and in terms of repulsive forces between adsorbed molecules [12].

The sorption of solute from liquid phase to solid phase may be considered as a reversible reaction with equilibrium being established between two phases. If this can be described with a first order reversible kinetic model, then the overall rate constant for the process, k' , and the intra-particle diffusion coefficient, D_i , can be determined, respectively, from the relations [13]:

$$\ln [1-U(t)] = -k' t \quad (2)$$

$$t_{1/2} = 0.030 r^2/D_i \quad (3)$$

where the fractional attainment of equilibrium, $U(t) = X/X_e$, X = fraction of adsorbate sorbed at time t , X_e = fraction of adsorbate sorbed at equilibrium, $t_{1/2}$ = time at which $X/X_e = 0.5$ (given by $(\ln 2)/k'$), and r = mean radius of adsorbent particles (assuming spherical geometry for the adsorbent).

For a fixed-bed unit operating at a steady liquor flow rate, and for which a symmetrical breakthrough S -curve has been obtained experimentally, the height of the mass transfer zone, h_Z , and the specific dynamic adsorption capacity, C_T , are given, respectively, by the relations [14]:

$$h_Z = h_T [V_Z/(V_T - 0.5 V_Z)] \quad (4)$$

$$C_T = \int_0^{V_T} (X_0 - X) dV/m \quad (5)$$

where h_T = bed height, V_T = volume of effluent collected upon exhaustion of the bed, V_E = volume of effluent collected up to breakthrough, $V_Z = V_T - V_E$, X_0 = influent concentration, X = effluent concentration, V = effluent volume, and m = mass of adsorbent.

2. EXPERIMENTAL

2.1 Materials and apparatus

The fly ash sample (Matla fly ash, M432) was obtained from PPC Technical Services (Germiston, South Africa). The sample was analysed there by XRF and XRD using Siemens SRS 3300 and D 5000 spectrometers, respectively. Particle sizes were also measured there with a Malvern Mastersizer instrument. A temperature-regulated Labcon platform shaker was used for solution agitation. A sieving system from Labquip was used for particle fractionation. Absorbance measurements were made using a Unicam UV-Visible spectrophotometer. All chemicals used were of analytical grade. De-ionised water was used for preparing solutions.

2.2 Procedures

The chemical oxide composition of the fly ash was determined by XRF spectrometry after being prepared as fused disks according to standard procedures. XRD scans were performed using Cu K α radiation at a speed of 0.2 degrees 2 theta/min. For particle size analysis, 1 g of the material was suspended in water with sodium metaphosphate as dispersing agent and pumped past a laser beam. Laser Fraunhofer diffraction principles were used and an algorithm applied to the data collected by computer to calculate the parameters of interest.

The determination of phosphate (as phosphorous) was done spectrophotometrically using the yellow ($\lambda = 470$ nm) vanadomolybdo-phosphoric acid method [15]. The method is widely used to determine dissolved phosphorous in natural waters and wastewaters. The calibration curve obtained was linear up to *ca.* 55 mg/l P, with a detection limit (3σ) of 0.2 mg/l P.

2.2.1. Kinetics of phosphate removal

2-g samples of fly ash were weighed and placed in several 250-cm³ Erlenmeyer flasks, each containing 200 ml of 80 mg/l PO₄³⁻ (as P) solution at pH 9.0 and 25°C (anhydrous KH₂PO₄ was used to prepare a 500 mg/l PO₄³⁻ (as P) stock solution). The flasks were stoppered and continuously shaken at a speed of 120 cycles per minute. The shaking was interrupted momentarily at pre-determined time intervals for a flask to be removed and the concentration of phosphate in the decanted and filtered (Whatman No. 42) supernatant solution to be determined. The phosphate monitoring was carried out at 10-minute intervals for the first 1 hour, then at longer intervals thereafter until the absorbance values levelled off.

2.2.2. Effect of concentration

Solutions of different initial concentrations- 20, 40, 60, 80 mg/l PO₄³⁻ (as P)- were used to investigate the effect of concentration on the kinetics of phosphate removal by 2 g of fly ash at pH 9.0 and 25°C following the procedure described in 2.2.1.

2.2.3. Effect of particle size

400 g of fly ash were shaken mechanically for 20 minutes in a stack of sieves of various apertures to obtain fractions of different particle size. 2 g of 45-, 75-, 90-, 150- and 300- μ m fractions were placed in Erlenmeyer flasks, each containing 200 ml of 80 mg/l PO₄³⁻ (as P) solution (pH 9.0 and 25°C). The flasks were then shaken continuously for 16 hours to attain equilibrium, after which the residual concentration of phosphate in the supernatant solutions was determined.

2.2.4. Effect of temperature

2 g of fly ash were placed in Erlenmeyer flasks, each containing 200 ml of 80 mg/l PO₄³⁻ (as P) solution at pH 9.0. The flasks were shaken continuously for 16 hours to attain equilibrium, surrounded by water set at various temperatures (25, 40, 50 and 60°C), after which the residual concentration of phosphate in the supernatant solutions was determined.

2.2.5. Effect of pH

2 g of fly ash were placed in Erlenmeyer flasks, each containing 200 ml of 80 mg/l PO₄³⁻ (as P) solution at 25°C and at initial pH values of 3.0, 5.0, 7.0, 9.0 and 11.0. The required pH values were obtained using 0.1 M HCl or 0.1 M NaOH. The flasks were shaken continuously for 16 hours to attain equilibrium, after which the residual concentration of phosphate in the supernatant solutions was determined.

2.2.6. Adsorption isotherms

0.5, 2, 3, 4 and 5 g of fly ash were shaken continuously with 200 ml of 100 mg/l PO_4^{3-} (as P) solution at pH 9.0 and 25°C for 16 hours to attain equilibrium, after which the residual concentration of phosphate in the supernatant solutions was determined.

2.2.7. Breakthrough curves

A glass column (4 cm I.D., 35 cm high) with a tap at one end was clamped vertically and a 10-mm layer of glass wool inserted near the bottom. The space above the plug was packed with a bed made by intricately mixing 5 g fly ash and 8 g inert sand (to improve the porosity) and another layer of glass wool was placed at the top of the bed. The space above the bed was filled with a 400 mg/l PO_4^{3-} (as P) solution (at pH 9.0, 25°C), which was then allowed to flow continuously through the bed at a steady velocity of 2.0 cm/min (volumetric flow rate of 25 cm³/min). The concentration of phosphate in the effluent was monitored at half-minute intervals by collecting 5 cm³ of it for analysis until the effluent concentration approached that of the influent.

3. RESULTS AND DISCUSSION

The chemical composition and particle dimensions of the fly ash are shown in Table 1. XRD analysis showed that the main mineral phase is quartz with smaller amounts of mullite and sillimanite. Figure 1 illustrates the variation of percent removal of PO_4^{3-} with time. It can be seen that the uptake of PO_4^{3-} virtually ceased after a contact time of about 6h.

Table 1. Chemical composition and physical characteristics of fly ash

Component	Mass %
SiO_2	52.4

Density (g/cm ³)	2.21

Figure 1. Kinetics of PO_4^{3-} removal from 80 mg/l solution
(Conditions: 2 g FA, pH 9.0, 25°C)

A plot according to Eq. (2) is presented in Figure 2. The good straight-line fit observed indicates that the sorption reaction may be approximated by first-order reversible kinetics. It was found that the adsorption rate was not significantly affected by the rate of mixing, providing evidence that intra-particle diffusion is the controlling resistance rather than the external diffusion. The values of the rate constant and intra-particle diffusion constants, calculated using Eq. (2) and Eq. (3), respectively, are given in Table 2.

Table 2. The values of first-order reaction rate constant and intra-particle diffusion coefficient

Parameter	Value
k' (per hour)	0.423
D_i (cm ² /s)	8.40×10^{-12}

Figure 2. Application of first-order kinetics to the data in Figure 1

The rate and separation efficiency of PO_4^{3-} from aqueous solution was found to increase with the initial phosphate concentration over the concentration range studied; the data is shown in Figure 3.

Figure 3. Effect of concentration on the kinetics of PO_4^{3-} removal
(Conditions: 2 g FA, pH 9.0, 25°C)

Although there was some increase in the percent PO_4^{3-} removed as the adsorbent particle size decreased (Figure 4), this increase was not proportionate to the increased surface area.

Figure 4. Effect of particle size on the efficiency of PO_4^{3-} removal
(Conditions: 80 mg/l PO_4^{3-} (as P), 2 g FA, pH 9.0, 25°C)

This gives an indication that for this adsorbent chemisorption is a more significant contributory phenomenon to the removal of PO_4^{3-} than physical adsorption. This observation is consistent with the findings of Johansson and Gustafsson [16], who suggested that Ca-P precipitation pre-dominates

surface adsorption as a mechanism for phosphate removal by slag. The effect of temperature on the efficiency of PO_4^{3-} removal by fly ash, slag and OPC is illustrated in Figure 5.

Figure 5. Effect of temperature on the efficiency of PO_4^{3-} removal.

The percent PO_4^{3-} removed was observed to increase with increasing temperature as expected, and it appears that some de-sorption may be occurring at higher temperatures. The decreasing slope of the temperature curve in the order fly ash, slag, OPC is indicative of decreasing activation energy for the PO_4^{3-} adsorption process.

Figure 6 illustrates the variation of percent PO_4^{3-} removed with the initial pH of the aqueous solution. It can be seen from the figure that the efficiency of PO_4^{3-} removal increases steadily in acidic pH.

Figure 6. Effect of pH on the efficiency of PO_4^{3-} removal
(Conditions: 80 mg/l PO_4^{3-} (as P), 2 g FA, 25°C)

There could be two reasons for this. Firstly, it may be due to the accumulation of positive charge on the adsorbent surface that increases its affinity for the negatively charged phosphate ions. Secondly, an increased proportion of phosphate ions will be converted to the acidic forms (H_2PO_4^- and HPO_4^{2-}), which may be more readily removed from solution via de-protonation and subsequent precipitation as $\text{Ca}_3(\text{PO}_4)_2$ as suggested by Tabikh and Miller [17]. The acidic pH would also release some Ca^{2+} ions from the fly ash via hydration to precipitate $\text{Ca}_3(\text{PO}_4)_2$. The observed slight increase in the efficiency of PO_4^{3-} removal beyond pH 9 could be due to the creation of favourable conditions for calcium phosphate precipitation at high pH, thus enhancing the removal of PO_4^{3-} by dissolved calcium, which is always present in the system.

Table 3 shows the experimentally obtained adsorption data. The fit of the data to the Frumkin isotherm is shown in Table 4, and the application of the Frumkin equation to the data is illustrated graphically in Figure 7. Attempts to fit the data to the Langmuir and Freundlich isotherms yielded non-linear plots with values of $R^2 < 0.4$. It is evident that the Frumkin isotherm is the appropriate one for fitting the data. The Frumkin constants were calculated and are shown in Table 4. The value of the lateral interaction coefficient α reflects the phosphate-adsorbent strength of interaction.

Table 3. Experimental adsorption data

mass of fly ash (g)	mg/l P^a after adsorption	mg P^a adsorbed
0.5	72.8	5.44
2	71.9	5.62
3	71.4	5.72
3.5	70.2	6.43
4	65.0	7.00
5	58.7	8.26

$^a\text{PO}_4^{3-}$ (as P)

Table 4. Frumkin isotherm constants and linear correlation coefficients

R^2	α	β
0.9918	3.061	0.0254

Figure 7. Application of the Frumkin isotherm to the data in Table 3
(Conditions: 100 mg/l PO_4^{3-} (as P), pH 9.0, 25°C)

The data obtained for the breakthrough experiments are shown in Table 5, and a typical breakthrough curve is represented in Figure 8.

Table 5. Breakthrough data

t_E^a (min)	V_T (cm ³)	V_Z (cm ³)	h_Z (cm)	C_T (mg PO ₄ ³⁻ /g)
2.8	187	116	1.742	32

^aBreakthrough time

Figure 8. Breakthrough curve for PO₄³⁻ adsorption by fly ash
(Conditions: 5 g FA, pH 9.0, 25°C)

The curves obtained were good approximations for characteristic symmetrical breakthrough *S*-curves. For practical purposes the breakthrough and exhaustion times were taken to be the times at which the effluent concentration reached 5 and 95 %, respectively, of the influent concentration. The value of the height of the exchange zone h_Z (see Eq. (4)) is a measure of the rate of ion exchange and/or phosphate removal, while the value of the breakthrough time t_E is indicative of the adsorption capacity. The capacity value C_T was obtained by graphical integration of Eq.(5). This value (Table 5) is quite substantial, and is of a similar order of magnitude as the 67 mg/g (calculated from adsorption isotherms and not from breakthrough curves) reported by Akgerman and Zardkoohi [8] for the adsorption of phenol on fly ash. Capacity values obtained experimentally from breakthrough curves can be extrapolated to calculate the capacity of a large-scale bed [14].

4. CONCLUSIONS

The by-product fly ash has been successfully used for the removal of phosphate from aqueous solution. Potential economic utilisation of this materials might be either as a lining to slow down the seepage of nutrients such as phosphate from landfills or as a fixed-bed for treating agricultural and other waste waters. The phosphate-loaded solid waste may then be solidified by the addition of lime or Portland cement to a concrete mass that is stable and durable enough for safe disposal.

POZZOLANIC PROPERTIES OF CALCINED PAPER SLUDGE

Jean Péra¹ and Jean Ambroise¹

¹Unité de Recherche Génie Civil, Institut National des Sciences Appliquées, Villeurbanne, France.

E-mail: Jean.Pera@insa-lyon.fr

ABSTRACT

Worldwide, the paper industry produces more than 20 million t/y of residues from wastewater treatment and de-inking. Traditionally, papermills deposit these residues in landfills or burn combustible residues and landfill the resulting ash.

These sludges consist basically of water (50%), organic matter (25%), and minerals (25%). The organic matter contains binders and fibres that cannot be re-used in new paper products. The minerals consist of calcium carbonate and kaolin used for various quality reasons in the papermaking process.

Through a European research project, a thermally controlled process, in which these minerals were converted into a valuable product with pozzolanic properties, was developed.

This paper deals with the influence of the sludge composition and the calcination parameters on the pozzolanic activity of the calcined product. A multiple linear regression analysis shows that the main factors affecting the pozzolanic activity of the calcined sludge are: the kaolin content of the raw sludge, the quantity of lime produced during calcination, and the quantity of particles lower than 10 μm present in the product.

1. INTRODUCTION

The recycling of paper has become an important industry in the past decade. Recycling reduces the requirement for virgin fibre and energy and can lower the environmental impact of paper manufacture. Between 1983 and 1995, the amount of recovered paper utilized by the European paper industry increased from 14.4 to 30.7 million t/y [1]. The re-use of recovered paper in papermaking inevitably results in the generation of process residues that cannot be used in paper production. These residues most often are disposed of landfills. However, landfills are becoming increasingly undesirable and prohibitively expensive. Therefore, it is important to find alternate disposal means for these sludges.

Recovery of energy, useful materials, or both from the sludge could provide an economical alternative to landfill disposal. Many mills are choosing incineration as a way to handle sludge [2-4]. Air emissions are not a problem for combustion temperatures above 870°C. The ash produced is not a hazardous material. The volume of ash from the incineration process is significant, typically around 25 % of total dry solids. Disposal of incinerator ash is a problem that is becoming increasingly important. Few constructive uses for incineration ash have been developed, and none that are used by the pulp and paper industry. Typically, it is used for land-spreading or as a component of cement [5].

The disposal option considered in the present paper is developing a controlled calcination process which utilizes the organic content of the sludge as fuel and allows the re-use of the resulting ash as a pozzolanic material usable in cement and concrete [6-7]. Such application is possible due to the composition of the sludge: 50 % water, 25 % organic matter and 25 % minerals consisting mainly of calcium carbonate and kaolin. When burnt in the range of 650 to 750°C, kaolin is transformed into metakaolin, a very reactive pozzolan. During the process, the following three main steps occur:

- i) organic matter is incinerated, producing sufficient energy to keep the process running autothermally,
- ii) water is evaporated,
- iii) kaolin is transformed into metakaolin, while calcium carbonate is preserved.

This paper deals with the influence of the sludge composition and the calcination parameters on the pozzolanic activity of the resulting ash. The behavior of calcined sludge in concrete is also presented.

2. COMPOSITION OF RAW PAPER SLUDGES

Sixteen sludges supplied by different European facilities were investigated. The moisture content of the sludges as received was in the range of 35 to 60 % by weight. The average wet density of sludges was 600 kg/m³. The mineralogy of dried sludges was assessed by means of X-ray diffraction (XRD), Infra-red spectrometry (FTIR), Differential thermal analysis (DTA) and chemical analysis. The results are shown in Table 1.

Table 1. Mineralogy of raw dried sludges (w_t %).

S15	54.2	15.7	3.0	4.1	1.3	20.3	44.4
S16	32.3	26.5	2.6	1.7	0.8	36.1	67.7

The inorganic fraction of dried sludges is in the range of 45 to 75 %. It is mainly composed of kaolinite and calcite. The ratio between kaolinite and calcite varies from 0.36 (S8) to 2.94 (S1). In this inorganic fraction, the proportion of kaolinite reaches 61 % for S1 and S11, while it is only 25 % in S6 and S8. The calcium carbonate content is as low as 21 % in S1 and reaches 70 % in S6. Some sludges (S2 and S11) contain more than 5 % talc. The amounts of muscovite and quartz are generally low.

3. THERMAL PROCESSING OF SLUDGES

Sludges were burnt in a laboratory electrical fixed-bed furnace. The volume of the furnace was 125 L and 5 kg of wet sludge was calcined per batch. The temperature was limited to 700°C. A previous study has shown that higher temperatures led to significant decarbonation of calcite and yielded unreactive products (i.e, anorthite and gehlenite) [6].

The temperature was increased at a rate of 250°C/hr and the product was maintained at 700°C for 5 hours. Then, it was cooled, with the furnace being closed. Discharging took place as the furnace recovered to ambient conditions. The cooled burnt sludge was de-agglomerated to get particles smaller than 100 µm. Laser granulometry and BET surface area analyses were carried out to characterize the physical properties of residual ash. XRD and FTIR spectrometry analyses were also performed to investigate the transformation of kaolinite into metakaolinite, as well as the preservation of calcite during calcination.

The evolving gases were analyzed during the tests. The values recorded for SO₂ and NO_x were under the European standard limits; that for CO above the limit. This result needs the presence of a post-combustion chamber to decrease the CO content of gases. As sludges contain chlorides and heavy metals and the calcination occurs at about 700°C, the formation of dioxin-furans may be promoted during calcination. Within the sixteen sludges investigated, only two of them presented this risk. Therefore, emissions have to be treated by a post-combustion system in an industrial process.

4. CHARACTERIZATION OF CALCINED SLUDGES

XRD and FTIR spectrometry data show that kaolinite was completely dehydroxylated during incineration and transformed into metakaolinite. Calcite was somewhat decarbonated, especially in sludges containing the lowest proportions of kaolinite (i.e, S3 and S6). The presence of an IR band at 3645 cm⁻¹ revealed the formation of Ca(OH)₂ after cooling. The intensity of the band allowed the determination of the quantity of calcium hydroxide present in the final product. The results obtained are shown in Table 2. Table 2 also presents the particle size distribution and the BET specific surface area of calcined sludges.

From Table 2, it appears that important agglomeration occurred during the incineration of S1, S9, S10 and S16, in which 14 to 27 % particles were found to be larger than 100 µm. The average diameter of the particle size distribution is in the range of 7 µm (S4) to 29 µm (S1). The ultra-fine particle content (< 5 µm) varies from 18 % (S8) to 40 % (S4) and the BET surface area ranges from 5.7 m²/g (S10) to 15.9 m²/g (S1).

5. POZZOLANIC ACTIVITY OF CALCINED SLUDGES

5.1 Assessment of the Pozzolan Activity

The term "pozzolanic activity" includes two parameters, namely the maximum amount of lime that a pozzolan can combine and the rate at which such combination occurs. Therefore the pozzolanic activity of the thermally converted paper residues was measured on pastes containing 50 % calcium hydroxide and 50 % calcined sludge, hydrated at equivalent consistency (W/S = 0.70). The control paste was a mixture of 50 % calcium hydroxide and 50 % fine quartz. The residual DTA peak of calcium hydroxide was measured at different ages and the lime consumption was calculated by comparing the peak obtained in pastes containing quartz and calcined sludge. The behavior of calcined sludges was compared to that of a commercial metakaolin (MK) presenting the following properties: metakaolinite content: 97 %; D₅₀ = 1 µm; BET surface area: 14 m²/g.

Table 2. Quantity of $\text{Ca}(\text{OH})_2$ present in calcined sludges (w_t %) and physical properties.

Sludge	$\text{Ca}(\text{OH})_2$	Particle size distribution (%)			D_{50} (μm)	BET surface area (m^2/g)
		< 5 μm	< 10 μm	< 100 μm		
1	0	20	32	73	29	15.9
2	0	30	62	98	8	8.4
3	36	20	40	91	17	10.6
4	12	40	68	100	7	16.5
5	15	28	54	94	10	10.2
6	27	15	30	96	20	9.2
7	11	18	34	95	17	9.4
8	7	22	48	95	11	7.0
9	9	20	32	74	19	16.0
10	5	28	56	86	9	5.7
11	0	30	48	90	11	12.6
12	7	25	45	97	14	14.6
13	10	28	48	95	11	10.2
14	2	26	50	97	10	7.0
15	6	30	58	95	9	10.7
16	2	22	42	73	16	9.6

5.2 Lime Consumption

The results are shown in Figure 1.

Figure 1. Lime consumption of calcined sludges and MK.

After 3 days of hydration, the best pozzolans are calcined S4, S11, S2, S1 and S15; the less reactive are calcined S3, S6, S7 and S8. This ranking is confirmed after 7 and 28 days, except for calcined S7 which consumes a lot of lime between 7 and 28 days. After 28 days of hydration, 100 % calcium hydroxide is consumed by calcined S1, S11 and S12 which present a kaolinite content varying from 43.3 to 61.4 % in the organic fraction. This result is remarkable compared to MK which consumes less lime than those pozzolans (only 94 % after 28 days). The kaolinite content itself seems to be insufficient to explain the reactivity of calcined sludges, as shown in Figure 2.

Figure 2. Relationship between the lime consumption and the kaolinite content of the inorganic fraction after 28 days of hydration.

A multiple linear regression analysis was therefore undertaken to explain the pozzolanic activity of calcined sludge at different hydration times: 3, 7 and 28 days. The parameters investigated were:

- the lime consumption: C,
- the quantity of calcium hydroxide present after cooling: D,
- the kaolinite content of the inorganic fraction: K,
- the BET specific surface area: S,
- the quantity of particles smaller than 10 μm : G10,
- the average diameter of the particle size distribution: D50.

The software used for this task was SPSS for MS Windows. The main findings of this investigation are as follows:

i) after 3 days of hydration, the pozzolanic activity of calcined sludge is explained by 4 parameters (D, K, G10 and D50):

$$C_3 = -0.77D + 0.61K + 1.67 \text{ G10} + 2.30 \text{ D50} - 89 \quad R^2 = 0.86$$

ii) after 7 days of hydration, the main parameters are K and D:

$$C_7 = 1.07K - 1.17D + 24.5 \quad R^2 = 0.76$$

iii) after 28 days of hydration, the main parameters remain K and D:

$$C_{28} = 1.18K - 1.42D + 34 \quad R^2 = 0.84$$

A general conclusion may therefore be drawn for practical use. The main parameters influencing the pozzolanic activity of calcined sludge are:

- the quantity of kaolinite in the inorganic fraction,
- the quantity of calcium hydroxide produced during thermal treatment and which has to be minimized,
- the quantity of particles smaller than 10 μm , which has to be maintained at a certain level to get high activity at early ages.

The BET surface area does not play any role.

6. BEHAVIOR OF CALCINED SLUDGE IN CONCRETE

Calcined S1 was used for these experiments and compared to other pozzolans at a cement replacement of 15 %: commercial metakaolin (MK), fly ash (FA) and silica fume (SF). The cement was a Type CEM I CPA 52.5 according to European standards. The mixture proportions of the control concrete were:

- cement: 350 kg/m³,
- sand (0/4 mm): 785 kg/m³,
- coarse aggregate (14/20 mm): 1,070 kg/m³,
- water: 177L/ m³,
- superplasticizer in liquid form (SP): 9.8 L/m³.

The slump was 160 mm. In other concretes, 15 % cement was replaced by each admixture, and the water and superplasticizer contents were adjusted to get about the same workability, as shown in Table 3.

Table 3. Properties of fresh concrete.

Mineral admixture	Water (L/m ³)	SP (L/m ³)	W/CM	Slump (mm)
S1	178	13.3	0.51	150
MK	177	13.3	0.51	150
FA	167	8.8	0.48	150
SF	200	10.9	0.57	165
Control	177	9.8	0.51	160

The compressive strength was measured on cylinders ($\varnothing = 110$ mm, h = 220 mm) at different ages: 2, 7, 28 and 90 days.

The results obtained are presented in Figure 3.

Figure 3. Compressive strength of different concretes.

Figure 3 points out that all admixtures behaved very well and led to high strength at 28 days. Calcined sludge (S1) developed the same performance as commercial metakaolin (MK).

7. PILOT TESTS OF INCINERATION

Pilot tests were undertaken using different types of combustors: rotary kiln, gas suspension calciner, screw-kiln, fluidized-bed combustor and multi-hearth furnace.

7.1 Rotary Kiln

Wet sludge was introduced in the colder part of the kiln heated by gas. The air admission, the kiln speed and the draught were adapted according to the characteristics of the product (calcite content, heat value) and the reactions that can occur.

A de-inking sludge was treated in such conditions. When the temperature reached 700°C, kaolinite disappeared and calcite was completely destroyed, yielding gehlenite and free lime. In any case, no pozzolanic material was formed. Suitable product was obtained as the temperature dropped to 650°C, but organics were not totally destroyed. Therefore, the color was too dark for applications in concrete. The control of the temperature profile seems very difficult in a rotary kiln.

7.2 Gas Suspension Calciner

Before being calcined, paper sludge had to be dried. A drier-crusher was used for this task. The moisture of the sludge dropped from 60 % to less than 1 % and a powder was handled during the calcination process. The temperatures measured at the top of the gas suspension riser pipe were in the range of 520°C to 630°C. The temperature close to the material inlet was up to 100°C higher than the average calcination temperature. At 520°C, a second heat treatment is necessary.

XRD analyses showed that kaolinite has been dehydroxylated and pointed out the formation of detectable amounts of free lime. Chemical analysis of ash confirmed the presence of approximately 2 % free lime in the heat treated product, and the conduction of a CaO balance showed that 7-8 % of the CaO present in the drier-crushed material cannot be accounted for and, thus it must be assumed to have reacted as a result of the heat treatment.

The pozzolanic activity of the final product was lower than that observed in laboratory tests: 83 % instead of 100 % lime consumption, for S1.

7.3 Screw Kiln

Screws are installed in the furnace heated by gas or fuel burners. The furnace is composed of two cells:

- the first one which receives the raw material, is used to dry the sludge,
- the second one is fed with dried sludge and used for calcination.

A sewage sludge was treated using this equipment. No decarbonation occurred and the kiln was very easy to manage. The kiln should be able to treat about 3 t/hr wet sludge. The main problem is that such equipment is still in development and has not yet been used in industrial applications. It allows low inputs of sludge.

7.4 Fluidized Bed Combustor

The wet sludge was discharged on a fluidized bed where it dried and burnt. The furnace was also equipped with a post-combustion chamber.

According to the conditions of the calcination process (temperature in the range of 550 to 700°C), the free lime content of the ash was lower than 2 % and the calcined sludge developed good pozzolanic properties.

When the sludge presented a heat value higher than 1500 kcal/kg, it could be burnt without any additional gas. The process was stable and the final product presented a suitable whitish color. However such equipment cannot treat more than 3 t/hr wet sludge.

7.5 Multi Hearth Furnace

The tests were done at NESA facilities (Belgium), using a Nichols Herreshoff Pyrolyser multi-hearth furnace. Development of the Nichols Herreshoff Pyrolyser started with the fact that in the conventional process of incinerating sludge and refuse, it is sometimes possible to start volatilizing organic matter at a temperature only slightly higher than that needed for the evaporation of free water.

In order to make use of this behaviour, a modified form of the Herreshoff multi-hearth furnace was applied. The furnace consisted of a vertical cylinder constructed of steel and lined with refractory brick. The sludge entered at the top and descended through a series of hearths until the final dry sterile ash was discharged at the bottom.

Circulating rabble teeth constantly turned and moved material on each hearth, exposing fresh surfaces for contact with the gas in order to ensure consistent processing during the various stages. In the Nichols Herreshoff Pyrolyser the crucial processing stages start with the pre-drying of the sludge on the upper hearths. As the feed descends to the middle of the furnace its temperature rises, so that the organic materials drive off their volatile constituents in a strongly reducing atmosphere. As this stage, close control of solid and rising gas temperature is assured. A very stable process results.

Gases given off from the feed are led out of the furnace and into a separate post-combustion chamber, where complete burning of the volatile organics takes place. These gases are held at a minimum temperature of 800°C for half a second or more in order to achieve complete combustion of gases, thus ensuring that there is no possibility of odours in the off-gases.

In the case of pyrolysis followed by incineration of the solid product, excess air is provided to the bottom combustion zone of the furnace and to the post-combustion chamber. Exhaust gases from the post-combustion chamber are controlled in the range 20 to 30 per cent. That is to say, excess air is kept low, enabling high gas temperatures to be reached economically. In an alternative design there is no post-combustion chamber as such, the pyrolysis gas being ducted away for use as a separate source of fuel.

Meanwhile, inside the furnace itself, the residual solid material, having given off its volatiles, passes down into the third zone, where, with the addition of further pre-heated air, total oxidation is carried out and the residual fixed carbon is oxidized. No more than 0.3 per cent of original fixed carbon remains. Immediately before discharge there is a final cooling zone to provide thermal recovery from the ash.

The calcination with pyrolysis allowed a significant reduction of the air flow in the furnace (- 36 %) and the gas consumption (- 50 %). Therefore, it is possible to reduce the size of equipment needed for emission treatment. The quantity of dust present in the emissions was very low: about 4 % of the sludge weight.

In each case (with or without pyrolysis), the final product was very reactive. The temperature of treatment was 630°C and the free lime content of the ash was lower than 0.5 %.

7.6 Ranking of the Different Calciners

The criteria used to rank the different calciners used for the pilot tests were:

- the precision of the temperature,
- the quality of the final product,
- the stability of the process,
- the energy consumption,
- the investment cost.

Each criterion received a mark from 0 (bad) to 3 (excellent). The higher the final mark, the better the calciner. The results of this ranking are shown in Table 4.

Table 4. Ranking of the different calciners used for pilot tests.

Calciner	Criteria used for rating					Total	Rank
	Precision	Quality	Stability	Energy	Investment		
Gas suspension calciner	2	2	1	0	Non available	5	3
Fluidized-bed combustor	3	3	2	1	3	12	2
Rotary kiln	1	1	0	0	1	3	4
Multi-hearth furnace	3	3	3	2	2	13	1

From Table 4, it appears that the multi-hearth furnace and fluidized-bed combustor are the more suitable equipment to calcine paper sludge in order to get a highly reactive pozzolan. Therefore, they were chosen for industrial tests.

8. CONCLUSION

The transformation of paper sludges into a high-value added material represents a reliable and long-term issue for the paper industry. Despite a lower kaolinite content, some calcined sludges are able to develop higher pozzolanic activity than metakaolin obtained by calcination of clays. The main parameters playing a role in this activity are the kaolinite content in the organic fraction and the quantity of calcium hydroxide produced by calcite decarbonation during calcination. These two parameters are closely linked and, when considered separately, insufficient to describe the reactivity of calcined sludges. At early ages, the proportion of particles smaller than 10 μm also influences the reactivity. The average diameter of the particle size distribution and the BET specific surface area do not play a main role in this activity.

ABSTRACT

This work presents the application of a mathematical model for predicting concrete strength in anticipated experimental concrete mix design and quality control. Strength development model is based on cement paste hydration and its relation with porosity in various levels of water-cement ratio. Using recent data as examples, with the use of silica fume and HRWR admixture, the main steps of an anticipated experimental concrete mix design method is briefly presented as an improvement of the traditional “IPT concrete mixture design method”. Additionally, the “AMEBA” anticipated concrete strength control method, adapted to ACI quality control philosophy is illustrated, with data from a precast concrete plant using pozzolan to prevent effects from alkali-silica reactivity of cement with gravel aggregate.

1. INTRODUCTION

The Technological Research Institute (IPT) of the São Paulo State Government has continuously improved a concrete mixture design method since 1927 [1]. This dynamically changing procedure is intensively used and is well known as the “IPT Concrete Mixture Design Method” in the cement and concrete media of Brazil [2,3], as well being disseminated worldwide by old IPT collaborators [4].

Additionally, models for strength-time function were derived and verified with data from the Institute [5], and a derivative concrete strength prediction method was published and called “AMEBA Method” [6].

This work briefly presents the model’s fundamentals, a practical example of mixture design method application with its strength anticipating improvements, as well anticipated concrete quality control results, adapted to the international ACI concrete control procedure with an example using pozzolan addition to ordinary portland cement for precast elements.

2. HYDRATION AND STRENGTH DEVELOPMENT MODELS

2.1 Basic mathematical model: strength versus w-c ratio versus time

One of Powers' approaches for compressive strength as a function of gel/space ratio, which is a function of the non-evaporable water and hydration degree in a cement paste, is similar to Abrams' “law” [7] and is given by equation 1 [8]:

$$f_{c,j} = A_p / B_p^{x/w_n} \quad (1)$$

Where:

$f_{c,j}$ = compressive strength at age j ;

A_p and B_p = Powers' constants for paste, depending on materials and test conditions;

x = water-cement ratio;

w_n = relative mass of non-evaporable water,

Equation 1 can be seen as a time generalization of Abram's "law", because it is valid for any age, and paste-aggregate transition zone effects, not considered for paste, can be regarded by adequately adjusted constants A_p and B_p also for concrete. From equation 1 it is possible to arrive at equation 2 [6]:

$$f_{c,j} = A / B^{x/h_j} \quad (2)$$

Where:

A and B = constants depending on materials (paste-aggregate transition zone included) and test conditions;

h_j = hydration degree at age j .

Inverse of hydration degree can be given by equation 3 [5]:

$$1/h_j = 1 + j^{-n} \cdot (h'_{\max}{}^{-1} + h''_o{}^{-1} \cdot x^{-1}) \quad (3)$$

Where:

j^{-n} = transformed time, age j elevated to $-n$, with $n = 0.5$ for no-slag or low-slag cements;

h'_{\max} = maximum initial hydration "speed" considering the transformed time T ;

h''_o = derivative of the initial hydration "speed" as a function of x , when $x = 0$.

Then, we can write equation 4 substituting equation 3 given values in equation 2:

$$f_{c,j} = A / B^{(x+x \cdot j^{-n} / h'_{\max} + j^{-n} / h''_o)} \quad (4)$$

We can write equation 4 as equation 5:

$$f_{c,j} = A / (B^x \cdot E^{x \cdot j^{-n}} \cdot D^{j^{-n}}) \quad (5)$$

Where:

$E = B / h'_{\max} = \text{constant}$;

$D = B / h''_o = \text{constant}$.

Equation 5 assumes the aspect shown in Figure 1 when graphically expressed.

Figure 1. 3-D diagram representing equation 5, adjusted from concrete data using OPC, silica fume, and HRWR admixture.

2.2 Linearization for extrapolation and prediction of strength

Equations 4 and 5 are linearizable, that means, it is possible to transform a surface shown in Figure 1 to a ruled (composed by straight lines) surface, applying the logarithm function to compressive strength, and elevating age to exponent $-n$. Figure 2 shows a view of a linearized graphic with plotted real compressive strength data from three different concrete mixture proportions (with ingredients from the same samples) poured in 1935 by Ary Torres [9, 10]. Transformed time ($j^{-0.5}$) is represented on abscissa's axis, where real age grows from right to left and zero means infinite age.

Figure 2. Transformed strength-transformed age diagram ($n = 0.5$)

3. DESCRIPTION WITH AN EXAMPLE OF ANTICIPATED EXPERIMENTAL MIXTURE DESIGN METHOD

The following steps briefly describe and exemplify the IPT concrete mixture design method [3]:

3.1 First step, rough estimative of concrete mixture proportions

First step utilizes the equation 5, and also equation 6, this last one as follows:

$$m_{est} = x_{est} / [F + G \cdot \log(d_{max}) + H \cdot a_{tc}] - 1 \quad (6)$$

Where:

x_{est} = estimated water-binder ratio, in the example calculated as 0.362 kg/kg using equation 5 for compressive strength (f_{cj}) at age (j) of interest, (in the example, 49,1 MPa at 28 days, exponent $n=0.5$) and constants with prior adjusted values for similar concretes, (in the example, for Brazilian type V-ARI cement with 10 % of silica fume, $A = 106.7$; $B = 4.320$; $D = 19.81$; and $E = 1.260$);

d_{max} = required maximum aggregate size, in the example, 19.0 mm;

a_{tc} = required slump, in the example 100 mm;

F , G , H , previously found empirical constants [2], in the example with the values 8.029×10^{-2} , -1.946×10^{-2} , and 7.447×10^{-5} , respectively, for ordinary portland cement with silica fume with HRWR admixture, crushed granite cubic aggregate;

m_{est} = roughly estimated aggregate-binder proportion, in the example calculated as 4.75 kg/kg.

3.2 Second step, experimental establishment of dry mortar-dry concrete proportion

The second step is an operation with fresh concretes [2], the procedure being to vary mortar content (dry mortar = cement + fine aggregate) in a mixer, (each tentative mixture varying 2%) with constant coarse aggregate amount and constant aggregate-binder proportion, making the mortar content choice for desired workability. In the example, experiments resulted in 50 % for mortar/concrete (dry basis, weight). A necessary amount of water for workability can be used without preoccupation at this step.

3.3 Third step, preparing of specimens with “rich”, “medium” and “poor” mixture proportions

The third step consists of making experimental concretes with aggregate-binder proportions m_{est} (“medium”), $m_{est} - 1$ (“rich” in cement), and $m_{est} + 1$ (“poor” in cement). Each of these mixtures is made with mortar-concrete proportion above determined (50 %) and its water-binder ratio is tentatively established to obtain desired slump; practical binder consumption is calculated from density measuring of the fresh mixtures. Specimens are poured and cured to desired ages for each of the three mixtures. Table 1 shows results obtained for the given example.

Table 1. Example of fresh concrete data at third step

HRWR/ binder (% Weight)	Silica fume/ binder (% Weight)	Slump range (mm)	Aggregate/ binder (kg/kg)	Water/ binder (kg/kg)	Binder content (kg/m ³)
1.0	10	100 ± 10	3.75	0.454	461
			4.75	0.515	382
			5.75	0.614	325

Note: Binder = cement + silica fume

3.4 Fourth step, hardened concrete tests

Specimens are tested at different ages, as shown in table 2, that summarizes the results.

Table 2. Example of hardened concrete data at fourth step

Water/binder (kg/kg)	Mean Compressive strength of 3 tests, (MPa) at age					
	3 days	7 days	14 days	28 days	63 days	91 days
0.454	41.3	51.3	58.0	63.3	66.1	65.2
0.515	36.3	44.1	49.0	55.2	59.0	59.2
0.614	29.3	36.5	43.1	46.0	50.2	53.3

3.5 Fifth step, adjusted equations and mixture design diagram

At the end of this step, the anticipated or definitive experimental concrete proportioning is obtained for a specified job.

Equation 5 is the generalization of Abrams’ “law” for any age, and above results lead to the following exemplificative situations when it is adjusted using Minimum Square Method and exponent n is assumed 0.5:

$$f_{c,j} = 189.1 / (7.615^x \cdot 2.562^{x \cdot j^{-0.5}} \cdot 1.234^{j^{-0.5}}) \quad (5a)$$

When only results till 7 days where available (equation 5a is the anticipated equation), and

$$f_{c,j} = 141.6 / (4.179^x \cdot 4.286 \cdot E^{x \cdot j^{-0.5}} \cdot 1.399^{j^{-0.5}}) \quad (5b)$$

using all results in the regression.

For the desired compressive strength 49.1 MPa at 28 days, the above equations lead to necessary water/binder of respectively 0.593 (anticipated 21 days) and 0.584 (definitive).

Of course, the later result prevails for the establishment of designed definitive mixture proportions. For establishment of mixture proportions at 28 days, extrapolation from 3 and 7 days is acceptable and calculations agree reasonably [6].

Relating concrete proportions water/binder (x), aggregate/binder (m) and cement content (C) in the fresh state, equations 7 and 8 (called “Lyse’s” and “Molinari’s”) are inferred [3, 4]:

$$x = 0.08016 \cdot m + 0.1466 \quad (7)$$

(Adjusted Lyse’s equation [3] for the example)

$$1/C = 0.0004549 \cdot m + 0.0004623 \quad (8)$$

(Adjusted Molinari’s equation [3] for the example)

Anticipated curves from the anticipated situation are graphically expressed in the IPT Mixture Design Diagram shown in Figure 3 (Diagram for a concrete family with OPC, silica fume, HWRA admixture, 19 mm crushed granite, river sand and 10 ± 1 cm slump. Curves without experimental points are extrapolations to the future).

Figure 3. “IPT Mixture Design Diagram” [2, 3, 4] relating predicted (after 7 days) concrete compressive strength to mixture proportions.

In the example, it is possible to arrive to the mixture proportions given in table 3.

Table 3. Concrete mixture weight proportions for the example (binder is considered unity)

Status of mixture design	Used equations	Cement	Silica fume	HRWR admix.	Fine Aggr.	Coarse Aggr.	Water
Anticipated from 3 and 7 days ages only	5a and 7	0.900	0.100	0.010	2.283	3.283	0.593
Definitive after 91 days age	5b and 7	0.900	0.100	0.010	2.228	3.228	0.584

Note: proportions for obtention of 49.1 MPa at 28 days age, dry mortar/dry concrete = 50%.

4. ANTICIPATED CONTROL METHOD (E.G. FOR PRECAST POZZOLAN CONCRETE)

The “AMEBA” method name is due to the general principle of extrapolating compressive strength at a late or high (“Alta” in Portuguese) age with results obtained earlier at medium (“Média”) and low (“Baixa”) ages. It was demonstrated that the method applies to cement products such as concrete, grout or mortar, including cement plant control [6].

Basic principles reside on the linear aspect shown in Figure 2 for the strength-time transformed curve of a given set of constituents and mixture proportions, mainly water-binder ratio.

Prediction is made with a simple rule of three with transformed time and transformed strength differences; after re-transforming, calculation results in equation 9:

$$f_{ca} = f_{cm}^{\text{AMEBA}} / f_{cb}^{\text{AMEBA-1}} \quad (9)$$

Where:

f_{ca} = compressive strength at a late age "a" or control age, example, 28 days;

f_{cm} = compressive strength at a medium age "m", example, 7 days;

f_{cb} = compressive strength at a low age "b", example, 3 days.

AMEBA = function of the three ages in study, given by equation 10:

$$\text{AMEBA} = (a^{-n} - b^{-n}) / (m^{-n} - b^{-n}) \quad (10)$$

Equation 9 was used to simulate an anticipated control using the American Concrete Institute control principles [11], with the concrete production data of precast elements in the Ilha Solteira Hydroproject, Brazil, with the following characteristics:

4.1 Concrete design requirements for strength simulated control in the example

Practical control age: 3 days;

Required minimum (5 % percentile) compressive strength at practical control age: 14,7 MPa;

Design control age: 28 days (simulation);

Required ACI [11] minimum compressive strength f'_c at 28 days(simulation)= 36.6 MPa;

Initially estimated production standard deviation of compressive strength $s_d = 7.0$ MPa (simulation);

Mean mixture design target strength $f'_{cr} = 46$ MPa.

Concrete composition (weights for 1 m³ of concrete): Cement, 271 kg; Pozzolan, 53 kg; Water, 132 kg; Natural Sand, 571 kg; Gravel 19 mm, 690 kg; Gravel 38 mm, 690 kg; Plastifying Admixture, 0,810 kg.

Slump range: 40 ± 5 mm.

Available control results: 186 series with compressive strength average results at 3, 7, and 28 days corresponding to a period

4.2 Characterization of concrete constituents in the control example – need for pozzolan

Cement in the example was an ordinary portland type with Brazilian standard strengths 19.5, 27.8, 39.1, and 45.3 MPa at 3, 7, 28, and 90 days, respectively, and Blaine fineness 354 m²/kg (averages of all the production).

Blaine fineness of the pozzolan was 790 m²/kg; pozzolanic activity indexes were 84.7 % with cement and 7.3 MPa with lime, with a water requirement of 105 %. Reduction in expansion was 97.2 %. Results of all job averages for cement and pozzolan chemical analysis are given in table 4.

Table 4. Chemical analysis of cement and pozzolan (average values for the whole job)

Average for	Ignition loss	I.R.	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	Na ₂ O	K ₂ O	Eq. Alkalis
Cement (%)	1.14	0.13	21.36	-	3.53	63.77	2.47	1.65	0.15	0.66	0.58
Pozzolan (%)	1.39	-	66.65	24.45	5.36	-	1.10	Nihil	-	-	-

The concrete aggregates used were a blend of natural aggregates (river gravel and sand). In the studies carried out it was observed that the alluvial aggregates were made up of medium and coarse sand and gravel with a certain mineralogical uniformity and predominant presence of quartz, quartzite, agate, chalcedony, silicified sandstone, silicified limestone, chert and ferruginous concretions. The petrographic evaluation (ASTM-C-295), chemical analysis (ASTM- C-289) and mortar bar tests (ASTM-C-227) showed the presence of deleterious minerals and expansion due to the alkali-aggregate reaction. Because of the potential reactivity of the aggregates, a pozzolanic material, from calcined kaolinitic clay, was used as a partial cement replacement, including the use for precast elements with higher earlier strengths.

4.3 Concrete control simulation with example's real data

For 28, 7 and 3 days ages, $n = -0.50$, AMEBA can be calculated as 1.9478, and equation 9 is expressed as equation 9a:

$$f_{c28} = f_{c7}^{1.9478} / f_{c3}^{0.9478} \quad (9a)$$

The above equation was used with the first series (n exponent is 0.5, indicated when materials have not a previous background). At series number 72, n (see equation 9) was changed because in a real situation it would be reasonable to have sufficient available data for a better evaluation of the exponent. For subsequent series, equation 9b, which n value is 0.67, was used:

$$f_{c28} = f_{c7}^{1.7917} / f_{c3}^{0.7917} \quad (9b)$$

Effectively, exponent 0.67 was considered good for this condition as shows the linearity obtained in Figure 4.

Figure 4. Transformed strength-time diagram for three points, each one being respectively the representation of all job average strengths at 3, 7 and 28 days, using $n = 0.67$ in time transforming.

Figures 5 and 6 show control charts for the job with simulated-predicted and effective results of tests at 28 days.

Figure 5. Predicted and effective mobile averages of 3 series along concrete production.

ACI lower limit f'_c not being respected is an alert for changes in the production process. As seen in Figure 5, concrete became better at the beginning of production and remained stable after series about number 40.

Figure 6. Predicted and effective individual values along concrete production.

In Figure 6, ACI individual limit is stated as $f'_c - 3.0$ MPa. One single value below this limit implies a revision of control, additional verification tests if judged necessary, and revision of corresponding concrete utilization or demolition in worst situations. Note that dispersion of prediction values is higher than of effective, but dispersion has a preference for higher values of strength.

5. CONCLUSIONS

This work summarizes and exemplifies methods for utilization in concrete technology of a linear model given by equation 5 and illustrated by Figure 1, derived from hydration evolution theories. Examples and refereed works permitted the conclusion that it is possible to use those methods efficiently for anticipated experimental concrete mixture design or for anticipated concrete control (in this work, specifically, with ordinary portland cement and pozzolan addition, and adapted to ACI control procedures).

Obviously a prediction method is not deterministic, and uncertainties are associated, as can be seen by observed differences and dispersion more accentuated for predictions than for effective values. As a result, the methods can be advantageously used with precautions, based on a reasonable knowledge of their principles and characteristics.

THERMODYNAMIC ANALYSIS OF THE SOLIDIFICATION PROCESS OF MIXED CEMENTS

M.S. Garkavi, D.M. Garkavi and E.A. Krishan

Magnitogorsk State Technical University, Magnitogorsk, Russia. E-mail: mgarkavi@mail.ru

ABSTRACT

The solidification of binding agents is the result of two interrelated processes - the formation of hydrates and the formation of structures. An artificial stone formed during this process undergoes a number of structural changes in its formation according to the evolution of the binding system which takes place continuously and only in one direction.

One can judge the thermodynamic stability of the structural state of the solidifying system by the value of the production of entropy, the minimum value of the production of entropy corresponding to a thermodynamically stable state.

The experimental study of the solidification of mixed cements on the basis of metallurgical slags and fly ashes shows the fact that the thermodynamic stability of the structure of the final stone depends on the content of mineral additives in the composition of the cement. The more mineral additive the less the thermodynamic stability of the structure of the cement stone. However, there is a certain mineral additive content range in mixed cements, which depends on their nature. The thermodynamic stability of cements with a certain content of mineral additive will be higher than that of the cement stone without any additive. Such mixed cements possess great strength and have a long life. It gives us an opportunity to use them successfully instead of Portland cement in different fields of construction.

According to the thermodynamic stability of the structure of the final stone, mixed cements are divided into a number of groups, and reasonable fields of application are proposed.

1. INTRODUCTION

The solidification of binding systems depends on thermodynamically irreversible interactive processes – the formation of hydrates and the formation of structure. The first process is determined by the chemical reaction between the binding agent and water and the specific products – hydrated new formations – are produced. The second process is connected with the formation of the spatial frame η (which shows the strength of an artificial stone).

While developing, this artificial stone undergoes a number of structural states, changing of which can be determined by the generalized thermodynamic coordinate the degree of the structure formation completion [1].

We may consider that the solidification process is a gradual change of different structures, i.e. the structures of the superior hierarchy arise from the structures of the inferior hierarchy [2,3]. In fact, the structure formation process may be considered as a process of formation and development of inter - particle contacts, and during this process their nature, type and strength change.

Mixed cements exist as two-component systems, consisting of PC clinker and mineral additive. During the solidification process several chemical reactions take place, connected with the different hydraulic activity of the components. At the same time, only one structure formation process that has physical nature, may take place in any isolated volume of the solidifying system. And every chemical reaction, taking place in the given binding system, is connected with the structure formation process and has influence on its development.

If the interaction of these chemical reactions with the structure formation process is separated in time, it can lead to the multi-stage process.

Multi-stage structure formation is in fact the formation of the separate structural states in binding system. This shows that inter – particle contacts of the same nature periodically take place. The number of stages in the structure formation depends on the correlation of hydraulic activity of components and their quantity in mixed cement.

1. EXPERIMENTAL RESULTS

In this paper we present the results of thermodynamic analysis of solidification of mixed cements on the basis of fly - ashes and waste metallurgical slags with different proportions of the slags in the investigated binding agents.

Figure 1 shows the change of the degree of completion of structure formation of mixed cements on the basis of fly ash.

Figure 1. The completion degree of mixed cement structure formation on the basis of fly – ash ($t = 20^{\circ}\text{C}$): 1 – 100% PC; 2–4 – the content of fly - ash 20, 50,80% correspondingly

The process of solidification may be divided into several periods, characterized by different kinetics. These periods reflect the changes in structural conditions of the resulting cement stone.

In Figure 1, related to PC, one can separate three main periods:

- The first period is characterized by the increase of the degree of completion of structure formation η , which is connected with the formation of a coagulation structure in the binding system, and it coincides in time with the induction period of hydrate formation.

- The second period is accompanied by the reduction of the degree of completion of the structure formation process, which is connected with the destruction of the coagulation system owing to acceleration of the hydration process. During this period a transition coagulation– condensation structure takes place in the binding system.
- The third period is also characterized by the increase of the degree of completion of the structure formation, which is connected with the formation of the condensation – crystallization structure of the cement stone.

As it follows from Figure 1, mixed cements, containing 20 and 80 percent of fly–ash (curve 2, 4), have the nature of structure formation analogous to the structure formation of PC. Mixed cements, containing 50 percent of fly-ash (curve 3), have two maxima at the curve of changing of degree of completion of structure formation, that is the evidence of a multi stage process which takes place in the given binding system.

The mixed cement, containing 80 percent of dump steel-smelting slag, has the same nature of structure formation. When there is less quantity of steel-smelting slag in mixed cements, these cements have the nature of solidification analogous to PC (Figure 2).

Figure 2. The completion degree of mixed cement structure formation on the basis of waste steel – smelting slag ($t = 20^{\circ}\text{C}$): 1 – 100% PC; 2-4 – the content of steel – smelting slag 20, 50, 80% correspondingly

The emergence of the second maximum on the curve of changing of degree of completion of the structure formation is connected with the intensification of the hydrate formation process owing to the pozzolanic reaction of mineral additives to the mixed cement. It prolongs the existence of transition coagulation – condensation structure in the solidification system. And so we can observe a competition between the appearing condensation – crystallization contacts and coagulation – condensation ones, which already exist. And it results in the emergence of the second maximum at the curve of changing of η (Figures 1 and 2).

If there is a low proportion of mineral additive in the mixed cement, the pozzolanic reaction develops practically synchronously with the hydration reaction of clinker component, i.e. the simultaneous interaction with the process of structure formation takes place and this process is

developed according to a single stage mechanism. If there is a high proportion of mineral additive, this synchrony is broken. This is connected with the fact, that apparent self-energy of mineral additive hydration activation considerably exceeds the activation energy of clinker components of the mixed cement [4]. It is important to mention, that when the solidification temperature increases owing to heat activation the asynchrony disappears and the structure formation process goes on according to single-stage mechanism.

According to all these facts, we can conclude that the precondition for the development of multi-stage structure formation during the solidification of mixed cement is the essential difference between apparent self-energies of activation of hydrate formation of these cement components.

In Figure 3 there are values of the apparent energy of hydration activation of mixed cement components. Figure 3, shows that the blast-furnace granulated slag has apparent self-energy of hydration activation similar to the activation energy of PC. This fact explains the absence of the multi-stage structure formation process in slag Portland cements even when there is a high proportion of slag in them.

Figure 3. The apparent hydrate formation activation energy of mixed cement components: 1 – clinker; 2 – fly-ash; 3 – blast – furnace granulated slag; 4 – waste steel – smelting slag

As the hydrate formation is only one aspect of the cement stone formation, we should observe the structure formation criteria for developing multi – stage structure formation in a binding system.

The strength of the forming cement stone in mixed cements is determined by adhesion contacts. The hydrated new formations of both components take part in the formation of these contacts. The contribution of mixed cement components in the formation of contacts of the particular type structure development can be estimated by the quantity of the instantaneous power of structure formation W_{η} , which is the product of the constant K_{η} of the process velocity and the quantity of its apparent activation energy $E_{A\eta}$, i.e. $W_{\eta}=K_{\eta}E_{A\eta}$ [4].

During the synchronous interaction of the hydrate formation and the structure formation processes, i.e. during the single – stage structure formation the following ratio is carried out:

$$W_{\eta \text{ [mix]}} < W_{\eta \text{ [cl]}} + W_{\eta \text{ [min.ad.]}} \quad (1)$$

where $W_{\eta \text{ mix}}$, $W_{\eta \text{ cl}}$, $W_{\eta \text{ min.ad.}}$ – the instant power of the structure formation of mixed cement, its clinker component and mineral additive.

Ratio 1 shows, that both components of mixed cements simultaneously take part in the process of cement stone structure formation. However the component which has greater instant power of structure formation, predominates.

When the synchronous interaction is interrupted during the indicated processes, i.e. during the multi-stage structure- formation process, this ratio is fulfilled:

$$W_{\eta \text{ [mix]}} = W_{\eta \text{ [cl]}} + W_{\eta \text{ [min.ad.]}} \quad (2)$$

The given ratio means, that the components of mixed cements take part in the structure formation process in succession, and the first portion is carried out by the reactions of the component with greater instant power of structure formation.

Taking into account the content of mineral additive in the mixed cement, the ratio (2) will be:

$$W_{\eta \text{ [mix]}} = (1-\varphi) W_{\eta \text{ [cl]}} + \varphi W_{\eta \text{ [min.ad.]}} \quad (3)$$

where φ - mass quota of mineral additive in mixed cement.

The experimental examination of the ratio (3) with the help of mixed cements on the basis of waste steel-smelting slag and fly – ash showed, that this ratio can be carried out in case of $\varphi=0,8$ for slag cement and $\varphi=0,5$ for fly - ash cement. It is well coordinated with the above mentioned character of changing of degree of completion of mixed cement structure formation η .

That is why equation (3) serves both as a ratio of values of apparent activation energy of hydrate formation of mixed cement components and as an index of multi stage process of structure formation in binding systems.

Note: With increased solidification temperature all mixed cements have the single stage structure formation process because in the following conditions the asynchrony of the hydrate formation and structure formation development is eliminated.

From the above we can consider that the structure formation character of mixed cements is determined by the quantity of mineral additive in it and its nature.

Evidently, during the solidification processes in mixed cements with different structure formation character final and intermediate structural states appear with different thermodynamic stability, and this predetermines their different physical, mechanical and performance qualities.

3. THE THERMODYNAMIC STABILITY OF STRUCTURAL STATES

The stability is the capacity of the binding system to keep its properties under the influence of internal and external factors [6,7].

The breach of stability of any structural state is connected with the removal of the last one from the balance, the degree of which is characterized by the value of entropy production. If the variation from equilibrium is small, the production of entropy serves as a criterion for establishing a stationary state, when this value is minimum, and in case of its equilibrium this value is equal to zero [6].

In binding systems the stability of developing structural states is determined by the quantity and sign of the redundant production of entropy. And the quantity of the redundant production of

entropy is determined by the interactive processes of structure and hydrate formation, and the sign is determined by the correlation of velocity and motive power of these processes.

In general, the quantity of the redundant production of entropy for a binding system is determined by the following ratio [8,9]:

$$\delta_x P = \delta_x P_\xi + \delta_x P_\eta \quad (4)$$

where $\delta_x P_\xi$ - portion in the redundant production of entropy, which is determined by hydrate formation; $\delta_x P_\eta$ portion in the redundant production of entropy, which is determined by structure formation.

The instability of a binding system (when $\delta_x P < 0$) can appear in the following cases:

$$1) \delta_x P_\xi < 0, \delta_x P_\eta > 0, |\delta_x P_\xi| > |\delta_x P_\eta| \quad (5)$$

i.e. in this case a “ dangerous “ portion in the redundant production of entropy is produced by the hydrate formation, which causes the instability of the binding system structure;

$$2) \delta_x P_\xi > 0, \delta_x P_\eta < 0, |\delta_x P_\xi| < |\delta_x P_\eta| \quad (6)$$

in this case the instability of the binding system comes from the structure formation process;

$$3) \delta_x P_\xi < 0, \delta_x P_\eta < 0 \quad (7)$$

In this case the instability of the binding system is determined by the joint influence of hydrate and structure formation processes.

During the solidification of mixed cements with single stage structure formation only one unstable structural state appears (Figure 4a).

Figure 4. The redundant entropy production during the mixed cements solidification:

- a) with single – stage structure formation;
- b) with multi – stage structure formation

This thermodynamically unstable structural state corresponds to the formation of a transitional coagulation – condensation structure in the binding system. This structure represents a temporal - spatial dissipation structure, according to [6,7].

It is important that thermodynamic instability of the given structural state in all mixed cements with single stage structure formation comes from the joint influence of the hydrate and structure formation processes, and this is related to the ratio (6).

During the solidification of mixed cements with multi stage structure formation two thermodynamically unstable structural states appear and the second one is more stable, as it follows from Figure 4b. The origin of the second instability comes from a pozzolanic reaction, developing in the binding system, in which the elements of the thermodynamically stable condensation crystallization structure have already taken place.

The experiments of the solidification of mixed cements on the basis of fly ash showed that the most thermodynamically stable condensation crystallization structure forms during the solidification of cement, containing 20 percent of fly ash. Such mixed cement has the highest strength characteristics (Figure 5).

Figure 5. The correlation of the mixed cement strength and the mineral additive content (fly – ash)

When there is more fly ash in mixed cement the thermodynamic instability of structure of forming cement stone increases and the strength reduces.

4. CONCLUSION

According to the analysis of the solidification process of mixed cements one can divide them into three groups and determine areas of their application:

- 1st group mixed cements with the single stage structure formation and normal solidification conditions.
These cements are characterized by high thermodynamic stability of the forming solidification structure. These cements are substitutes of PC.
- 2nd group mixed cements with the multi stage structure formation.
It is expedient to use these cements for the production of concretes, which are solidifying during the heat treatment and for the production of slowly solidifying concretes for mass concrete.
- 3rd group highly filled mixed cements with high percentage of mineral additive.

These cements are characterized by the low thermodynamic stability of structure of the forming stone and its low strength. It is expedient to use these cements for the production of concretes and mortars of low strength.

Therefore, the thermodynamic analysis data of the mixed cements solidification can serve as the basis for the developing of rational compositions on the basis of various waste products.

PERFORMANCE BASED DESIGN SYSTEM FOR CONCRETE MIXTURE WITH MULTI-OPTIMIZING GENETIC ALGORITHM

Takafumi Noguchi¹, Ippei Maruyama¹ and Manabu Kanematsu¹

¹ Department of Architecture, University of Tokyo, Tokyo, Japan.

E-mail: noguchi@bme.arch.t.u-tokyo.ac.jp

ABSTRACT

This paper presents a method for optimizing concrete mixture proportions according to the required performance and also presents several case studies. Since various qualities are usually required of concrete, we characterize the proportioning problems as multi-criteria optimization problems. We dealt with the notion of Pareto optimality to derive the optimum solution and applied it to a genetic algorithm. In this contribution, two proportioning problems are solved by the genetic algorithm: a request of cost-performance at 60 MPa in strength as a simple problem, and a concrete mix for mass concrete in cold weather at the coast.

1. INTRODUCTION

Concrete is required to exhibit performance corresponding with applied environment. And nowadays, thanks to technological progress, it is possible to make the concrete meet those requirements. However, there has been no established method. Only a few attempts [1][2] have so far been made in relation to these problems. The main reason for few outcomes is that a wide variety of mixture proportions are possible and there is no way to optimize mathematically the problem under many criteria, which are represented by objective functions. This contribution describes the method of optimizing mixture proportions of concrete by application of the Genetic Algorithm (GA) and several engineering models representing the relationship between the properties of concrete and mix proportions.

Proportioning problems cannot be solved by the usual methods that consist of searching for the best solution with a single objective function, such as linear programming problems and nonlinear programming problems. The reason for this impossibility is that various performances are required of concrete corresponding to the environments in which the concrete is used, and it is impossible to express the plural requests in a single objective function. It follows from the features of the proportioning problem mentioned above that a proportioning problem is considered to be a multi-criteria optimization problem.

2. HOW TO APPLY GENETIC ALGORITHM TO MULTI-CRITERIA PROBLEMS

2.1 Genetic Algorithms

Genetic algorithms are optimizing, learning and searching algorithms based on the mechanism of natural selection and natural genetics. What is important in GA is that it is unnecessary to develop a method to solve the target problem. Because GA can solve the problem with the relative evaluation of the non-inferior set and is easier to formulate rules of evaluation than any other existing method, GA is widely applied to the engineering field, especially to combination problems. Since proportioning is a type of combination problem, there is a good reason to apply GA.

In GA “genotype” is the parameter set, which means a vector in the set of optimization problem, coded as a finite-length string with binary digits. The simple string is called “individual”. To apply GA to a proportioning problem, the genotype is designed to represent various components and various mixture proportions (see Fig.1). The genotype consists of two parts. One is a coded binary string and the other is a database containing components such as cement, aggregate, admixtures, and so on. As demonstrated in Figure 1, the string has linkage parts and volumetric ratio parts. The linkage parts have a connection to the database, which is used when the fitness is calculated with volumetric ratios. The volumetric ratio parts show the volumes of components in concrete as component/water ratios. In reality, the binary string is fixed as 256 bytes whereas it is not shown in Figure 1.

The algorithms make a “phenotype”, which demonstrates characteristic form and quality in the designed system, from each individual according to its genotype. Each designed genotype has its phenotype. In our system, the term phenotype means the concrete properties and performance that are estimated from mixture proportions coded in the genotype. The kinds of concrete properties and performance are also shown in Figure 1. Prediction formulas are formulated statistically for each property.

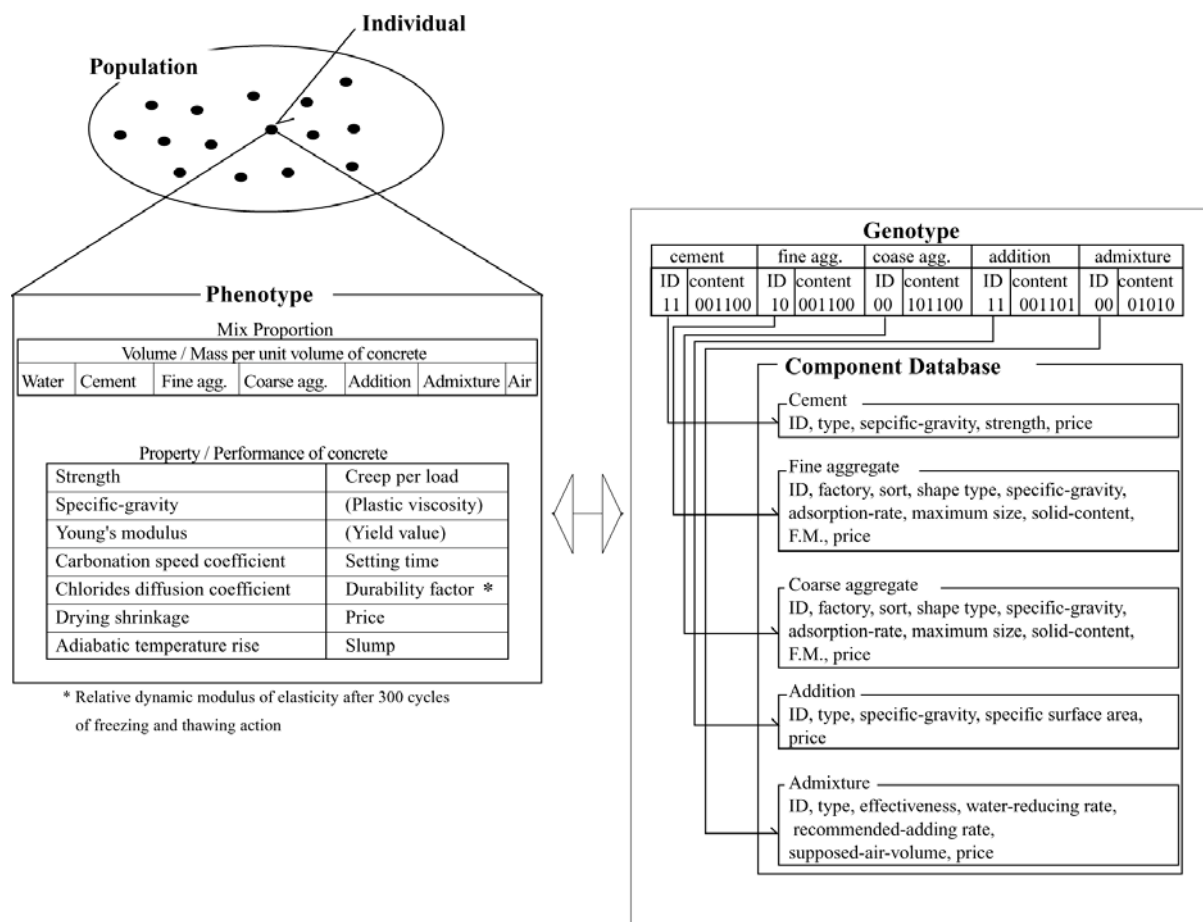

Figure 1. Schematic of GA applied for proportioning problem

“Fitness value” gives the numerical evaluation of each individual and each phenotype in the designed system. According to the fitness values, which can be plural in Pareto optimality problem, an individual in the “population” representing the set of individuals will be reproduced with crossover and mutation from generation to generation. Thus the individuals in the set become fitted under applied environment. In the developed algorithm, suitable functions are designed to meet the way of performance requesting and those are shown in Figure 2 together with the equations. U is the parameter representing the required performance of concrete mixture and T is the parameters

that determine shape of function. These two parameters express the allowable range of requirements for performance.

Figure 2. Fitness function and its shapes

2.2 Genetic Algorithms Applied to Multi-criteria Problem

In multi-criteria optimization, the notion of optimality is not obvious at all. For example, it is difficult to compare strength with fluidity. There does not exist the way to evaluate and compare different things. But the concept of Pareto optimality helps the evaluation of multiple criteria in a rational way. The Pareto optimal set is defined as stated below.

When a vector \mathbf{x} is partially less than \mathbf{y} and all criteria are minimizing criteria, the mathematical expression of the vector \mathbf{x} in the Pareto optimal set is:

$$(\mathbf{x} < \mathbf{py}) = (\forall i)(x_i < y_i) \wedge (\exists i)(x_i < y_i) \quad (1)$$

Under the condition of equation (1), point \mathbf{x} “dominates” point \mathbf{y} . If the point is not dominated by any other, that point is “non-inferior”. The set of these non-inferior points is what we call a Pareto optimal set. According to this definition, if there is a point, which is not less than any other points by all criteria, only the best point will get a good evaluation. If there is no such a point, a set of non-inferior points, which trade off one of the set of points for another, will be evaluated as good.

To apply genetic algorithms to a multi-criteria problem, an algorithm that can derive the Pareto optimal set is developed. Goldberg [3] had designed similar algorithms. Improvement on Goldberg’s algorithms and application to the proportioning problem are conducted. The developed program applied to concrete mixture problem is named MixGA. The program-flow of MixGA is detailed as follows.

1. Assume that there exist P criteria and N individuals
2. Make N individuals randomly.
3. Select criterion No. 1 and determine the fitness value of each individual's genotype. Choose parents A and B with the roulette method in which the probability of its selection is in proportion to fitness value. Crossover A and B, and reproduce child C and child D.
4. Repeat steps (2) and (3) from criteria No. 1 to No. P .

5. After getting N individuals in the new population (child generation) and N individuals in the old population (parent generation).
6. Produce a temporary generation with the child and parent generations.
7. Mutate genes by reversing the number at certain loci arbitrarily with a constant probability of 1%. (Loci is the plural word of locus. Locus means the position of the gene.)
8. Select Pareto individuals from the temporary generation and make the next generation that consists of N individuals. Reduction rule of population is dominated by two roles below.
 - (i) If the number of Pareto individuals is less than N, then preserve all the Pareto individuals. Up to the number of all individuals becomes N, select individuals one by one from the rest with the criteria No. 1 to No. P. The probability of selection is in proportion to their fitness value. This method intends that the good genes in the remainder should be carried on in the next generation.
 - (ii) On the other hand, if the number of Pareto individuals is N or more, select individuals from the Pareto individuals according to criteria No. 1 to No. P. The probability of selection is in proportion to their fitness in order.
9. Iterate steps (2) to (8) until the given number of times.
10. Conduct final selection.

The algorithm detailed above is characterized by the evolution of population with highly evaluated genes and Pareto optimal conditions. The highly evaluated individual has a good feature in a part of the binary string. And these parts of a binary string in individuals are inherited to next generation explicitly. An individual in the next generation inherits several good parts of a binary string that can be highly evaluated through phenotype. This process of evolution makes it possible to find out the optimal concrete mixture among an almost infinite number of combinations of materials and proportions; otherwise the process can be a random search and that will fail.

But it should be noted, however, that a Pareto optimum set is a set of non-inferior points. This definition implies it is possible that the evolved population has individuals, which have an outstanding performance by a certain performance criterion in exchange for bad fitness values of the others. The Pareto set conditions do not provide a single exact solution but help to search for an optimal set widely. Because of this undesirable aspect of Pareto optimality, the concept of “meta-property” is used. In MixGA the average of fitness values of target properties is used as one of properties and this kind of property of individual is called meta-property. With the meta-property concept it is possible to inherit another possibility in gene that shows balancing in target properties of concrete to the next generation. Besides a final process of evaluation, a final selection is conducted using the fitness values and eliminating the individuals that do not meet the required performance.

3. TRIAL OF MIXGA

The followings are two case studies, in which the mixture proportion of concrete is optimized under required conditions by using MixGA.

3.1 Case study 1

In case study 1, simple cost performance problem of strength property is examined. In detail, the concrete is required to have 60 MPa, Slump 18 cm and lower cost. Other properties are less significant.

3.1.1 Prediction of Strength of Concrete

As is mentioned above, predicting functions that enable us to calculate the properties of concrete with any mix proportion are formulated. Regarding the strength properties of concrete, the

formulating is partially based on the theoretical approach and partially based on the statistical approach. The formulas used are shown below.

Strength of mortar:

$$F_m = (a(B/W) + b) \cdot K \quad (2)$$

where F_m denotes the strength of mortar, a , b and K denote material parameter depending on cement, W denotes the water content per unit weight [kg/m³], and B denotes the summation of cement and admix content per unit weight [kg/m³]. In this contribution 4 kinds of cement are formulated; namely Ordinary Portland Cement (OPC), Low Heat Cement (LHC), Moderate Heat Cement (MHC) and High Early Strength Cement (HESC).

Effect of coarse aggregate on strength:

$$r_g = \left(1 - \left(d \left(\frac{1}{W/B + 1} \right) \cdot \frac{V}{1000} \right) \right) \times (1 - (e \cdot B/W + f) \cdot (\text{Log}X - \text{Log}A)) \quad (3)$$

where r_g denotes the effect of coarse aggregate on strength, d , e and f denote material parameter depending on aggregate, V denotes the volume of coarse aggregate per unit weight, X denotes the maximum size of coarse aggregate and A denotes the minimum size of aggregate that is able to affect the loss of strength.

Effect of type of coarse aggregate focused on the paste interface:

$$r_{g2} = k \quad (4)$$

where r_{g2} denotes the effect of coarse aggregate type and k denotes the material parameter of aggregate type depending on crushed aggregate (CR) or gravel (GR).

Effect of air content:

$$r_{air} = 1 - k_2 \cdot V_{air} \quad (5)$$

where r_{air} denotes the effect of air content on strength, k_2 denotes the parameter depending on water to binder ratio and type of coarse aggregate, and V_{air} denotes the volume of air per unit volume of concrete.

Effect of addition of Ground Granulated Blast furnace Slag (GGBS):

$$X < 0.3: \quad r_{mix} = 1 + \left((g(X_2 - h)^{3/2}) \cdot \left(\frac{1}{X_1 + 1} \right) + (lX_2 + m) \right) \times \frac{X}{0.3} \quad (6)$$

$$X \geq 0.3: \quad r_{0.3} \times (a_1 X_2 + b_1) \times \frac{X - 0.3}{0.4} \quad (7)$$

where r_{mix} denotes the effect of admixture on strength, g , h , l , m , a_1 , b_1 denote the material parameter, X denotes the replacement ratio, X_1 denotes the water to binder ratio, X_2 denotes specific surface area of slag and $r_{0.3}$ denotes the value calculated by equation (6) with X of 0.3.

Effect of addition of Fly-Ash (FA):

$$X < 0.45: \quad r_{mix} = 1 - (a_2 X_1 - b_2) \times X \quad (8)$$

$$X \geq 0.45 \quad r_{mix} = 1.0 \quad (9)$$

where r_{mix} denotes the effect of admix on strength, a_2 and b_2 denote the material parameter, X denotes the replacement ratio and X_1 denotes the water to binder ratio.

Effect of addition of Silica Fume (SF):

$$X > 0.2 \quad r_{mix} = 1 + X \quad (10)$$

$$X \geq 0.2 \quad r_{mix} = 1.2 \quad (11)$$

where r_{mix} denotes the effect of admix on strength, X denotes the replacement ratio.

Strength of Concrete:

$$F_c = F_m \times r_g \times r_{g2} \times r_{air} \times r_{mix} \quad (12)$$

where F_c denotes the strength of concrete.

3.1.2 Prediction of cone slump

Function for predicting of the value of cone slump is developed statistically with rheological approach. Kikukawa [4] proposed equation (13), which expresses the rheological parameters of cement paste at 20 °C that are plastic viscosity and yield value, as a function of solid content of cement and volumetric density of cement paste. This expression was on the basis of study of Roscoe [5].

Plastic viscosity of cement paste:

$$\eta_p = \eta_w \left(1 - \frac{V}{c} \right)^{-(K_1 V + K_2)} \quad (13)$$

where η_p denotes plastic viscosity of cement paste [Pa s], η_w denotes plastic viscosity of water, V denotes volumetric density of cement paste, c denotes solid content of cement, K_1, K_2 denote constants affected by the properties of the cement paste. -17.5 and 12.0 are used respectively.

Yield value :

$$\tau_p = a\eta_p + b \quad (14)$$

where τ_p denotes yield value of cement paste [Pa], a and b denote constant parameters. 15.505 and 1.244 are used respectively

Temperature effect on the rheological parameters:

$$\eta_{pT} = 0.00387\eta_{p20} \cdot T + \eta_{p20} \quad (15)$$

$$\tau_{pT} = 3.03\tau_{p20} \cdot T + \tau_{p20} \quad (16)$$

where η_{p20} denotes plastic viscosity of cement paste at 20 °C, τ_{p20} denotes yield value of cement paste at 20 °C, T denotes temperature, η_{pT} denotes plastic viscosity of cement paste at T °C and τ_{pT} denotes yield value of cement paste at T °C.

Effect of admixtures and additions:

Collecting the result of experiments, the effects of the contents on the rheological parameters are integrated into the formulas statistically.

$$r_{admix,\eta} = f_i(X) \quad (17)$$

$$r_{admix,\tau} = G_i(X) \quad (18)$$

where $r_{admix,\eta}$ and $r_{admix,\tau}$ are the coefficient of viscosity and yield value depending on the admixtures and X is the admixture to cement ratio. In this contribution, 4 type of admixtures are formulated; namely High Range Water Reducer (HRWR), AE agent (AE), Accerelator (AC) and Retarder (RE)

$$r_{add,\eta} = f_j(X) \quad (19)$$

$$r_{add,\tau} = G_j(X) \quad (20)$$

where $r_{add,\eta}$ and $r_{add,\tau}$ are the coefficient of viscosity and yield value depending on the addition and X denotes the replacement ratio.

Solid content of aggregate:

Ooi [6] investigated the complex nature of packing particles with random shape and wide grading, and developed mathematical model predicting the compacted bulk density of aggregate. This model is expressed as a second order polynomial of the sieve residuals as follows:

$$Z = \sum_i^n \sum_j^n A_{ij} X_i X_j \quad (21)$$

where Z denotes solid content of combined fine aggregate and coarse aggregate, A_{ij} is coefficient representing the packing performance of combined aggregates of two different diameter, X_i and X_j express volumetric ratios of the aggregates at the representative sieve sizes.

Rheological parameters of fresh concrete:

Recently Oh [7] found a phenomenon that the rheological parameters of fresh concrete have good correlation to a relative thickness of excess paste on the basis of excess paste theory developed by Kennedy [8]. The relation between the relative thickness of excess paste and the rheological parameters of fresh concrete is formulated as follows:

$$P_e = 1 - V_a / Z \quad (22)$$

$$\Gamma = \frac{P_e}{\sum_i^n n_i s_i D_{pi}} \quad (23)$$

where P_e denotes volume of excess paste, V_a is volume of aggregate, Γ denotes relative thickness of excess paste, n_i is number of aggregate of size i , s_i denotes surface area of each aggregate of size i , D_{pi} is diameter of aggregate of size i .

Using relative thickness of excess paste and rheological parameters of cement paste, the viscosity and yield value of concrete can be calculated.

$$\eta_c = \eta_p \times (1 + 0.0705\Gamma^{-1.69}) \quad (23)$$

$$\tau_c = \tau_p \times (1 + 0.0705\Gamma^{-2.22}) \quad (24)$$

where η_c denotes plastic viscosity of fresh concrete and τ_c denotes yield value of fresh concrete

Cone slump:

Using the experimental data of slump predicted rheological values, the regression curve is formulated as the function of yield value and parameter of mix proportion as below:

$$S = a_3 \times \ln(\tau_c) \times \frac{1}{1 + W/B} + b_3 \quad (25)$$

where S denotes the value of slump, a_3 and b_3 are coefficients.

3.1.3 Costs

In this problem, the function of cost is simply the summation of material cost.

3.2 Case study 2

In case 2, assuming that construction site is in cool temperate zone and average temperature is 10 °C, concrete is required 15 cm of slump, 40 MPa of strength, 6.0×10^{-4} of drying shrinkage, 35°C of adiabatic temperature rise at 7 day for mass concrete. Additionally 100 of durability factor, which means relative dynamic modulus of elasticity after 300 cycles of freezing and thawing actions, and 5.0×10^{-8} of Chlorides-diffusion-coefficient are required strictly. The other parameters are less important.

3.2.1 Adiabatic temperature rise

Adiabatic temperature rise is modelled as follows:

$$Q = Q_\infty (1 - \text{Exp}(-\gamma t)) \quad (26)$$

$$Q_\infty = a_4 B + b_4 \quad (27)$$

$$\gamma = a_5 B + b_5 \quad (28)$$

where Q denotes the adiabatic temperature rise at t day, a_4 , b_4 , a_5 and b_5 denote the material parameters and B denotes the weight of binder per unit volume.

3.3 Results

The required parameters of concrete in both cases are summarised in the same Table 1.

Table 1. Required performances

	Durability factor	Chlorides diffusion coefficient	Carbonation speed coefficient	Strength	Young's modulus	Drying shrinkage	Adiabatic temperature rise	Initial setting	Final setting	Slump	Cost
Unit		cm ² /year	cm/year ^{0.5}	MPa	GPa	10 ⁻⁶	K	hour	hour	cm	Yen
Case 1	0	1.00E-06	0.27	60	26	800	40	5	8	18	5000
Case 2	100	5.00E-08	0.25	40	25	600	35	5	8	15	10000

Case 1:

After running the MixGA with 120 individuals and 100 generations, mix proportions shown in Tables 2 are derived regarding with case 1. As final selection, elimination of the individuals, which do not meet required performance of strength and slump simultaneously, is conducted. Additionally in the final selection, as an index of cost performance, a value of strength divided by cost is used. Three mix proportions listed in Table 2 are top-to-third in strength-cost index. In left of Figure 3 shows the degree of conformity of three mix proportions listed in Table 2. Among three proportions, mix A has the best strength-cost index. It should be noted that, as is shown in left graph of Figure 3, mix C is much cheaper than mix A. The value of strength of mix A is higher than that of mix C. But in MixGA both mix A and Mix C is evaluated equally and they survive selections from generation to generation.

Table 2. Pareto optimal mixture proportions derived by MixGA

		W/B	Water	Cement (type)	Addition (type)	Fine aggregate (type)	Coarse aggregate (type)	Admixture 1 (type)	Admixture 2 (type)
Case 1	A	0.42	138	275 (OPC)	52 (GGBS)	936 (CR)	987 (GR)	0.000	0.000
	B	0.43	145	264 (HESC)	76 (GGBS)	967 (CR)	925 (GR)	0.232 (AC)	0.006 (AE)
	C	0.41	145	301 (MHC)	52 (GGBS)	962 (CR)	921 (CR)	0.000	0.048 (AE)
Case 2	D	0.47	132	280 (LHC)	0	1035 (CR)	898 (CR)	0.115 (HRWR)	0.512 (AE)
	E	0.47	132	281 (LHC)	0	1029 (CR)	893 (CR)	0.005 (HRWR)	0.526 (AE)
	F	0.47	131	281 (LHC)	0	1028 (CR)	906 (CR)	0.195 (HRWR)	0.512 (AE)
	G	0.48	132	273 (MHC)	0	1034 (CR)	898 (CR)	0.0215 (HRWR)	0.526 (AE)

Figure 3. Ratio between phenotype and required performance of concrete mixtures derived by MixGA

Case 2:

After running the MixGA with 140 individuals and 200 generations with meta-property concept, mix proportions shown in Tables 2 are derived regarding with case 2. As final selection, elimination of the individuals, which do not meet required performance of strength, slump, drying shrinkage, chlorides diffusion coefficient, durability factor and adiabatic temperature simultaneously, is conducted. In right of Figure 3 shows the degree of conformity of four mix proportions listed in Table 2. As shown in Figure 3, almost all the mixtures meet the required performance. It should be noted here that mix E has low value in slump and this mix is evaluated equally from the Pareto optimal point of view. If only the Pareto optimization is used, it is possible that such undesirable individual that do not have good value in all several properties is able to survive the selection. The genetic algorithm with the notion of Pareto optimality has a good potential in initial convergence tendency but it has a risk of undesirable acceleration in a few properties as well. With meta property concept, which disappreciate the prominence and unbalancing it is possible to derive the sufficient set of mixture proportions. Using the suitable fitness function and evaluation method is important to get sufficient set.

4. CONCLUSIONS

The results of this contribution are summarized as follows:

1. A genetic algorithm system integrating the concept of Pareto optimality, which is named MixGA, was developed for solving multicriteria optimization problems in concrete mix proportioning.
2. As shown in the examples presented in this study, MixGA can derive the appropriate mix proportions from the vast combinations of sorts of content and proportions of mixture to explore. This system is maintained by suitable fitness evaluation, reasonable reproduction and correct prediction formulas.
3. The genetic algorithm with the notion of Pareto optimality has a good potential in initial convergence tendency but it has a risk of undesirable acceleration in a few properties as well. Using meta property concept, it is possible to compensate for this risk of the notion of Pareto optimality.

HIGH-BELITE PORTLAND CEMENT – AN UPDATE ON DEVELOPMENT, CHARACTERIZATION AND APPLICATIONS

Anjan Kumar Chatterjee

TCG, Kolkata, India. E-mail: dr_akc@vsnl.net

ABSTRACT

Interest in high-belite Portland cement has progressively grown over the last three decades for its anticipated multidimensional benefits like lower energy consumption, raw materials conservation and constructional durability of the resultant concrete. Notwithstanding prolonged research and development efforts, the product and its manufacturing technology are yet to be of extensive commercial significance as there are still no viable technologies to substantially enhance the intrinsic reactivity of the belite phase and to generate large surface area for the cement at a reasonable energy input to achieve a higher rate of hydration in concrete.

Since the last review made in early nineties, a substantial amount of information and data have been generated on doping and rapid cooling of the belite phase, on its NMR spectra for characterization, on remelting reactions to make belite softer to grind, on chemical processes to synthesize belite cements of very high surface area, and on the properties of such cements.

The present paper is an attempt to review the status of development of high-belite cements and draw up the emerging scenario of this class of binder.

1. INTRODUCTION

High-belite Portland Cements, in the context of the present paper, are those in which there is a reversal in the preponderance of alite by belite without any significant sacrifice of early age strength in mortar and concrete. Since this implies higher levels of early reactivity in belite, such cements are also termed as reactive or active belite cement. This definition of course excludes the modified Portland Cements in which alite is replaced by the calcium sulfoaluminate phase.

Interest in the high-belite Portland Cement was triggered by the energy crunch of early seventies as its production was expected to be less energy intensive. Subsequently the interest was enhanced by the potential of raw-material conservation but ultimately the growing interest in the product gravitated towards its capability of producing a more durable hydrated matrix with a very steady rate of strength gain with time. But the realization of the goal continues to elude the scientific and technical community primarily for two reasons:

- Search for a practical and viable means of improving the hydration rate of the belite phase, and
- Establishing the technology to overcome the high-energy consumption in grinding belite for surface generation.

A fairly comprehensive review on the subject was attempted by the author in mid nineties [1]. Over the last decade, sizeable information and data have been generated on the manufacturing, characterization and application of high-belite Portland Cement. The present paper is aimed at highlighting the essence of newer findings.

2. ADAPTING THE TRADITIONAL PROCESS TECHNOLOGY

It goes without saying that there could be a rapid proliferation of the high-belite Portland Cement technology, if it could be adapted to the existing process of cement manufacture. The technological adaptations required are primarily for a rapid cooling process and homogeneous dispersion of dopants or chemical stabilizers used in small dosage [1]. In fact, it is known that at least in countries like India and Poland alkali-stabilized moderately high-belite (35 – 45%) cements have been in production and use with satisfactory performance. Taking cue from this and for faster exploitation of the high-belite cement technology, further studies were carried out at the author's erstwhile laboratories in the above perspectives. Experiments were conducted with raw mixes designed for two tentative levels of lime saturation factors (LSF) 0.82 and 0.78 and incorporating the dopants like K_2O , B_2O_3 , Mn_2O_3 , Cr_2O_3 , SO_3 , BaO . All firings were carried out in a pilot rotary kiln provided with a specially designed cooler that achieved a cooling rate of $500^\circ - 600^\circ C / min$. Some of the relevant findings are summarized below.

2.1 Effect of Rapid Cooling

A representative set of experimental data is given in Table 1, from which the following observations could be made :

- i) The effect of rapid cooling on the cement strength was visible, when the LSF was in the range of 0.81 – 0.82, the proportion of a given dopant was near-optimal and the C_2S/ C_3S ratio by the Bogue computation was not abnormally high (say, above 6).

Table 1. Effect of clinker cooling rate on the cement strength parameter

Type of Dopant	Rapid Cooling				Slow Cooling			
	Dopant (%)	C_2S/ C_3S (Bogue)	Clinker LSF	28-day Comp. Str. (N/mm^2)	28-day Comp. Str. (N/mm^2)	Clinker LSF	C_2S/ C_3S (Bogue)	Dopant (%)
None	-	4.85	0.813	54.5	46.5	0.813	3.98	-
	-	11.05	0.780	45.0	50.5	0.784	4.21	-
B_2O_3	0.68	1.84	0.823	78.6	67.0	0.814	2.89	0.65
	0.60	13.14	0.780	64.0	67.0	0.783	5.39	0.62
K_2O	0.28	2.26	0.819	78.0	61.2	0.824	2.00	0.31
	0.14	3.51	0.789	66.0	68.5	0.792	3.14	0.18
Mn_2O_3	1.24	3.59	0.820	61.0	54.0	0.820	2.04	1.19
	1.20	4.60	0.780	49.0	41.5	0.776	5.08	1.20
Cr_2O_3	0.70	3.47	0.820	61.5	56.0	0.813	2.31	0.70
	0.68	3.69	0.794	67.7	69.6	0.793	3.54	0.68
SO_3	0.39	3.07	0.820	69.0	55.0	0.820	2.14	0.21
	0.27	6.15	0.770	47.0	47.0	0.770	6.10	0.21
BaO	0.97	8.01	0.811	51.4	-	-	-	-

- ii) The positive effect of rapid cooling was not observed in the case of samples having LSF below 0.80, even when the amount of dopant or the C_2S/ C_3S ratio was in the acceptable range.
- iii) A high cooling rate appeared to be important for the retention of sulphate in the clinker but not so critical for B_2O_3 or K_2O retention. In some of our previous studies [1], however, it was seen that slow heating of clinker often led to higher losses of K_2O and consequently to its low retention in clinker.

On the whole, the need and relevance of rapid cooling from 1300° – 850°C have been phenomenologically reconfirmed. The higher the cooling rate, the more reactive is the stabilized belite phase as reflected by the cement strength parameter. It may be relevant to mention that rapid cooling did not result in any significant increase in the proportion of belite phase in clinker.

2.2 Effects of Dopants Incorporation

The optimal incorporation of dopants is expected to primarily influence the formation of clinker phases, stabilization of belite polymorphs, fixation of alite crystal systems, and the distortion of lattice structures of the stabilized phases. Based on a large number of experiments, now and earlier, attempts were made to retain the dopants in clinkers at the following levels:

The subsequent data and discussions will relate to clinkers containing dopants at the above levels.

2.2.1 Phase quantification

The quantification of the belite phase, irrespective of its polymorphic form, was attempted by the usual techniques of x-ray diffractometry, optical microscopy and scanning electron microscopy. A set of typical results are given in Table 2 along with the Bogue composition for clinkers having LSF 0.82. The comparison revealed that the quantification of the belite phase by both the microscopic techniques appeared quite close and the deviations with reference to Bogue compositions were also not very high, except in the case of boron-doped clinker. The XRD values, however, showed larger variations.

Table 2. Quantification of the belite phase in clinker with LSF around 0.82

Clinker with	C ₂ S				C ₃ S				Non-silicate			
	B	X	O	E	B	X	O	E	B	X	O	E
No dopant	61.9	42.0	57.1	58.0	12.8	42.5	28.3	29.0	25.2	14.8	14.6	13.0
B ₂ O ₃	49.8	53.8	61.3	60.0	27.1	26.9	24.3	25.0	23.1	18.9	14.4	15.0
K ₂ O	51.9	35.3	52.2	53.0	23.0	43.2	33.5	34.0	25.0	21.5	14.2	13.0
Mn ₂ O ₃	58.1	47.1	55.5	56.0	16.4	33.9	26.8	27.0	25.4	19.0	17.7	17.0
Cr ₂ O ₃	57.7	51.9	58.4	56.0	16.6	30.1	25.5	28.0	25.7	17.1	15.6	16.0
SO ₃	56.4	45.5	54.4	57.0	18.3	39.1	29.7	29.0	25.1	15.2	15.9	14.0
BaO ⁺	54.2	-	49.0	-	20.8	-	30.0	-	27.1	-	17.7	-

Note : B = Bogue computation
X = X-ray diffractometry
O = Optical microscopy

E = Scanning electron microscopy
+ = Clinker frelime high (around 3%)

Thus, relying more on the microscopic techniques, five high-belite clinkers with different dopants were produced from the same raw mix. The microscopically estimated amounts of the silicate phases (in comparison to the corresponding Bogue compositions) were used to grade the influence of the dopants on belite formation (Table 3), which can be summarized as follows:

Needless to mention the reverse is the trend of influence on the alite formation.

Table 3. Influence of dopants on the belite formation.

Phases	Clinkers doped with														
	B ₂ O ₃			K ₂ O			Cr ₂ O ₃			SO ₃			Mn ₂ O ₃		
	B	M	M/B	B	M	M/B	B	M	M/B	B	M	M/B	B	M	M/B
Alite	22.2	12.8	0.58	21.3	24.5	1.15	24.9	31.0	1.24	25.2	30.4	1.21	23.6	38.5	1.63
Belite	57.3	73.1	1.3	57.3	59.5	1.04	54.5	50.7	0.93	53.6	48.8	0.91	55.3	42.3	0.76
Nonsilicate matrix	20.5	14.1	0.69	21.1	16.0	0.76	20.5	18.3	0.89	21.2	20.8	0.98	21.1	19.2	0.91

2.2.2 Identification of polymorphic forms

Based on the precise measurement of 2 θ values and their comparison with the reference data, the presence of different polymorphs of the belite phase was detected. The results are furnished in Table 4. From the table it is evident that in all the clinkers, irrespective of the dopants used, there was predominance of the β -phase. The α -phase appeared only in the K₂O-doped clinker, apart from the undoped reference clinker. In all the doped varieties α'_H phase was detected while the α'_L phase was noticed in all the doped clinkers except those, which contained SO₃ and BaO.

Table 4. Presence of belite polymorphs as detected by XRD in the rapidly cooled clinkers.

Clinker with	Clinker LSF	2 θ values in degree			
		β	α	α'_H	α'_L
No dopant	0.82	31.100	31.669	-	-
No dopant	0.78	31.096	31.809	-	-
B ₂ O ₃	0.82	31.058	-	32.197	32.073
B ₂ O ₃	0.78	31.092	-	32.197	32.065
K ₂ O	0.82	31.092	31.669	32.196	32.074
K ₂ O	0.78	31.105	31.801	32.461	32.085
Mn ₂ O ₃	0.82	31.102	-	32.465	32.076
Mn ₂ O ₃	0.78	31.054	-	32.449	32.073
Cr ₂ O ₃	0.82	31.063	-	32.201	32.076
SO ₃	0.82	31.096	-	32.469	-
BaO	0.82	31.067	-	32.430	-

Further some attempts were made to assess the relative proportions of the different polymorphs. The β -phase appeared to vary from 88 to 96% of the total belite phase and no other discernible trends were noticed in the variously doped clinker samples.

2.2.3 Effect of doping on lattice parameters

The lattice parameters were measured for the β -belite phase in some of the doped clinker samples. The results are furnished in Table 5. It is evident from the table that the incorporation of B₂O₃ and Mn₂O₃ resulted in significant dimensional change in the cell parameters and consequently in the cell volumes. The changes were not so significant for potash doping.

Table 5. Changes in the cell parameters of the belite phase on doping in rapidly cooled clinker of LSF around 0.82.

Clinker with	Cell Parameters				Cell volume (nm) ³
	a (nm)	b (nm)	c (nm)	β	
No dopant	0.93761	0.66569	0.55124	91.5274°	0.34406
B ₂ O ₃	0.94395	0.67595	0.56528	100.2715°	0.36068
Mn ₂ O ₃	0.94545	0.67175	0.56589	94.4991°	0.35940
K ₂ O	0.92477	0.67384	0.55687	92.4015°	0.34701
Reference values (JCPDS)	0.93100	0.67565	0.55059	94.46°	0.34633

If one were to draw some conclusions by juxtaposing Tables 1, 3 and 5 on the reactivity of the different polymorphs of the belite phase, one would still be baffled as in the past. The variable reactivities of these polymorphs can be attributed to differences in ionicity of M-O bonds (where M is a cation) or to different levels of crystal imperfection. However, the effectiveness of boron in making the belite phase more reactive is worth noting, while the other dopants tend to give anomalous structure-property relationships.

3. NMR STUDIES OF THE HIGH-BELITE CLINKERS

During the last two decades, the nuclear magnetic resonance (NMR) spectroscopy has found wide application in cement science [2]. Nuclei with odd mass numbers (e.g. ¹⁷O, ²⁷Al, ²⁹Si) have half integer spins and are of most interest in this method of characterization. It is also known that in many instances the isotropic chemical shift is the most important NMR parameter for structural investigations. Many NMR investigations of cement materials are based on it.

It has been reported [3] that the nine crystallographically distinct Si sites of high-purity C₃S resonate between -68.9 and -74.5 ppm and the Q^o sites of the various C₂S phases resonate between -70.1 and -73.5 ppm. The ²⁹Si peaks for the high-purity phases are quite narrow (<1 ppm), if they are well crystallized and if the spectra are well resolved. Since, however, the alite and belite phases of commercial Portland Cements are quite impure and since these impurities cause distortions in the electronic environments of Si, their spectra become broad and poorly resolved. Despite such resolution problems, the recent work has shown that quantitative spectral deconvolution of the ²⁹Si MAS-NMR spectra of Portland Cements provides reliable alite / belite ratios.

Based on such advances seen in the application of NMR spectroscopy of cement silicate phases, some of the high-belite clinkers of the present study were subjected to MAS-NMR spectroscopy on a varian INOVA-400 spectrometer using CP/MAS probes for 7 mm (²⁹Si). The spectra are given in Figure 1. The observed isotropic chemical shifts for belite showed that the polymorph was in the β -form [$\delta_{\text{iso}}(^{29}\text{Si}) = -71.32$ ppm] in all the four doped clinker studies. There were no spectral features to identify the presence of α and α' forms that were detected by XRD to be present below 10% of the total belite phase. The spectra were further subjected to deconvolution in order to determine the quantities of alite and belite using the method discussed in [4]. The values obtained have been compared in Table 6 with corresponding values determined by XRD and computed by the Bogue formula. It seems from the table that the mean NMR values of the belite phase are higher than the corresponding XRD values and closer to Bogue values, except in the case of chromia doping. On the other hand, the NMR values of alite are lower than XRD estimates, with the some exception for the Cr₂O₃ doped samples.

Figure 1. ^{29}Si MAS NMR (9.4 T, $\nu_r = 7.0$ kHz)

Table 6. Quantification of alite and belite in doped clinkers by NMR spectroscopy.

Dopant	Belite %			Alite %		
	NMR	XRD	Bogue	NMR	XRD	Bogue
K_2O	48.2 ± 5.0	42.87	55.4	29.9 ± 6.0	32.48	20.5
B_2O_3	53.0 ± 4.0	50.67	54.8	23.5 ± 5.0	27.37	21.2
Mn_2O_3	46.7 ± 4.0	44.30	52.7	30.4 ± 4.0	34.48	22.5
Cr_2O_3	41.5 ± 4.5	48.13	52.0	37.7 ± 5.0	30.19	23.5

3.1 Boron Incorporation in the Silicate Phases

In the present study, an attempt was made to separate out the silicate from the non-silicate portion of the doped clinkers and to estimate the distribution of the dopants in the above two fractions. In all the samples studied it was observed that the incorporation of B_2O_3 in the silicate fraction was the highest in the range of 95-96%, followed by K_2O 85-90%, Cr_2O_3 78-80%, and Mn_2O_3 65-70%, when tested under identical conditions. The high level of incorporation of B_2O_3 in the silicate phases also prompted a careful look at the NMR spectra of the clinker doped with B_2O_3 . It was interesting to note that there was a unique second-order quadruple line-shape for ^{11}B spectra, which indicate that ^{11}B is incorporated in belite by substitution of Si. Some confirmatory studies are in progress.

4. GRINDABILITY OF BELITE-RICH CLINKERS

It has been shown by actual grindability tests that one of the most important parameters that determine clinker grindability is its belite content (Figure 2) [5]. This results in high-energy consumption in cement grinding, which has served as a major impediment in the popularization of the manufacturing technology for high-belite Portland Cement.

Figure 2. Relationship between belite content and power consumption.

Recently an interesting technological approach has been reported to make the high-belite clinker amenable to easier grinding. This is based on what has been termed as a “remelting reaction” for the belite phase [6]. The remelting reaction is an unusual decomposition reaction in which a solid decomposes into another solid and a liquid during cooling. When α -C₂S with a large amount of impurities is cooled from its stable temperature region, it decomposes into a liquid and α' _H-C₂S, which has a lower impurity concentration. The reaction is always preceded by the α - to - α' _H polymorphic transition, which forms six sets of α' _H-phase lermellae without a change in chemical composition. The subsequent remelting reaction requires an atomic diffusion process. The rate of the remelting reaction depends on the Al / Fe ratio of the parent α -phase and the temperature. In a recently conducted study with an industrially produced belite-rich clinker, two reheating and quenching regimes were adopted for two fractions of the same clinker so as to stabilize α -C₂S in one and α' -C₂S in another. When these two fractions were subjected to grindability and hydration studies under comparable conditions, the results showed marked improvements (Figures 3 and 4) [7].

Figure 3. Change in (a) median size and (b) De of Rosin-Rammlar distribution with grinding time (S-A and S-B contain α - and α' -belite phases respectively).

Figure 4. Cumulative heat evolution for 28 days at $w/c=0.4$ and 20°C (S-A and S-B contain α - and α' -belite phases respectively).

5. CHEMICAL PROCESSES FOR REACTIVE BELITE

Apart for the technology of doping and cooling to produce reactive and easily comminutable belite, there are also options of obtaining reactive belite of high surface area by chemical processes. In addition to the sol-gel and hydrothermal routes of processing summarized in [1], $\beta\text{-C}_2\text{S}$ has also been prepared by the Pechini process [8], a more popular synthesis technique for many ceramic phases, which utilizes a mixture of citric acid and ethylene glycol as the organic carrier phase. In all these preparations, the belite phase is stabilized in β -form. The Pechini process yields $\beta\text{-C}_2\text{S}$ with surface area as high as $40\text{ m}^2/\text{g}$ with proportional increase in its rate of hydration reaction.

Although, *prima facie*, the chemical processes indicate some distinct potential advantages such as low temperature operation, low energy consumption and high reactivity, there are issues like the purity of raw materials, scale of operation, continuity of process, etc. which would determine the viability of the processes concerned. From the perspective of economic viability, these processes seem to be quite distant at present.

6. RESPONSE OF CHEMICAL ADMIXTURES TO BLENDED HIGH-BELITE CEMENTS

The durability properties of high-belite Portland cements and their blends with fly-ash have been illustrated earlier [1]. In continuation of these studies an attempt has been made to prepare a fly-ash blended cement from a commercially produced potash bearing high-belite clinker of the following phase composition as determined microscopically : 57.4% belite, 29.3% alite and 13.3% matrix. The blended cement was prepared by inter-grinding of 15% fly-ash and gypsum equivalent to 2.3% SO_3 . In order to compensate the drop in early age strength, the effect of three different types of chemical admixtures were studied. The results are given in Table 7. From the table, one may observe that the effect of the three admixtures on improving the early as well as later age strengths can be rated as follows:

Acrylic Polymer-based > Melamine-based > Ligno-Sulphonate-based.

This is quite in line with the general expectation from these three varieties of chemical admixture.

Table 7. Effect of chemical admixtures on the physical properties of high-belite blended Portland cement.

Property Parameters	Cement without fly-ash	Cement with inter-ground fly-ash and no admixture	Cement with separately ground fly-ash and no admixture	Cement with inter-ground fly-ash plus		
				0.2% ligno-sulphonate based admixture	0.2% melamine based admixture	0.2% acrylic polymer based admixture
Specific Surface Area, m ² /kg	307.0	372.0	370.0	400.0	390.0	400.0
Normal Consistency, %	27.0	28.8	27.5	26.3	26.8	21.3
Setting Time (I), min	110.0	115.0	110.0	115.0	105.0	95.0
Setting Time (F), min	190.0	195.0	200.0	210.0	195.0	210.0
Compressive Strength, N/mm ²						
1-day	18.2	12.0	13.0	15.3	14.0	24.0
3-day	28.4	21.6	20.8	24.2	25.0	42.0
7-day	40.0	32.0	32.6	37.0	37.3	51.4
28-day	63.4	50.4	59.7	52.5	63.0	77.6

In order to ascertain the impact of the particle size distribution of the fly-ash on the cement properties, another batch of blended cement was prepared by blending 15% fly-ash ground separately to D₅₀ size of 8.2 μ m and 100% passing through 45 μ m sieve. The properties obtained for this blended cement without any chemical admixture are also included in Table 7. It may be seen that with improved particle size distribution of fly-ash, although there was significant enhancement of the 28-day compressive strength, the early age strengths remained more or less unchanged.

In other words, for effecting a rise in the early age strength levels of the high-belite Portland cements, the use of chemical admixtures may provide an easy and practical solution. Needless to mention that the effects of the acrylic polymer-based admixture on setting, hardening and strength gain of the high-belite Portland cement are noteworthy.

7. CONCLUSIONS

The present studies reconfirmed that the belite phase can be made more reactive to various degrees by incorporation of dopants or chemical modifiers along with rapid cooling of clinkers. Oxides like K₂O, B₂O₃, Mn₂O₃, Cr₂O₃, SO₃, and BaO were found to be variously effective. Of these dopants, the incorporation of B₂O₃ in the belite phase is almost total at a level of about a half a percent dosage with resultant distortion of the cell structure and high gain in later age strength.

Oxides like B₂O₃, K₂O and Cr₂O₃ do promote the formation of belite to a higher extent than SO₃ and Mn₂O₃. The incorporation of BaO may lead to higher free lime in clinker unless the dosage is very carefully optimized.

A rapid process of cooling at least in the range of 500° – 600°C / min improves the reactivity of high-belite clinkers, when their LSF is in the range of 0.81 – 0.82 and the dopants are present at optimal levels. At still lower LSF, this relationship could not be experimentally established.

The polymorphic form of the belite phase can be identified and quantified by both x-ray diffractometry and NMR spectroscopy. Both the techniques established the predominance of the β -form. Small presence of α , α'_H and α' were detected by x-ray diffractometry but not in NMR

spectra. The α -form was noticed in the K_2O -doped clinker only, while α'_L was absent in the SO_3 and BaO doped ones.

One of the ways of improving the reactivity of the belite phase is obviously to generate high surface area for rapid hydration. Since belite made by high-temperature pyroprocessing is hard to grind, chemical processes have been attempted. The Pechini process has yielded belites of high surface area of up to $40 \text{ m}^2/\text{g}$.

Recently, a technology has been developed based on “remelting reaction” to make even the high-temperature belite easy to grind. But the chemical processes as well as remelting technique are still in the experimental stage and would require further development.

The reactive belite manufacture based on doping and quenching continues to suffer from relatively poor early age strength, which can be compensated with the help of chemical admixtures, particularly, of the acrylic polymer-based type.

On the whole, the progress in perfecting the technologies for making reactive belite has been substantial. It appears that such technological features as clinker doping and quenching as well as use of appropriate chemical admixtures in grinding can be more easily adapted to the existing manufacturing process for immediate proliferation of the production technology of high-belite Portland cement. Optimization of the clinker cooling regime to realize the grinding benefits through remelting reactions will be an added advantage.

ACKNOWLEDGEMENTS

The paper is primarily based on the data generated by the author and his team in the laboratories of the Associated Cement Cos. Ltd., India. The contribution of Mr. S. A. Khadilkar and Dr. D. Venkateswaram in generating the experimental data is thankfully acknowledged. Thanks are also due to Dr. Pollemann of Germany and Dr. Skibsted of Denmark in helping the research program by providing valuable and relevant diffractometric and NMR spectroscopic data.

ABSTRACT

Studies on cement suspension rheology are often complicated because of the hydration reactions of cement, which modify surface properties over time. Less complex and better defined systems, model powders, have been used instead of cement for studies of interactions with superplasticizers. The powders previously proposed have all at least one major drawback: they cannot be used at high pH or do not have surface properties at this pH close to that of Portland cement suspensions. Dead burnt MgO and Mg(OH)₂ are good candidates. Their isoelectric points are around pH 12.4 and 12 respectively, in the same range as that of Portland cement. Unfortunately, Mg(OH)₂ powders initially chosen, produced by precipitation, were found to be porous and were rejected. Dead burnt MgO powders react with water, but they can be considered as non-reactive between 1/2 hour to 2 hours of contact with a basic solution. Such powders allowed us to study adsorption of superplasticizers, evolution of zeta potential as a function of adsorbed superplasticizer and rheology of suspensions. It is also possible to add different salts to study their influence on the preceding properties. MgO powders can be easily sintered to get compacts or single crystals which can be used for atomic force microscopy measurements with aqueous solutions of superplasticizers.

1. INTRODUCTION

Cement suspensions have an inherent complexity which is an obstacle to understanding cement/superplasticizer interactions. Indeed, cements are reactive multimineral powders, the surfaces of which evolve in time. Mineralogical and chemical compositions of the different particle size fractions can be different. Certain cements also contain mineral additions, like silica fume, fly ash, slag or filler. Organic grinding aids are generally used in the production route and remain on cement grain surfaces. Cements have variable C₃A content, the reactivity of which can also vary. The importance of the C₃A reactivity on the rheology of cement slurries is well known. Not only do the surfaces of the hydrating minerals evolve in time, but also the chemical composition of the solution is changing in the period between the mixing and placing of concrete.

Superplasticizers are anionic polyelectrolyte polymers with carboxylate and/or polysulfonate groups. The pH of the aqueous phase of cement suspensions being around 13, the acidic functions are completely dissociated. The conformation of these polymers is influenced by the pH and the ionic composition, and this point should be taken into consideration when trying to understand their performance.

Dispersion of agglomerated cement particles is recognised to be the main way by which superplasticizers improve the workability of concrete. The fluidifying effect of superplasticizers is essentially linked to their adsorption onto cement surfaces. A major factor is to ensure that the polymer adsorbs onto the particles and maintains a similar configuration.

During cement hydration, a part of the superplasticizer can be consumed by the formation of organo-mineral phases [1]. This part will no longer be able to contribute to the dispersion of cement particles.

A characteristic of cement suspensions is that the electrostatic surface potential of the particles is very close to zero at this high pH. Getting exact values of surface potentials near the isoelectric point (pH of zero zeta potential) is a difficult task and both slightly positive or negative ζ (zeta) potentials can be found reported in the literature. For what we are concerned with, however, it suffices to state that cement suspensions are very close to their isoelectric point and have a very small surface charge even though they are in a highly alkaline suspension.

2. DIFFERENT MODEL POWDERS PREVIOUSLY USED

The adsorption of a polynaphthalene sulfonate (PNS) has been measured on amorphous SiO_2 and quartz and found to be negligible [2, 3]. This is not surprising since amorphous SiO_2 has a very negative ζ potential at high pH (~ -60 mV at pH 12). Yet, the addition of silica fume to cement shows a higher adsorption than with the same amount of cement alone [4]. The same behaviour has been observed with a $\text{Mg}(\text{OH})_2$ powder used instead of cement [5]. The adsorption of PNS on TiO_2 strongly depends on the pH of the suspension [2, 6]. It has a maximum at pH 3 and the adsorption strongly decreases in the alkaline region. This behaviour is rationalised by taking into account the change in surface charge of TiO_2 with pH. Titanium dioxide has an isoelectric point around pH 6. Below this value, its ζ potential is positive and above, it is negative. This explains the pH dependent adsorption of the PNS which is an anionic polymer. Therefore, at high pH the significant viscosity decrease observed by Jolicoeur et al may be attributable to dispersion due to high surface charges [2].

α -Alumina has been used successfully for different measurements [2, 3, 7, 8]. Its isoelectric point is around pH 8.5. It should be noted that alumina reacts at high pH and forms soluble aluminates. Numerous other compounds like $\text{Al}(\text{OH})_3$, gypsum, attapulgite, kaolin, portlandite and graphite have also been studied by Nkinamubazi [3].

CaCO_3 (calcite) has been used for adsorption and rheological measurements [9, 10]. Its isoelectric point is at pH 10. It is the highest value of the different powders used which should start approaching a surface behaviour not dissimilar to cement, especially as there is a high calcium content in cements.

A model system should mimic cement surfaces as closely as possible i.e. have a potential close to zero. In addition, the elevated pH seems an important criterion to assure a similar polymer conformation as would be found with cement. So, a model powder having an isoelectric point at a high pH should be used. Suspensions such as those containing titanium dioxide cannot simultaneously fulfil both conditions (high pH and positive zeta potential). Though they can provide some information on adsorption, it would not be wise to use such data to differentiate the effects involved in superplasticizing of concrete. As a matter of fact, very few systems can fulfil simultaneously the conditions mentioned above and conserve the essential inertness required for a model system. To the best of our knowledge, no adsorption experiments have been carried out at pH around 12 with model powders that are positively charged before the work of Flatt et al [5, 11].

The limitations linked to the powders cited above, led the preceding authors to examine carefully the different possibilities. Among the materials compiled by Parks [12] dead burnt magnesium oxide and magnesium hydroxide, which have nominal isoelectric points respectively at pH 12.4 and 12, were retained as candidates. They were used successfully to study the adsorption isotherms of different superplasticizers and their influence on zeta potential [11] and on rheology [5, 13].

It should be noted that the magnesium hydroxide used in [5] was found to be agglomerated and hence porous. Superplasticizers can adsorb onto the pore walls. In such a case, it is no longer possible to measure correct adsorption isotherms and the use of such porous powders should be avoided.

3. MAGNESIUM OXIDE

3.1 General properties

Magnesium, which lies above calcium in the periodic table, has a similar outer electronic shell and a smaller radius than calcium. This makes its bonding to oxygen much stronger than that of calcium. This stronger bond makes magnesium hydroxide almost insoluble. The rate of hydration of MgO can be further decreased by *dead burning*. This produces a very interesting model powder. The main cement phases (calcium silicates and calcium aluminates) contain calcium oxide, which is probably the dominant surface leading to the positive zeta potential of cement [14]. It is therefore possible that the initial effects involved in superplasticizing will be closely linked to the adsorption of superplasticizers on calcium oxide-like surfaces. This makes magnesium oxide an even more interesting model powder. As for magnesium hydroxide it offers a surface expected to offer many similarities to that of the hydrated cement phases.

We must point out that it is possible to add electrolytes to these model suspensions in order to obtain very similar ionic compositions of the pore solution. However, in the experimental work below, the suspensions were only prepared in 0.01 M NaOH in order to work at a pH close to the isoelectric point of the suspensions. Though losing a little of the cement specificity, it is believed, however, that such suspensions maintain the three major features of interest, small zeta potential, high pH and inertness. MgO powders can be easily sintered to get compacts or single crystals which can be used for atomic force microscopy measurements with aqueous solutions of superplasticizers [15].

The promising results obtained [5, 11, 13] with MgO, led us to study in more detail the properties and physical characteristics of MgO. Its reactivity in contact with water and its ζ potential were more precisely studied. Finer powders are needed for ζ potential measurements ($< 10 \mu\text{m}$) and still finer powders for the determination of the adsorbed polymer layer thickness (median size $\sim 100 \text{ nm}$ or less). Corresponding MgO powders are included in the following study.

3.2 Thermodynamic properties

Magnesium oxide reacts with water to form magnesium hydroxide. Thermochemical calculations allowed us to draw Figure 1 which shows that the stability range of $\text{Mg}(\text{OH})_2$ lies within the instability range of MgO. This confirms the irreversibility of the MgO hydration. A stable equilibrium in the system $\text{MgO-H}_2\text{O}$ is established only after all MgO has been hydrated. The calculated pH is then equal to 11.95. At equilibrium, the calculated pH in the system $\text{Mg}(\text{OH})_2\text{-H}_2\text{O}$ is 10.36.

Heat treatments of MgO strongly reduce the rate of hydration. According to the temperature of the treatment, the powders are called *dead burnt* or *hard burnt*.

Figure 1. Stability range of MgO and Mg(OH)₂ in pure water at 25 °C.

3.3 Materials characterisation

3.3.1 General properties

Three MgO powders and one Mg(OH)₂ powder have been selected. Amongst the MgO's, one was *dead burnt*, another one was *hard burnt* and the last one is an ultrafine powder. The commercial name and type of powder are given in Table 1. A certain amount of the powder MagChem P-98 was classified by air in order to obtain a finer fraction < 10 µm (P98-C). Classification was preferred to grinding which may have increased the reactivity of the powder by creating new surfaces during the milling process.

3.3.2 Size characterisation

The particle-size distribution (PSD) of all these powders was measured by laser diffraction (Mastersizer S, Malvern, G.B.). The coarse powders MagChem P98 and P10 have a PSD close to that of cement. The volume diameter of the fraction finer than 10% of the total, D(v, 0.1), the median volume diameter D(v, 0.5), and the volume diameter of the fraction at 90% of the total cumulative distribution D(v, 0.9), as well as the span $\{[(D(v, 0.9) - D(v, 0.5)] / D(v, 0.5)\}$, are reported in Table 2.

Table 1. Powders studied as possible model inert cement particles

Commercial name	Formula	Producer	Description
MagChem P-98	MgO	Martin Marietta Magnesia (USA)	Dead burnt
MagChem 10	MgO	Martin Marietta Magnesia (USA)	Hard burnt
UBE 500 Å	MgO	UBE Industries (Japan)	Ultrafine
MagChem MH-10	Mg(OH) ₂	Martin Marietta Magnesia (USA)	

It appears that the *ultrafine* powder (UBE 500 Å) is not particularly fine despite its high surface area (31.5 m²/g). A scanning electron microscopic examination of this powder has shown that it is heavy agglomerated. Despite powerful ultrasonic treatment, it was not possible to break these agglomerates.

Table 2. Percentile volume diameters of the powders measured by laser diffraction.

Name	D(v, 0.1) [μm]	D(v, 0.5) [μm]	D(v, 0.9) [μm]	Span
MagChem P-98	2.88	17.59	54.65	2.94
P98-C	0.33	1.82	5.40	2.78
MagChem 10	3.80	13.57	31.04	2.00
UBE 500 Å	2.01	5.91	11.87	1.67
MagChem MH-10	4.02	11.44	23.98	1.74

3.3.3 Reactivity

The reactivity of the different MgO powders was evaluated by contacting 10 g of powder with 200 ml of 0.01M NaOH solution. After given times, the powder was filtered on a 0.45 μm filter and dried at 110 °C. The evolution of the BET specific surface area over time was measured with a GEMINI 2375 (Micromeritics, USA) system. The results are given in Table 3. For MagCem P-98, old MagCem P-98 and P98-C, the final surface area after 24 hours is 3-4 times higher than the initial area. This factor is nearly 8 for MagCem P-10 indicating that this powder is much more reactive. A common characteristic for all these powders is that the surface remains roughly constant (within experimental error) between 30 and 60 minutes. The ultrafine UBE 500 Å powder exhibits a large surface area which surprisingly decreases after an initial increase as a function of time in NaOH. This could be due to the dissolution of small particles and to a re-precipitation phenomenon on the larger particles (Ostwald ripening),

Thermogravimetric analyses (Mettler TG50 thermobalance) were performed in order to quantify the amount of hydroxide present or formed during immersion in the NaOH solution. Samples were heated at 10 °C/min up to 800 °C in air. The results are given in Table 4.

Table 3. BET specific surface areas of the different powders versus treatment

S _{BET} (m ² /g)	As received	30 min in NaOH 0.01M	1 h in NaOH 0.01M	24 h in NaOH 0.01M
MagChem P-98	0.84 ± 0.05	2.48 ± 0.05	2.4 ± 0.5	2.24 ± 0.10
Old MagChem P-98	1.26 ± 0.20	1.74 ± 0.020	1.57 ± 0.10	4.68 ± 0.30
P98-C	2.44 ± 0.05	6.84 ± 0.40	6.90 ± 0.10	10.45 ± 0.10
MagChem 10	0.58 ± 0.05	1.14 ± 0.06	1.22 ± 0.05	4.40 ± 0.05
UBE 500Å	31.45 ± 0.43	47.8 ± 1.1	44.24 ± 0.33	34.61 ± 3.5

Considering the stoichiometric reaction of dehydration of magnesium hydroxide, the corresponding mass loss is 30.9 %. This allowed us to calculate the percentage of Mg(OH)₂ present in the raw powders or formed during NaOH treatment (table 4). For all powders, the amount of hydroxide has increased (some times significantly as with P98-C and UBE 500 Å) after 24 hours in NaOH compared to their raw content. All these results show, however, that our magnesium oxide powders are not really inert in NaOH solution (pH = 12). Hence, their use should be preceded by a pre-treatment (at least 30 min in NaOH).

Table 4. $\text{Mg}(\text{OH})_2$ formed during contact in NaOH 0.01M solution at 20 °C.

% $\text{Mg}(\text{OH})_2$ formed	As received	30 min in NaOH 0.01M	1 h in NaOH 0.01M	24 h in NaOH 0.01M
MagChem MH-P98	1.33	2.72	1.91	6.61
MagChem P-98	0.26	2.95	3.92	2.04
P98-C	3.56	9.36	8.71	24.88
MagChem 10	0.23	1.23	1.20	7.39
UBE 500Å	2.46	78.1	80.69	94.36

3.3.4 Acoustophoretic measurements

An Acoustosizer II device (Colloidal Dynamics, Warwick, RI, USA) was used on one hand to measure the isoelectric point of P98-C and, on the other hand, to follow the variation of zeta potential stemming from polymer adsorption. The characterisation of cement suspensions by acoustophoresis has been discussed recently [16]. Only particles with a diameter below about 10 μm give a signal with this instrument. Measurements with a coarse powder lead to erroneous results of ζ potentials. So, the use of P98-C is preferred.

The suspensions were prepared by dispersing 53 g of P-98C powder in 200 ml of freshly boiled aqueous solution (to ensure complete elimination of CO_2) containing 0.01 mol/l of KCl. The suspension (water/solid = 3.77) was kept under vigorous agitation and ultrasonic treatment for 15 minutes before the measurements. The suspension is then allowed to cool down to 25 °C for another 15 minutes (under magnetic agitation). The pH was close to 11.1. A NaOH (30 %) solution was progressively added by means of a micropipette. The results (points of 3 determinations) are given in Figure 2. The IEP measured at pH 12.45 on P98-C is close to the value commonly given in the literature, i.e. at pH 12.4 [12].

Similar suspensions (but with 18.5 g) were prepared and, instead of a NaOH solution, concentrated superplasticizer solutions were added. Four different superplasticizers (polycarboxylate based polymers) with equivalent chemical structures, but with different carboxylic group density and different side chain lengths were tested. The results are given in Figure 3. The variations of ζ potential are low comparatively to some preceding results [11]. The polymers tested here contain only carboxylate functions and the results are comparable to those obtained with a similar instrument, but on β - and γ - C_2S [17]. Such measurements allow us to estimate the adsorption isotherm plateau of superplasticizers. The adsorption plateau is situated at the beginning of the straight part of the curve [11].

3.3.5 Other utilisation of MgO powders

This study is part of a European research project and the powders have been used by different partners. An overview of some results is given in another article submitted for this Conference [15].

Figure 2. Variation of ζ potential of MgO P-98C as a function of pH.

Figure 3. Variation of ζ potential of MgO P-98C as a function of added polymer.

4. CONCLUSIONS

The different model powders used in the place of cement have been reviewed. As Portland cement particles are slightly positively charged or neutral at the pH of the cement pore solution (pH around 13), model powders should have similar properties. It has been shown that all these powders, except MgO or Mg(OH)₂, have the drawback of having an isoelectric point either in acidic regions (SiO₂, TiO₂) or lower than the pH of the cement pore solution, like α -Al₂O₃, Al(OH)₃ or CaCO₃. That means that the powders are negatively charged at this pH and that their adsorptive properties of superplasticizers are different from that of cement.

Different MgO and Mg(OH)₂ powders have been determined. Despite the fact that MgO was dead or hard burnt, it was found that it reacts in contact with an aqueous solution. However, after between 30 and 120 minutes, the surface properties are reasonably stable and the powder can be considered as inert during this period of time.

The Mg(OH)₂ at our disposal had to be eliminated because of its non negligible internal porosity and a nano-size MgO (primary particles size of 50 nm) because of its very high reactivity and of its high degree of agglomeration.

It has been shown that the finer fraction of MgO (< 10 μ m), obtained by air classification, is suitable for measurements by the acoustophoretic technique. It is particularly appropriate to estimate adsorption isotherms plateau of superplasticizers in a much shorter time than the traditional depletion method.

ACKNOWLEDGEMENTS

This work was funded by the 5th European Framework Programme (Contract G5RD-CT-2001-00435) and received a financial support from the Swiss Federal Office for Education and Science (contract No 00.0273-1).

ABSTRACT

As the world population increases and becomes concentrated in and around urban areas, the demand for habitable land and human services will drastically strain existing waste management systems. The quantities of wastes generated from construction and demolition, the chemical industry, healthcare, wastewater treatment plants, paper mills, refineries, incinerators, power plants, and contaminated sediments from lakes, rivers, and estuaries are all expected to increase.

Cement-Lock® Technology is a thermo-chemical manufacturing technology that transforms these wastes into construction-grade cement. The cement has properties similar to those of ordinary Portland cement. During processing all organic contaminants are completely destroyed and converted to innocuous carbon dioxide and water. Chlorine and sulfur compounds are sequestered and heavy metals are locked within the molten matrix to completely immobilize them. This paper describes the development of the this technology from laboratory testing to the current large-scale demonstration program.

1. INTRODUCTION

As the world population increases and becomes concentrated in and around urban areas, the demand for habitable land and human services will drastically strain existing waste management systems. The quantities of wastes generated from construction and demolition, the chemical industry, healthcare, wastewater treatment plants, paper mills, refineries, incinerators, power plants, and contaminated sediments from lakes, rivers, and estuaries are all expected to increase. With habitable land being at a premium, the shortage of appropriate land for landfills will become acute. An ecological alternative for integrated waste management is to consider these wastes as resources that can be utilized to benefit humanity. The technology has been specifically developed to accomplish this objective and for which patents have been obtained from the U.S. patent office (U.S. Patent Nos. 5,803,894 and 5,855,666).

2. TECHNOLOGY DESCRIPTION

The technology is a versatile, cost-effective, and environmentally friendly manufacturing technology capable of converting many types of contaminated wastes into salable commodities, namely, construction-grade cement, power, and/or steam [1, 2, 3]. The acceptable wastes include a wide variety of domestic, industrial, and contaminated as well as non-contaminated wastes. The technology provides a means to harness these wastes as resources for beneficial use. These wastes can be processed individually or in mixtures. In general, different types of wastes can be treated together so that the property associated with each waste can be utilized in achieving the goal of maximizing the desired products in the most cost-effective manner. For example, contaminated

soils, sediments, or ash can be co-processed with refinery sludge or tank bottoms to minimize fuel consumption while maximizing both power and cement production.

In the process as shown in (Figure 1) wastes are directed to a thermo-chemical transformation unit of the technology. The wastes are mixed with proprietary modifiers and subjected to temperatures in the range of 1260° to 1538°C (2300° to 2800°F) in the presence of oxygen. This step not only melts the mixture, but also facilitates chemical reactions between the waste and the modifiers that impart latent cementitious properties to the resulting melt upon quenching. The quenched melt is referred to as Ecomelt[®].

The thermo-chemical transformation unit can be a rotary kiln melter, for example, or any other type of suitable melting unit; this unit is referred to as the Ecomelt[®] Generator (EG). Any fuel, including natural gas, petroleum sludge, sewage sludge, shredded tires, waste fuels from industry, and tailings from coal washing plants, can be used in the process. The fuel is burned in the EG using air, enriched air, or oxygen. Excess oxygen, that is, oxygen in excess of the stoichiometric requirement for fuel combustion, is maintained in the EG to produce a matrix of stable oxides. The melt generated in the EG is quenched, ground, pulverized, and blended with an additive to produce construction-grade cement. The flue gas from the EG is directed to a power generating section for heat recovery and flue gas cleanup. In this way the heat content of the flue gas is utilized for the production of the electricity. Other details of the Cement-Lock Technology are given by Rehmat *et al.* [2, 3].

Figure 1. Integrated waste management system utilizing Cement-Lock[®] technology

3. BENCH-SCALE AND PILOT-SCALE DATA

The technology has produced construction-grade cement from a wide variety of waste materials including organic contaminated soils, dredged estuarine sediment, river sediment, contaminated debris/concrete, municipal incinerator fly ash, coal ash, municipal solid wastes, and PCB-contaminated wastes. The harbor sediments were contaminated with polynuclear aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), pesticides, insecticides, chlorinated dioxins and furans, and heavy metals. The river sediments also contain similar contaminants. The concrete waste was spiked with oil and chromium.

For each of these applications, the contaminated material was decontaminated through this process and subsequently converted into construction-grade cement. The typical cements produced by this process have been tested independently by Construction Technology Laboratories (the technical arm of the Portland Cement Association, U.S.A.), a cement manufacturer, the New Jersey Department of Transportation, and another independent testing laboratory in New Jersey. In all cases the cement product exceeded the compressive strength requirements per ASTM (American

Society for Testing and Materials) C 150 standards. Therefore, the product can be used in general construction projects as a replacement for ordinary Portland cement. The compressive strengths of cements produced from various wastes are shown in Figures 2 through 4. It is significant to note that the cement product did not require use of any activators (performance enhancing additives). The properties of the cement product can be adjusted to meet application needs by varying the types and quantities of modifiers and additives.

Unlike stabilization and solidification processes that encapsulate heavy metal contaminants within an artificial matrix, in the Cement-Lock process these metals become part of the cement matrix through a process of ionic replacement and, therefore, do not leach. The results of the U.S. Environmental Protection Agency (U.S. EPA) Toxicity Characteristic Leaching Procedure (TCLP) tests on cement produced from several waste materials showed that the priority metal concentrations in the leachate were several orders of magnitude below the regulatory limits. These results are summarized in Table 1.

The organic contaminant destruction from several of the wastes processed in the Cement-Lock Technology is presented in Table 2. The organic destruction exceeds 99.99 percent, thereby maximizing energy recovery and minimizing risks to public health.

Since contaminated wastes are used to produce cement, concern may arise as to the concentration of trace elements in the cement product itself. A comparison of the concentrations of trace elements in cement produced by the Cement-Lock process from contaminated wastes showed that the trace metal concentration is within or close to the range normally found in Portland cement (Table 3). Therefore, the cement is free of adverse public perception.

The pilot-scale plant data were consistent with the laboratory-scale data in terms of organic destruction, leachability, and the quality of the cement generated from the estuarine sediment.

4. TECHNOLOGY STATUS

Following successful testing of the process at the bench-scale and pilot-scale levels, a large-scale demonstration plant with up to 22,937 cubic meters (30,000 cubic yards) of harbor sediment per year capacity is under construction in the New York/New Jersey harbor area. The plant shakedown is expected in December 2002. The primary objective of this program is to demonstrate integrated operation of the process while converting contaminated dredged estuarine sediment into construction-grade cement. The demonstration facility will be integrated with an off-site cement manufacturing company that will grind the Ecomelt and blend it with appropriate additives. The construction-grade cement will be utilized in selected beneficial use projects in the New York/New Jersey harbor area.

** Less than the detection limit of the analytical procedure used.

The demonstration will also confirm the environmental benefits of the technology through sustained operation; it will also demonstrate that the plant meets all the regulatory requirements and that no secondary waste streams are generated during processing, and the plant does not adversely impact the air quality in the surrounding neighborhood.

The rotary kiln melter for the demonstration-scale project (Figure 5) is 3.1 meter (10 feet) in diameter and 9.1 meter (30 feet) long. The entire system consists of raw sediment storage hopper, hoppers for modifiers, screw conveyors for moving material to the melter, a pug mill for blending all of the feed materials before charging, the rotary kiln melter, quench/granulator, secondary combustion chamber, flue gas quench system, lime injection, bag house, and activated carbon adsorption system for air pollution control.

Figure 5. Rotary Kiln Melter for Demonstration Plant

The demonstration plant will be capable of processing other materials including contaminated soils, petroleum refinery wastes, and various other industrial wastes. Also, with process enhancements and improvements, the capacity of the demonstration plant can be increased to 76,456 cubic meters (100,000 cubic yards) per year.

Significant public input has already been incorporated into this project based on numerous public outreach meetings.

The next stage of the process development will be the construction of a commercial-scale plant having a treatment capacity of 382,280 cubic meters/yr (500,000 yd³/yr) of contaminated sediments and wastes. Other opportunities are also being pursued with different clients in the U.S. and around the world.

All equipment required for commercial applications is commercially available. Various vendors willing to provide turnkey production plants have already been identified.

5. CONCLUSIONS

The Cement-Lock Technology offers a significant improvement over conventional means of decontaminating many different types of wastes. The technology decontaminates and converts waste materials into products for beneficial use, namely, construction-grade cement, power, and/or steam. These commodities are among the most coveted commodities in all parts of the world. By converting wastes into useful products, we can conserve our natural resources for future generations while improving the condition of the environment for the present generation.

1. INTRODUCTION

The starting point of the research projects which are the basis of this paper was the question, whether the hydration of the cement is completely reversible. Because this question was not asked till now there are hardly any answers although this topic could be interesting from different points of view:

- The first point of view is connected with the material testing. If the hydration is reversible, then it should be possible to get back the phases of the non-hydrated original cement by a heat treatment. These “secondary“ clinker phases may be a tool for the identification of the original cement used in a concrete.
- The second point of view is concerned with recycling. From this angle, the reversibility would be one of the prerequisites for the generation of closed circles for all the constituents of concrete.

The following paper deals with both of these aspects. The results that were obtained by basic experiments with clinker phases, cement paste and mortars are presented here.

2. CEMENT IDENTIFICATION ON BASIS OF RECOVERED CLINKER PHASES

2.1 Motivation

Concrete damage, which occurs in structures during their service life, are frequently due to an insufficient durability of the hardened cement paste and a weak bond between the hardened cement paste and the aggregates. Since the repair of such damage is often connected with substantial costs, lawsuits appear frequently as a consequence. In these cases the determination of the cement type used in the concrete or mortar may be very helpful. Furthermore if a repair mixture must be designed it is also an indispensable prerequisite to know the composition of the original concrete.

In the literature only some descriptions of methods for the distinction of the type of cement of hardened concrete or mortars can be found [1,2,3,4]. A general identification of the cement type used, however, is not possible with all these methods.

2.2 Main Idea of the Method

The chemical and mineralogical compositions are, apart from the particle size distribution, the most important features of cement in the non-hydrated state. In this state the type of cement can be recognised by the mineralogical composition. By the hydration of the cement this composition is fundamentally changed. But the quantitative phase composition of the hydrated cement can hardly be determined. Furthermore the hydration mechanism is not yet well understood for all types of

cement, so conclusions from the hydration products to the original cement are practically impossible.

The method for the determination of the type of cement in hardened mortar and concrete described here aims at the recovery of the non-hydrated state by a heat treatment of the hardened specimen in order to recognise the type of cement by its original phases. The ideal case would be a complete dehydration of the hardened cement paste and a recovery of the phases of the original cement at temperatures up to the original cement burning temperature. With these phases then the type of cement can be recognised. Because aggregates are present this ideal case cannot be achieved. Because reactions between the aggregates and the paste may occur, or melting phases are formed, a burning temperature of 1400°C cannot be realized. So it is possible that the phase formation can only take place incompletely. Therefore additional analyses and features are required in order to capture the modifications in comparison with the original cement.

2.3 Test Sequence

The first experiments for the development of the new method were carried out with clinker phases as well as cements. The influences of the aggregates were excluded by using of pastes. In the experiments should be found out what kinds of non-hydrated phases are formed in dependence of the temperature. The tests were carried out in the following steps:

- Manufacturing of pastes from the clinker phases and cements and standard mortar prisms
- Hydration for a time of at least 180 days
- Sample preparation for the identification:
 - Pulverization of the pastes below a particle size of 63 µm
 - Crushing of the mortar below 1 mm and then separating the fraction below 63 µm for the further analyses.
- Heat treatment at following temperatures: 600°C, 900°C, 1100°C, 1200°C and 1400°C.
- Determination of the mineral phases formed by the heat treatment by X-ray diffraction.
- Additionally: chemical determination of the content of free lime by an extraction with ethyl acetoacetate.

This paper only deals with the experimental investigations in clinker phases. It is only one example given for the practical application of the cement identification by X-ray diffraction in a mortar.

2.4 Analyses of Clinker Phases

With the basic studies of the clinker phases the question should be answered first whether the hydration can be reversed completely by a heat treatment, and at which temperatures this reversibility can be achieved for the different phases. The nomenclature of the used samples is represented in Table 1.

Table 1. Used clinker phases and mineral admixtures

Sample	Content
C3S	100 % alite
C2S	100 % belite
C3A	100 % aluminate-phase
C4AF	100 % ferrite-phase
BFS	100 % blast-furnace slag

Technically manufactured clinker phases were used, so it can be assumed that the typical minor components are incorporated. Besides, mineral admixtures like blast-furnace slag were tested.

C3S-Sample

As shown in Figure 1, the only effect that can be clearly observed at a temperature of 600°C is the decomposition of the Portlandite. The free lime expected from this decomposition is hardly detectable. Also no other crystalline phases can be found out of the XRD-diagram. Interferences were found again in the sample that was treated at 900°C. On the basis of these peaks the crystalline phases belite (β -C₂S) and free lime (CaO) could be identified. Because this temperature was obviously not high enough for the formation of C₃S, the surplus of CaO is present as free lime. At 1000°C and 1100°C no modifications are observed in principle. However, compared with a heat treatment at 900°C, the intensities of the belite peaks and the CaO peaks increase.

Figure 1. XRD curves of the C3S-sample

At 1400°C modifications occur. Alite was determined as additional component. Since only little free lime could be proved, the plausible conclusion is, that a part of the belite has reacted with the CaO under formation of alite. The fact that the alite is formed in nearly the same temperature range during the burning of cement supports this result. A good correspondence of both curves is noticeable if the XRD-diagram of 1400°C is compared with that of the non-hydrated material. The somewhat smaller intensities can be attributed to a not complete conversion, which explains also the presence of residues of free lime. However, by a further temperature increase on approximately 1450°C that corresponds to the temperature during the burning of cement, these differences should not occur longer.

C2S-Sample

Non-hydrated belite residues and a small amount of portlandite are proved in the hydrated C2S-sample. At a heat treatment at 600 °C the portlandite decomposes. During the further heat treatment at temperatures of 900, 1000, 1100 and 1400 °C no general mineralogical modifications are detected. Only the intensity of the belite peaks increases clearly with rising temperature and achieves nearly the level of the original sample at 1400°C. It can be observed that in this sample also at very high temperatures of 1400°C no alite is formed, since obviously no CaO is available for the reaction. Therefore also no CaO peaks occur at the temperatures of 900 to 1100°C.

C3A- and C4AF-Sample

In the hydration product of the C3A-sample only C_3AH_6 (hexahydrate) was detectable (Figure 2). At the treatment temperatures of 600, 900 and 1000°C the intermediate phase mayenite ($C_{12}A_7$) was formed. In this stage free lime is also existing, as the result of the difference of the CaO content of the aluminate and the mayenite. By a heat treatment at 1100°C the starting point is reached again, i.e. the hydration of C_3A with water is completely reversible. A further increase of the temperature up to 1400°C leads to a decrease of the crystallinity because of the beginning of the melting.

If the hydration of aluminate takes place in the presence of gypsum, an important difference occurs. Ettringite and monosulfate are generated as hydration products. During the decomposition in the temperature range between 900 and 1100°C the mineral ye'elimite ($4CaO \cdot 3Al_2O_3 \cdot SO_3$) is formed instead of $C_{12}A_7$.

Figure 2. XRD curves of the C3A-sample

The hydration products of the C_4AF -phase can be distinguished hardly from those of the C_3A . As in the C_3A -sample the dehydration at temperatures above 600°C takes place under formation of the mineral mayenite ($C_{12}A_7$). However, no free lime appears, due to the fact that the CaO content of the mayenite is higher than that of the brownmillerite. As a further difference in presence of sulphate no ye'elimite could be identified.

BFS-Sample

Opposite to the clinker phases the ground, granulated blast-furnace slag was mixed for the hydration with a saturated solution of $Ca(OH)_2$. No crystalline phases were found in the hydrated sample after a hydration time of 10 months as shown in Figure 3. Since Portlandite peaks are not visible in the hydration product, it can be concluded that the $Ca(OH)_2$ is consumed by the hydration. However, no predictions are possible about the degree of hydration. At heating temperatures above 900°C a crystalline phase occurs which can be identified as gehlenite. It has been formed either from residues of non-hydrated blast-furnace slag or from the hydration products. At higher temperatures the XRD-diagrams show no changes.

Figure 3. XRD curves of the BFS-sample

In the initial state the granulated blast-furnace slag has, due to the quenching process in the production, a very high proportion of glass phase. Therefore no crystalline phases were detected in this sample. In order to enable a comparison with the heat-treated samples an additional XRD-diagram was taken up in Figure 3 (upper curve). It shows the non-hydrated granulated blast-furnace slag after an annealing at 1100°C and a slow cooling, by that the slag undergoes crystallization. In this sample gehlenite could be identified as the main component of the granulated blast-furnace slag.

2.5 Analyses of Mortars

The investigations of the clinker phases result in the following possibilities of differentiation:

- Distinction between portland cements and cements containing mineral admixtures is possible by the identification of typical mineral phases for the admixture, e.g. gehlenite for granulated blast-furnace slag.
- Distinction between ordinary and sulphate-resistant portland cements is possible on the basis of the ye'elimite phase after a heat treatment at 1100°C.
- Estimation of the content of alite is possible indirectly by the content of free lime formed at temperature of 1100°C.

For the identification at least two temperature ranges must be regarded. The first temperature range is from 1100°C to 1200°C. It is important for aluminate and ferrite identification. Higher treatment temperatures from 1400°C to 1450°C are necessary for the identification of the silicates. Since this temperature range is hard to apply because melting phases are formed in the presence of some aggregates and admixtures, the alite content of the original cement must be estimated, as an alternative, from the contents of belite and free lime after a heat treatment at 1100°C.

For the application of the identification features on mortars or concrete it is furthermore important to prepare the sample in such manner that the cement paste is enriched as much as possible. Then it is possible to distinguish between the types of cements used in a mortar as demonstrated in Figure 4.

Figure 4. XRD-curves of cement pastes made from three different cements, heat treated at 1100°C and extracted with salicylic acid

This figure shows the XRD-curves of the enriched and heat treated cement pastes of mortars made from an ordinary portland cement (CEM I), a sulphate resistant portland cement (CEM I-HS) and a blastfurnace slag cement (CEM III). After the heat treatment the calcium silicates have been extracted by salicylic acid. The blast furnace slag cement can easily be identified by the large gehlenite peaks. Both Portland cements can be recognized by the interferences of free lime and belite. But there is an important difference between the two Portland cements too. While the sample from the ordinary Portland cement contains significant amounts of ye'elimite ($4\text{CaO} \cdot 3\text{Al}_2\text{O}_3 \cdot \text{SO}_3$), in the sample from the sulphate resistant one no ye'elimite could be identified. So the distinguishing features are also confirmed in the experiments on mortars.

3. RECYCLING ON BASIS OF REVERSIBILITY OF CEMENT HYDRATATION

3.1 Motivation

Recycling of concrete becomes more and more important on the one hand to reduce the use of resources and on the other hand to minimize the waste of landscape for landfilling. Concrete debris can be reused as aggregate in new concrete. But from the theoretical point of view this application results in an inevitable degradation with regard to the properties since concrete is a composite material. A more fundamental possibility would be the division of the concrete into its components, which can then be recycled separately. Only a very few papers [5,6] are known from the literature about this topic. Therefore first experiments were done with the target to get an orientation.

3.2 Test Sequence

The experiments were carried out with an ordinary Portland cement and a blastfurnace slag cement. The cements were processed to pastes ($w/c = 0.4$) and placed under water for 180 days. Then they are dried, crushed and ground. The powdered materials were burnt at 600°C, 1100°C, 1200°C and 1400°C in an electrical furnace. The specimens, made from blastfurnace slag cement could not be treated at 1400°C because they melted completely at this temperature. The secondary binders were examined with regard to the chemical composition and the reactivity. Furthermore mortar prisms were manufactured for testing the strength development. In the following only the results obtained with the Portland cement shall be presented.

3.3 Properties of the Treated Samples

3.3.1 Composition

With regard to the chemical composition there are only small differences between the original and the secondary cements. Only the content of SO_3 decreases slightly in the secondary cements treated at 1200°C and 1400°C due to the decomposition of calcium sulfate.

Figure 5. SO_3 -content, CaO_{free} -content and loss of ignition of the samples

With regard to the phase composition there are considerable differences in dependence of the temperature. The loss on ignition as featured for the content of fixed water and the content of free lime is shown in Figure 5. As expected the loss on ignition decreases with increasing burning temperature. In contrast to this the free lime content shows a maximum at medium temperatures. The samples treated at 600°C , 1100°C and 1200°C have very high contents of free lime. Only when the specimens are burnt at 1400°C the free lime content drops below the limit of 2 %. These results are confirmed by the XRD analyses. In agreement with the results in the first part of this paper the reference cement and the sample, burnt at 1400°C have nearly the same XRD diagram. That means that the hydration as chemical reaction is reversible. The other samples show the following features: In the cement paste only portlandite is detectable. In the 600°C -sample only traces of portlandite remain. The free lime measured by the method according to FRANKE (Fig. 5) is not detectable with the XRD-measurements, i.e. it must be poorly crystalline. The samples, burnt at 1100°C or 1200°C contain belite, aluminat and ferrite. Because these temperatures are too low for the formation of alite, a considerable amount of free lime remains in these samples.

3.3.2 Granulometric Parameters

In Table 2 the specifications about the fineness and the density of the samples are summarized.

Table 2. Granulometric Parameters and absolute density of the samples

		Reference OPC	Heat Treated Samples	
			600°C	1400°C
Mean particle size ¹	[μm]	22,64	22,68	21,58
Specific surface ²	[cm^2/g]	3000	15500	5440
Absolute density ³	[g/cm^3]	3,20	2,75	3,22

¹measured with laser granulometer ²measured acc. to BLAINE ³measured with helium pycnometer

The reference material and the 1400°C treated sample have rather similar parameters. Only the specific surface of the treated sample is higher than that of the reference material.

Figure 6. Particle size distribution

The reason can be the higher portion of particles $< 1 \mu\text{m}$ (Figure 6). The 600°C -sample considerably differs from the others. Although the mean particle size is nearly the same the specific surface is more than three times higher. Besides the density is lower. Both point to the fact that this sample shows changes in its properties due to the high content of free lime.

3.3.3 Evolution of Heat of Hydration

The reactivity of the treated samples was measured by Differential Calorimetric Analyses. From the Figure 7 follows that there are considerable differences in the rate of heat evolution.

Compared with the reference cement in the first stage at 0,1 hours the rate is higher both for the sample heated on 600°C and for the sample heated on 1400°C . In the main stage at about 10 hours the reference cement has the highest rate of heat evolution. The following reasons may be responsible for the differences in the first stage:

- In the case of the 600°C -sample the reaction of the very reactive free lime with the water may be one of the reasons for the high rate of heat evolution.
- The difference between the reference cement and the 1400°C -sample points to a higher reactivity of the secondary cement either due to a higher activity of the recovered clinker phases or due to the higher portion of particles smaller than $1\mu\text{m}$.

With regard to the main stage in which the order of the rate of heat evolution is inverted compared with the first stage no reasons can be given.

Figure 7. Rate of heat evolution during hydration

3.3.4 Strength Development

The development of the compressive strength shown in Figure 8 is very different for the mortars from the three tested binders. From the experiments follows that the 600°C-sample is workable only, if the portion of mixing water is increased.

Figure 8. Strength development of the samples

The strength of these specimens is in the range from 11 MPa to 30 MPa. That is clearly more than the strength of a hydraulic lime mortar that may be one of the possible standards of comparison. On the other hand it is less than the strength of the original cement. The strength of the 1400°C-sample exceeds this one of the reference sample in the considered time of hydration. That means that the higher reactivity found in the DCA experiments for the initial stage of hydration at least is reflected also in the strength development.

4. CONCLUSIONS

With regard to the pure clinker or Portland cement the reactions of hydration are reversible completely if the material is heated to the burning temperature of cement. This reversibility is reduced if the temperatures are too low or if further materials are added. For instance the addition of gypsum can result already in the formation of an additional intermediary phase.

With regard to the identification of the type of cement used in concrete or mortars, three diagnostic features were figured out: After a heat treatment at 1100°C, a high content of belite and free lime points to a Portland cement; (i), the appearance of the ye'elimite phase points to a portland cement with high sulfate resistance; (ii) the appearance of gehlenite (iii) points to a blast furnace slag cement.

Concerning the inversion of the hydration, the presence of aggregates must be taken into consideration, because of their large amount in the mortar or concrete. Therefore it is necessary to enrich the cement paste as much as possible by special procedures.

Looking at the possibilities for the recycling of concrete or mortars, must be noticed that there is a start for using a heat-treated concrete or mortar at least as one component of a new binding material or as raw material for manufacturing of a binder because of their hydraulic potential. Generally it should be looked for a way which allows a recycling without a complete separation of the cement paste and the aggregates. This requires further research about the decomposition of heat treated concrete and mortar as well as the re-hydration behaviour.

THE STRUCTURE AND MICROSTRUCTURE OF AUTOCLAVED MATERIALS MODIFIED BY POZZOLANIC MINERAL ADMIXTURES

Pytel, Z. and Malolepszy, J.

Faculty of Material Science and Ceramics, Department of Building Materials, University of Mining and Metallurgy, Ave. Mickiewicza 30, PL-30-059, Cracow, Poland. E-mail: pytel@uci.agh.edu.pl

ABSTRACT

The structure and microstructure of autoclaved materials is mainly determined by the kind and amount of the chemical reaction products being formed. In the case of sand-lime bricks, the final products of hydration produced under hydrothermal conditions are hydrated calcium silicates (of various degrees of crystallization) which usually appear as amorphous C-S-H phase, and crystalline tobermorite. The presence of foreign ions in the reaction medium exerts a considerable influence on the morphology of these products. The presence of the ions may be due to impurities in raw materials, or they may be intentionally introduced as mineral additives. The influence of various mineral additives on the formation of the structure and microstructure of autoclaved materials was analysed in the course of model tests. The aforementioned autoclaved materials were obtained from the mixture of lime and silica (mixed at molar ratio $\text{CaO/SiO}_2 = 0.83$). This composition was subsequently modified by the introduction of a small amount of mineral additive. Fly ashes, flue gas desulphurisation products and the heat treatment products of silty materials were used as pozzolanic mineral additives. In order to heighten the chemical activity of the additives in question, they were activated by means of sulphates and alkalis.

The quality of the materials obtained was assessed on the basis of the results of the following studies: XRD analysis, SEM+EDS, mercury porosimetry and the study of physical characteristics. The cognitive effect of the studies is the presence of C-S-H phase and tobermorite in the materials obtained, which results directly from the introduction of mineral additives as well as the application of sulphates or alkalis in the chemical activation. The changes occurring in the morphology of basic/primary final products of hydration under hydrothermal conditions favourably modify the microstructure of autoclaved materials, as a result of which the improvement of application properties can be noted. It refers particularly to the strength development of such a kind of material which has a decisive influence on the application effects observed in the course of the studies conducted.

1. INTRODUCTION

Quartz sand and burnt lime are the traditional starting materials in sand-lime brick production [1,2]. These materials, mixed and formed, are subsequently autoclaved, to transform lime and silica into hydrated calcium silicates of a different structure [3,4,5]. The amorphous phase calcium silicate hydrate (C-S-H), being the first product, is the precursor of tobermorite and other phases synthesised in hydrothermal conditions [6]. In practice, the same impurities in the raw mixture can give the other products; in the presence of aluminium ions the stabilisation of tobermorite occurs [7] or even the formation of hydrogarnets takes place [8]. The latter phase affects significantly the strength of the final product.

The mechanical properties of autoclaved products are strongly related to the total amount of C-S-H and tobermorite [9]. Hence the materials should be processed with the aim of producing the highest content of these phases. Such an effect can be achieved by the incorporation of the same admixtures.

The phase composition and microstructure of autoclaved products is thus modified by the use of mineral additives such as fly ash, metakaolinite and by-products from fluidised bed combustion installations. These admixtures bring about the formation of additional C-S-H and subsequently tobermorite, as a result of the pozzolanic reaction. Simultaneously the capillary porosity of the products is reduced and consequently their strength and quality is increased [10].

The waste materials and by-products of pozzolanic character, e.g. fly ashes, slags, silica fume can be used in silicate building materials technology. Also very promising is the potential incorporation of a “new generation” of wastes (i.e. gypsum, etc) from desulphurization operations in the same fluidised bed combustion (FBC) installations [11].

These wastes exhibit high pozzolanic activity resulting from the presence of a decomposed clayey mineral - metakaolinite. The same amount of CaSO_4 and CaCO_3 can promote the formation of hydroellastadite [12] or scawtite [13,14] in hydrothermal conditions. The microstructure of materials is thus modified.

Some of the waste materials from the groups mentioned above show their pozzolanic activity under the presence of alkalis or sulphates [15,10]. Thus the determination of the effect of some ions on the formation and properties of hydration products during autoclaving is of special importance from both practical and scientific point of view.

2. CHARACTERISTICS OF STARTING MATERIALS

For the purpose of synthesis of autoclaved materials used as reference samples (T), quartz sand (MK) was applied as the silicate raw material. It was produced by Quartzwerke GmbH under the trade name of SIKRON-Feinstmehl SGL-300. The characteristic parameters of this raw material are as follows: specific density- 2.65g/cm^3 , bulk density- 0.72 g/cm^3 , Blaine specific surface $S_w = 550\text{ m}^2/\text{kg}$ and SiO_2 content = 99.2%. That's why this material is different to sand used in practice for the manufacture for calcium-silicate products. The other basic raw material was burnt lime obtained in the course of heat treatment of analytically pure CaCO_3 produced by Fluk Company (Firma Fluka). Thermal dissociation was conducted at 1050°C for 3 hours.

In order to modify the composition of the lime/sand mixture, the following pozzolanic mineral additives were used: metakaolinite (MU), fly-ash (S), and fluidised bed waste (ZFŽ). Although pozzolanic properties are typical of all the above-mentioned mineral additives, in each case pozzolanic activity is determined by different factors. In the case of fly-ash (S) such a factor is mainly its vitreous/glasslike phase, whereas the pozzolanic properties of fluidised bed waste (ZFŽ) are determined by the presence of dehydrated silty minerals. Metakaolinite (MU) was included in this study as a model material of high pozzolanic activity, obtained during thermal decomposition of kaolinite. The pozzolanic activity of the mineral additives was determined by the chemical method in the ASTM 379-565 Standard. This method consists of the analysis of components soluble in basic solutions. These components are considered as potentially active in the presence of calcium hydroxide. The ASTM method gives the ability to determine reactive of both silica and alumina to Ca(OH)_2 . The results are presented in Table 1.

With the aim of increasing the pozzolanic activity of the additives, they were activated chemically by means of sulphates and alkalis. Sulphates were introduced into the samples in the form of natural

gypsum (G) and anhydrite (AN). Alkalis were introduced in the form of water solutions of NaOH (NH), KOH (KH) and Na₂CO₃ (NC).

Table 1. Pozzolanic properties of mineral additives

Sample symbol	Pozzolan content (in weight %)		Total
	SiO ₂	Al ₂ O ₃	
Fly ash (S)	9.24	3.4	12.64
Fluidised bed waste (ZFZ)	12.84	4.62	17.46
Metakaolinite (MU)	21.19	17.66	38.85

3. SAMPLE PREPARATION

The reference samples of autoclaved materials were obtained from the mixture of basic raw materials which were mixed at the molar ratio CaO:SiO₂=0.83. This value shows stoichiometric relations of both oxides in tobermorite. These raw materials, i.e. silica powder and burnt lime underwent the process of homogenization, at first without water and then with the appropriate amount of water. Water was added to the mixture of solid components in the amount necessary to slake the burnt lime component and to guarantee an increase in humidity until the weight ratio w/s = 0.2 was obtained. The mixture composition shown above was modified with an appropriate amount of a mineral additive. In most cases the amount of mineral additives introduced was 20% in relation to the total mass of solid components, although in the case of metakaolinite MU it was 2%. Chemical activators in the form of gypsum and anhydrite constituted 1% of the total mass of solid components. Alkalis, in turn, were introduced together with make-up water containing the dissolved equivalent amounts of NaOH, Na₂CO₃ or KOH, which, calculated respectively by Na₂O and K₂O constituted 5% of the solid components of the mixture.

After the process of homogenization was completed, each mass thus obtained was placed in a hermetic container in a laboratory drier at 60°C for 4 hours with the aim of slaking burnt lime. Following this treatment, the process of homogenization was resumed and afterwards samples were formed with the use of a press. The cylinder-shaped samples had the following parameters: d x h = 25 x 25 mm. The process of sample pressing was two-stage, i.e. pressing pressure was respectively 10 and 20 MPa including interstage deaeration. The prepared samples were subsequently treated under hydrothermal conditions. Autoclaving took place at 180°C for 8 or 72 hours for mineral additive-free samples, and 8 hours only for the samples containing additives.

4. STUDY RESULTS

4.1 Physical properties of autoclaved materials

The influence of pozzolanic mineral additives on the quality of autoclaved materials was estimated on the basis of the analysis results of the primary physical characteristics. Thus in the course of a study, compressive strength R_c as well as volume density C_0 were established. The results are shown in Table 2.

The data obtained clearly indicate that when only a pozzolanic mineral additive is introduced into the lime/silica mixture, it does not result directly in the strength improvement of the autoclaved materials obtained. Only when it is combined with additional chemical activators, can we observe a significant increase in strength.

4.2 Phase composition analysis of materials obtained.

The mineral composition of autoclaved materials in question was determined by means of XRD analysis with the use of a Philips PW 1040 diffractometer. XRD patterns were examined for the

angle range $2\theta = 5$ to 55° . The interpretation of the XRD diffraction spectrums was carried out in accordance with ICPDS data. The results of phase composition analysis is presented in Figure 1 in the form of all XRD patterns for the samples of additive-containing autoclaved materials with chemical activation, which were compared with reference samples. The abbreviations used in the diagram stand for the following: Q- quartz; CH- calcium hydrate; CSH- calcium silicates hydrate, type C-S-H (I) or C-S-H (II); CC- calcium carbonate; AN- anhydrite.

Table 2. Physical properties of autoclaved materials obtained

Sample symbol	Type of mineral additive	Type of chemical admixtures	Type of property studied	
			compressive strength R_c , MPa	density C_0 , kg/m ³
T / 8	-	-	53,8	1475
S – 20	Fly ash (S) (20 wt. %)	-	35.1	1592
S – G		Gypsum (1 wt. %)	49.1	1643
S – AN		Anhydrite (1 wt. %)	49.8	1557
S – NH		NaOH (5 wt. % eqw. Na ₂ O)	104.6	1834
S – KH		KOH (5 wt. % eqw. K ₂ O)	85.1	1783
S - NC		Na ₂ CO ₃ (5 wt. % eqw. Na ₂ O)	96.2	1805
ZFZ - 20	Fluidal waste (ZFZ) (20 wt. %)	-	27.3	1549
ZFZ– G		Gypsum (1 wt. %)	38.2	1445
ZFZ – AN		Anhydrite (1 wt. %)	45.5	1549
ZFZ – NH		NaOH (5 wt. % eqw. Na ₂ O)	70.6	1659
ZFZ – KH		KOH (5 wt. % eqw. K ₂ O)	75.1	1790
MU – 2	Metakaolinite (MU) (2 wt. %)	-	35.1	1404
MU – G		Gypsum (1 wt. %)	37.6	1393
MU – AN		Anhydrite (1 wt. %)	39.6	1399
MU – NH		NaOH (5 wt. % eqw. Na ₂ O)	100.6	1742
MU – KH		KOH (5 wt. % eqw. K ₂ O)	54.2	1623
MU - NC		Na ₂ CO ₃ (5 wt. % eqw. Na ₂ O)	79.3	1617

In Figure 1 only the fragments of XRD patterns for the angle range $2\theta = 15$ to 40° were presented, these being the most interesting ones as far as the observed changes are concerned. The above-mentioned angle range comprises first of all the area of lines typical of the products being formed in the course of synthesis occurring at 180°C under hydrothermal conditions, as well as the highest intensity reflections coming from the reaction substrates. Thus, within the angle range mentioned the presence of a reaction product being formed as C-S-H phase can be corroborated on the basis of the highest intensity lines for the distance $d = 0.3070$ nm ($2\theta=29.09^\circ$). Similarly, the presence of reaction substrates in the form of quartz is detected due to reflections occurring when $d = 0.4255$ ($2\theta=20.88^\circ$), 0.3344 ($2\theta=26.66^\circ$), 0.2457 ($2\theta=36.58^\circ$) and 0.2283 ($2\theta=39.48^\circ$) nm (according to ICPDS file no. 33-1161). The presence of the unreacted calcium hydrate is corroborated by the lines occurring when $d = 0.4902$ ($2\theta=18.10^\circ$), 0.3115 ($2\theta=28.66^\circ$), 0.2625 ($2\theta=34.16^\circ$) and 0.2445 ($2\theta=36.76^\circ$) nm (according to ICPDS file no. 4-733). While comparing individual XRD patterns, one can easily notice considerable similarity, which may testify to a very similar mineral composition of the materials obtained, among which the dominant product is C-S-H phase.

However, after the in-depth intensity analysis of the appropriate reflections originating from the starting materials as well as the analysis of shape and intensity of the line coming from the main reaction product, an essential observation can be made. The additional chemical activation leads to an increase in the reaction rate; higher effectiveness, however, is connected with alkalis rather than with sulfates. The results of compressive strength analysis of the samples support this. It can be

seen from the results that the samples of alkali-activated materials exhibit the best strength properties (Table 2 data).

Figure 1. Analysis results of mineral composition of autoclaved materials

- a) XRD pattern of reference sample (molar ratio C/S=0.8)
- b) XRD patterns for fly ash (S) samples
- c) XRD patterns for metakaolinite samples (MU)
- d) XRD patterns for fluidised bed waste samples (ZFŽ)

4.3 Porosity analysis of autoclaved materials

Microporosity analysis was conducted by means of mercury porosimetry with the use of a Carlo-Erba PO-225 porosimeter. The measurements were taken for the mercury pressure range 0.1 to 200 MPa. Figure 2 presents the microporosity analysis results for the samples of autoclaved materials in the form of curves showing pore size distribution in the samples containing a mineral additive, in comparison to T/8 reference sample.

Figure 2. Pore size distribution
a) samples containing fly ash (S)
b) samples containing metakaolin (MU)

When comparing the curves showing the size distribution of pores in T/8 sample and in the samples of S and MU series, it can be stated that the introduction of a mineral additive into the quartz sand/lime mixture (molar ratio $C/S = 0.83$) without additional chemical activation did not result in any considerable changes in the structure of pores, both capillary and gel-like. An entirely different effect is observed in the additive-containing samples that were activated by alkali and sulfate ions. The detailed analysis indicated that the general porosity of these samples decreased and the structure of pores changed. It was observed that the volumetric participation of capillary pores decreased for the radius range 10 to 50 nm, whereas gel-like pores were on the increase. The latter type of pores is connected with the formation of an additional amount of C-S-H phase. The aforementioned tendency of changes in porosity is supported by the volume density values of the analyzed materials.

4.4 Microstructure analysis of autoclaved materials

In order to explain the differences occurring in the microstructure of the autoclaved materials in question, related to the presence of pozzolanic mineral additives as well as to the type of chemical activation used, the samples of the materials obtained were observed by means of scanning microscopy. For research purposes, a JSM 5400 scanning microscope was used (produced by JEOL), which was equipped with a microanalyzer of XRD dispersion – EDS-Oxford Instruments LIKN-ISIS (serial number 300). The typical microstructure picture of an autoclaved material obtained from quartz sand/lime mixture with molar ratio $C/S = 0.83$ (T/8 reference sample) is shown in Figure 3, whereas the microstructure changes of autoclaved materials modified with mineral additives can be seen in Fig. 4. The influence of pozzolanic mineral additives as well as individual

types of chemical activation on the microstructure of the materials were presented on the basis of the sample series containing fluidised bed waste (ZFŽ).

Figure 3. Microstructure of autoclaved material without mineral additives

- a) sample obtained in 8-hour synthesis (T/8 sample)
- b) sample obtained in 72-hour synthesis (T/72 sample)

While analyzing the microstructure pictures seen in Figure 3, it can be stated that the forming microstructure of the autoclaved materials results from the presence of a basic product of synthesis occurring under hydrothermal conditions, i.e. amorphous C-S-H phase with molar ratio $C/S = 0.8$ to 1.0 . When this product is formed in the systems that are not activated additionally, it appears in its typical sponge-like form, known as “honeycomb”. However, with the prolonged time of synthesis, it shows tendency to the formation of crystalline tobermorite. This phenomenon is directly connected with the structure of the pores present in this type of material. Two main categories of pores can be distinguished, namely capillary pores (connected with the method of cast profile formation), and gel-like pores, typical of the synthesis products being formed, especially C-S-H phase.

When pozzolanic mineral additives are introduced into the quartz sand/lime mixture in the above-mentioned amounts, it leads, in the course of a pozzolanic reaction, to the formation of additional amounts of products such as hydrated silicates and calcium aluminosilicates, which slightly modifies the microstructure of the autoclaved materials obtained. The further changes in the microstructure of the materials are expected after small amounts of sulfates or alkalis are introduced into the system in the course of reaction. These changes are clearly seen in Figure 4, where the main product of a hydrothermal reaction, i.e. C-S-H phase, adopts various morphological forms (with dominant oblong-shaped forms) under the influence of chemical activation, particularly by alkalis.

Figure 4. Microstructure of autoclaved materials with fluidal waste additive

f) microstructure of sample ZFZ-NC

5. SUMMARY

When taking into account the configuration of interrelated factors that determine the structure and microstructure of the autoclaved materials in question, it must be stated that we can influence their practical properties to some extent by means of pozzolanic mineral additives. As can be seen from the research results, the introduction of such additives into quartz/lime mixture (molar ratio C/S = 0.83) combined with chemical activation by sulfate or alkali ions, exerts a positive influence on the strength properties of the autoclaved materials.

The strength development/increase of the samples that was observed, results from the fact that during the pozzolanic reaction the additional amounts of products (hydrated calcium silicates of amorphous C-S-H phase type) are formed. It is also due to the favourable modification of the morphological forms of this product, which is caused by the presence of the accessory ions in the product structure.

C-S-H phase being formed during a synthesis of short duration and without additional activation usually occurs in its typical sponge-like form (Figure 3a), whereas in the presence of chemical activators, particularly alkalis, it tends to develop oblong and more compact forms. This has an essential influence on the structure of pores in the material.

These observations can be corroborated by the porosity analysis results of the materials obtained (Figure 2). According to these results, chemical activation by means of alkalis, and to a lesser extent sulfate ions, contributes to a decrease in porosity in general as well as to the changes in porosity structure. The above-mentioned changes concern mostly a decrease in the volumetric participation of capillary pores in favour of gel-like ones. The direction of these changes can be rationally explained when taking into account the physical and chemical aspects of the additives function.

As far as the physical impact of pozzolanic additives is concerned, they function as micro-aggregate, which due to considerable size reduction exerts an influence on the resultant curve of grain-size distribution of the raw mixture in the process of pressing. However, the influence of pozzolanic mineral additives on the quality of autoclaved materials should be discussed mainly from the chemical point of view, as an active chemical admixture. Active SiO_2 and Al_2O_3 forms, pozzolans bound/set in amorphous phases, react in solution with calcium ions. As a result, the formation of products takes place, the structure of which shows some similarity to the typical products of pozzolanic cements hydration. The main representative of these products is amorphous C-S-H phase (Figure 1), the structure of which normally contains gel-like pores. When the additional amount of this phase is formed in the course of a pozzolanic reaction in hydrothermal conditions, at a much higher reaction rate, it contributes to an increase in this type of pores (diameter range 5÷10nm).

A wealth of information is also provided by the analysis results of phase composition of the materials; the results were obtained with the use of XRD diffraction. These data confirm the earlier observations, namely that additional chemical activation leads to an increase in substrates consumption rate. Such a conclusion can be drawn on the basis of the growing intensity of the reflex coming from the main product of synthesis in hydrothermal conditions, with the simultaneous decrease in lines typical of reaction substrates. It can be clearly seen from the above-mentioned data that as a result of the introduction of pozzolanic mineral additives, no considerable qualitative changes in the materials are observed, as the dominant product is, in each case, amorphous or semi-crystalline C-S-H phase (molar ratio C/S = 0.8 to 1.0) present in various morphological forms. There are, however, quantitative changes.

A good confirmation of the above-mentioned conclusions are the results of the microstructure observations of the materials in question, which were obtained by means of scanning microscopy. The analyzed patterns of microstructures for the fluidal waste samples series (ZFŽ), shown in Figure 4, point to the changes caused mainly by a type of activator used.

ABSTRACT

By-products as pozzolanic additions are now routinely used for the production of high-performance concrete. Recently some activated materials such as metakaolin have been shown to be excellent pozzolans.

Alkaline activation of metakaolin as well as mixtures of metakaolin, Portland cement, granulated blast furnace slag make it possible to produce very dense and high strength materials. The products formed in the alkaline activation reaction of metakaolin and its mixtures strongly depend on what type of activator is used. In the study described, properties of metakaolin pastes were determined after 3, 28, 90 and 180 days.

The influence of OPC, $\text{Ca}(\text{OH})_2$, GBFS, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ and NaOH on the mechanical strength, microstructure and phase composition of the pastes was measured.

The most interesting properties were observed for metakaolin paste activated by mixture of OPC, gypsum and calcium hydroxide. Concentration of NaOH plays also very important role in the formation of dense microstructure. The pastes containing slag with higher glassy phase and Al_2O_3 content achieved significantly better mechanical properties.

The influence of curing conditions (natural, low pressure steam curing and autoclaving) on the mechanical properties and microstructure of the pastes was also very visible.

For samples cured in low-pressure steam conditions and autoclaved, the average pore radius is significantly lower.

XRD tests and SEM observations indicate that besides the C-S-H gel phase some amounts of amorphous alkaline aluminosilicates are present in activated pastes.

1. INTRODUCTION

Making newer and better materials is an inevitable process related to development of civilisation. In recent years, the research on the possibility of obtaining binders based on chemically activated metakaolinite has been intensified. Application of calcined clays as pozzolanic additive makes it possible to significantly alter the properties of the produced binders [1-5]. Their properties depend on the applied components, type and amount of the activator and curing conditions. Good activators of metakaolinite include calcium hydroxide, Portland cement or sodium hydroxide.

Water glass or gypsum may also be used as additional components. Numerous studies revealed that the metakaolinite activation involving sodium hydroxide requires an appropriate concentration of this substance [3, 5, 6]. Other factors that have an impact on the metakaolinite activation process are the temperature of kaolin clay calcinations and the curing temperature of hydrating pastes.

Application of appropriately high temperatures may contribute to the formation of additional phases. One of the binders that has recently been a subject of broad research includes so called alkali-activated slag binders that are composed of natural or artificial aluminosilicates activated by appropriate alkaline activators [7-9]. The production of hydraulic clinker-free binding materials combines the environmental and economic aspects. It is related to both the use of slags that are industrial waste and reduced power consumption in comparison with the production process of Portland cement. Appropriate activation of vitrified calcium and magnesium aluminosilicates gives a binding material that features high strength and resistance to chemical attack. A group of binders of this type includes so-called geocements containing metakaolinite [10, 11].

Alkaline activation of metakaolinite produces an inorganic polymer of good mechanical properties. Formation of this binder may be compared to the synthesis of zeolites. The structure of these materials consists of a three-dimension framework composed of SiO_4 and AlO_4 tetrahedrons bound together by common oxygen. The alkaline metal cation deriving from the added activator compensates for insufficient charge of aluminium. The difference, in comparison with the synthesis of zeolites, is the form in which it occurs - the alkaline activation of metakaolinite leads to the formation (in most cases) of the amorphous phase [5, 12, 13].

The materials of this type, apart from high strength, are resistant to the exposure to low and high temperatures, feature low shrinkage and a high resistance to corrosive attacks, as well as the ability to bind heavy metals and immobilise other noxious substances.

The objective of the conducted tests was to determine the properties of activated slag-cement-metakaolinite pastes. These tests included, but were not limited to, checking of strength properties of the samples with different activators added, the influence of curing conditions and testing of phase composition and microstructure of pastes.

2. EXPERIMENTATION

2.1 Characteristics of the applied materials

The tests involved the following raw materials: kaolin clay, crushed granulated blast-furnace slag, CEM I 32,5 R Portland cement, quick lime, β semi-hydrate gypsum.

2.1.1 Metakaolinite

Metakaolinite was obtained by roasting kaolin clay at high temperatures. For the requirements of this research, kaolin clay of the chemical composition presented in Table 1 was used to obtain this material.

Table 1. Chemical composition of kaolin clay.

Component	Share [mass %]
SiO ₂	53.20
Al ₂ O ₃	32.80
Fe ₂ O ₃	0.55
TiO ₂	0.45
CaO	0.30
MgO	0.25
K ₂ O	0.60
Na ₂ O	0.20
L.O.I.	11.6

The clay was calcined in different scenarios in the following environments:

750⁰C for 24 h – denoted as MK1 or 850⁰C for 2 h – denoted as MK2

Application of kaolin clays initially roasted in different conditions (750⁰C and 850⁰C) was aimed at testing the impact of the temperature of this process on the activity of metakaolinite.

2.1.2 Ground granulated blast-furnace slag

Two types of ground-granulated blast furnace slags were used in the research i.e. the Polish slag from Huta Sendzimir [Sendzimir Steelworks] (hereinafter denoted as SP) and the British slag from Scunthorpe (hereinafter denoted as SE). Chemical composition of slags is summarised in Table 2.

Table 2. Chemical composition of slags.

Component	Share [mass %]	
	SP slag	SE slag
SiO ₂	38.8	35.7
Al ₂ O ₃	7.1	12.6
Fe ₂ O ₃	1.5	0.7
CaO	44.2	39.5
MgO	6.4	8.4
Others	2.0	1.69
Glass content	87	97

2.1.3 Portland cement

Another component applied to make pastes was CEM I 32.5 R Portland cement (according to EN – 197-1). The specific surface of cement was 310 m²/kg (according to Blaine).

2.1.4 Quick lime and gypsum

A commercial product – quick lime (denoted as CH) and β semi-hydrate CaSO₄ were used in the research (denoted as G).

2.1.5 Alkaline activators

NaOH solutions (concentration: 5M, 12M and 15M) and sodium water glass with silicate modulus of 1.5 (denoted as WG) were used as alkaline activators.

2.1.6 Superplasticizer

Melamine-naphthalene superplasticizer was used in the preparation of the pastes.

2.2 Characteristics of prepared pastes

The applied denotations of specific pastes and their compositions are summarised in Table 3.

Table 3. Denotations and compositions of specific pastes.

No.	Type of component [mass %]									SP	W/S
	MK1	MK2	CEM	SP	SE	G	CH	NaOH	WG		
1	50	-	50	-	-	-	-	-	-	3	0.45
2	45	-	-	-	45	-	5	-	5	3	0.45
3	45	-	-	45	-	-	5	-	5	3	0.45
4	45	-	45	-	-	5	5	-	-	3	0.45
5	40	-	-	-	45	-	10	-	5	3	0.45
6	40	-	-	-	45	-	10	5(12M)	-	3	0.45
6A	40	-	-	-	45	-	10	5(5M)	-	3	0.45
6B	40	-	-	-	45	-	10	5(15M)	-	3	0.45
7	-	50	50	-	-	-	-	-	-	3	0.45
8	-	45	-	-	45	-	5	-	5	3	0.45
9	-	45	-	45	-	-	5	-	5	3	0.45
10	-	45	45	-	-	5	5	-	-	3	0.45
11	-	40	-	-	45	-	10	-	5	3	0.45
12	-	40	-	-	45	-	10	5(12M)	-	3	0.45

The pastes were cured at +20°C and relative ambient humidity of approximately 60%.

In order to determine the impact of curing conditions upon the properties of pastes, the samples marked as 6A and 6B underwent the process of low-pressure steam curing (4-2-6-2 cycle at the maximum temperature of 70°C) or 6-hour autoclaving at the temperature of 180°C.

3. RESULTS

The strengths of pastes were tested within the range of 1-180 days. The results of strength testing of the samples cured in natural conditions are presented in Figures 1 and 2.

Figure1. Compressive strength of the samples containing different activators (clay calcination temperature - 850⁰C)

Figure 2. Compressive strength of the samples containing different activators (clay calcination temperature - 750⁰C)

It is clear that the samples containing cement feature considerably higher mechanical strengths compared with "cement-free" samples. Addition of gypsum to the cement-containing samples causes a conspicuous increase in strength. It is also observed that the strength gain over time for "cement-free" mixtures is low. In some cases, the latter even demonstrate slight drops of strength after 180-day curing.

It may be observed that in most cases the impact of the temperature of initial kaolin clay treatment upon the strength of paste is negligible; it pertains mainly to "cement-free" pastes. In the case of samples that contain cement (nos 1 and 7 as well as 4 and 10), these differences are much more significant. These pastes, based on the clay calcined at the higher temperature, featured higher

strengths than the analogous samples containing clay calcined at the temperature of 750°C . Thus, one may assume that the thermal treatment temperature did not impact their pozzolanic activity to a significant extent. On the basis of the conducted tests, it is possible to conclude that the slag-containing samples of higher contents of Al_2O_3 (SE) feature higher compressive strengths than analogous pastes prepared on the basis of the SP slag (lower Al_2O_3 content).

3.1 Impact of activator type on the microstructure and phase composition of pastes

The microstructure testing of hardened pastes was conducted using a scanning microscope for each type of mixture. The phases that occurred were identified by means of the EDS analysis.

The selected average pictures of the microscope observation are presented in Figures 3-5. A basis phase that occurs in all mixtures is an amorphous C-S-H phase. Etringite crystals can be seen in the cement-containing pastes.

Figure 3. Microstructure of paste No. 1 - 50% MK, 50% CEM; amorphous C-S-H phase.

Figure 4. Microstructure of paste No.1 – ettringite crystals

Figure 5. Microstructure of paste No. 3 – 45% MK1, 45%SP, 5% CH, 5% WG; amorphous C-S-H phase on the slag grains.

The X-ray test results (XRD) confirmed the observations conducted by means of the scanning microscope. XRD patterns of the pastes containing different activators are presented in Figure 6

Figure 6. XRD patterns of the pastes (natural curing).

The following notations of phases are used in the figure: Q – quartz, CH – Ca(OH)_2 , C – C-S-H ; CaCO_3 , E – ettringite, A – C_2S .

The hump in the XRD patterns indicates high contents of the amorphous phase in the tested samples.

3.2 Impact of alkaline activator concentration and curing conditions on the strength properties of pastes

Table 4 presents the strengths of activated NaOH pastes of different concentration and cured in different conditions.

Table 4. Influence of NaOH concentration and curing conditions on the strengths of pastes.

Type of paste	Compressive strength [MPa]			
	3 days	28 days	90 days	180 days
6 (natur)	5.4	7.8	8.0	7.9
6 (low press)	6.8	8.8	9.2	10.1

6B (natur)	6.4	8.9	9.4	10.3
6B(low press)	9.2	10.2	11.1	12.0
6B (autocl)	12.1	13.6	14.2	16.8

On the basis of the presented data, one may conclude that the concentration of the alkaline activators has an impact upon the properties of tested pastes. The samples activated with a 15M solution of NaOH featured higher strength than analogue pastes containing 5M and 12M activator.

It may be concluded that the samples that were steam cured or autoclaved featured higher mechanical strength than naturally cured samples. It pertains to both "cement-free" pastes as well as cement-containing samples.

The rise of the curing temperature of pastes also resulted in certain alterations of the microstructure view. The intergrain boundaries between the hydrating grains of slag and metakaolinite were significantly blurred and considerable amounts of the C-S-H of the "honey comb" type phases as well as some amounts of sodium zeolites occurred.

3.3 Impact of curing conditions on the porosity of pastes

The testing of pore size distribution was made by means of the mercury porosimetry. The tested 6A pastes were subject to natural curing, low pressure steam curing and autoclaving. Figure 6 presents the comparison of the pore size distribution for the three mentioned types of pastes.

Figure 7. Pore size distribution for paste 6A: (1) - natural curing; (2) – low pressure steam curing; (3) - autoclaving.

The testing showed that the total porosity is comparable for all the samples. The temperature increase contributed to a reduction of the number of capillary pores. These differences pertain also to the average pore sizes that were 124.229 nm (natural curing), 120.249 nm (steam curing) and 55.462 nm (autoclaving), respectively.

4. CONCLUSIONS

- [1] The testing confirmed the possibility of application of chemically activated metakaolinite as a slag and slag-cement binder component.
- [2] Application of alkaline activator (NaOH) of the higher concentration resulted in a significant growth of paste strength.
- [3] The pastes containing a several-ten-percent addition of Portland cement featured the highest strengths. The best mechanical properties were obtained for the mixtures containing 45% metakaolinite and cement and 5% of calcium hydroxide and gypsum.
- [4] A major product of the reaction of naturally cured pastes was the C-S-H amorphous phase.
- [5] The increase of the initial curing temperature (steam curing or autoclaving) leads to a significant (several-ten percent) growth of compressive strength of pastes and forming of the C-S-H I phase, calcium aluminosilicates and zeolites. Autoclaving of pastes resulted also in a two-fold reduction of an average pore radius.

ABSTRACT

Self-compacting concrete (SCC) is a new kind of concrete that doesn't need any compaction. The two essential properties of SCC are a high flowability and a high segregation resistance obtained by a large amount of fine particles and the use of superplasticizers. It is known that the pore structure of SCC differs from the pore structure of traditional concrete. Many research programmes are already done concerning the fresh properties of SCC, but almost nothing is known about the durability of SCC. The durability of concrete is strongly affected by the water permeability, water absorption and capillary suction.

This project includes laboratory studies of the water permeability, water absorption and capillary suction of 7 SCC and 2 traditional concretes. A constant amount of cementitious materials (cement and filler), as well as a constant amount of water, sand and gravel was considered. The influence of the amount and type of cement and filler is studied (Portland cement, limestone filler, fly ash). The results of this study are compared with models found in literature.

1. INTRODUCTION

Self-compacting concrete (SCC) was developed in Japan in the 1980's. The aim was to develop a concrete that could be placed without vibration. In this way, some health risks as well as environmental problems could be avoided. Also durability problems related with badly vibrated concrete structures could be reduced.

The two essential properties of SCC are a high flowability and a high segregation resistance obtained by a large amount of fine particles and the use of superplasticizers. Due to the high amount of fine particles, the pore structure of SCC concrete is somewhat different from the pore structure of traditional concrete [1]. The pore structure is one of the major influencing factors concerning durability. The actual application of SCC might be somewhat risky due to a lack of knowledge concerning the actual durability of the new cementitious material.

Many research programmes have already been carried out concerning the fresh properties of SCC, but little is known about the durability of SCC. Durability is not like strength a bulk property but (with some exceptions) in the first place a surface property, determined by composition and properties of the surface layers, indicated with the word 'skin'. Concrete has three skins: the cement skin (about 0.1mm thick), the mortar skin (about 5 mm) and the concrete skin (about 30mm). These are due to the wall effect, to sedimentation and segregation as a result of gravity and to permeation

and evaporation of water in and out of concrete. Therefore durability is not only influenced by the concrete composition, but also by curing and the quality of the concrete cover.

The ease with which fluids enter and move through the concrete matrix influences largely the durability of concrete (for example: deterioration due to chloride ions caused by the transport of a chloride solution into the material). There are two mechanisms controlling the transport of water into concrete: permeability and sorptivity. Permeability is a measure of the flow of water under pressure in a saturated medium and sorptivity is the ability to absorb water by capillary suction.

In this article results of water permeability, water absorption and capillary suction of SCC found in literature are described and the results of tests carried out at the Magnel Laboratory of Concrete Research on 7 SCC and 2 traditional concretes (TC) will be discussed. These test results will be compared with models found in literature predicting the water permeability and capillary suction for traditional concrete.

2. LITERATURE RESULTS OF SCC

Many test methods exist to determine the behaviour of concrete in the presence of water: capillary suction, absorption by immersion, vacuum absorption, water permeability, water penetration depth, etc. For each of these types of test, different procedures exist with regard to the dimensions of the test specimen, the preparation of the sample (which is extremely important with regard to the internal humidity), duration of the test. For SCC, some test results are available in literature but comparing these results is difficult because there is no standardized way to test. Generally, it appears that better results are found for the SCC-mixes compared to traditional concrete mixes. Table 1 presents a summary of results found in the literature.

Table 1. Summary of test results found in literature

reference	Test description	Test method	# SCC mixes	slump flow (mm)	compr. strength (N/mm ²)	unit	Range of results
2	vacuum absorption	-	1	740	84 (90days)	vol %	14

3. EXPERIMENTAL PROGRAMME

3.1 Concrete composition

At the Magnel Laboratory for Concrete Research, 7 SCC and 2 TC were investigated. In these mixes, a constant amount of fine material (cement and filler) is considered: 600kg/m³; as well as a constant amount of water, sand and gravel, respectively 165 kg/m³, 853 kg/m³ and 698 kg/m³. Three types of cement (CEM I 42.5 R, CEM I 52.5 and CEM I 52.5 HSR) and two types of filler (Betocarb P2 and Superfine S, the last having a much finer grading) were used. The amount of

superplasticizer was determined to obtain a suitable flowability without segregation. Also the value for the V-funnel was measured (values between 5s and 10s), air content (values between 1.5% and 3%) and the U-box requiring self levelling.

In Table 2 the mix compositions are given together with the slump flow and the compressive strength at 28 days measured on concrete cubes of 150mm.

Table 2. Mix design

	SCC							TC	
	1	2	3	4	5	6	7	1	2

W/C [-]	0.46	0.46	0.46	0.55	0.41	0.37	0.46	0.46	0.41
W/(C+F) [-]	0.27	0.27	0.27	0.27	0.27	0.27	0.27	0.46	0.41
slump flow [mm]	685	740	820	750	840	780	785	-	-
compressive strength [MPa]	55	63	70	44	63	68	56	46	52

3.2 Test method

Three kind of tests were carried out: water absorption by immersion and capillary suction following the RILEM procedure [11,12] and water permeability test.

3.2.1 Water absorption by immersion

From the mixes described above, cubes 100 x 100 x 100mm were made. These concrete cubes were stored in a climate room at 20°C ± 2 °C and more than 90% R.H. At the age of 28 days, these concrete cubes were stored for 1 week at 20°C ± 3 °C and 60 ± 3 % R.H. The cubes were then immersed in water until the change in weight during 24 hours is less than 0.1%. The cubes were then placed in an oven at a temperature of 105 ± 5°C until the difference in weight during 24 hours was less than 0.1%. These tests were carried out on three specimens for each concrete mix. This procedure was also carried out in water containing 3.5% by mass NaCl in order to verify if there was any difference. The results are given in Table 3.

Table 3. Water absorption by immersion

mix	absorption by immersion (% of dry mass)	
	in water	in water with 3.5% NaCl
SCC1	4.8	4.8
SCC2	4.9	4.5
SCC3	4.3	4.3
SCC4	5.0	5.0
SCC5	4.7	4.3
SCC6	4.2	4.3
SCC7	5.1	4.7
TC1	4.9	5.0
TC2	4.6	4.4

From this table the following can be concluded:

- the results for the absorption in the solution containing 3.5% NaCl are the same or somewhat lower than the results in water. This is in accordance with the formula given in [13] that predicts that the results of the absorption in water must be multiplied by 0.975 to obtain the results for the solution containing 3.5% NaCl.
- cement type: a cement type with a higher strength (SCC2, SCC3), resulting in a higher concrete strength (using the same W/C-ratio), does not necessarily give a lower water absorption. For SCC2 and SCC3, the water absorption is respectively somewhat higher and lower than water absorption for SCC1. In the presence of a solution containing NaCl, a higher strength for the cement type gives a lower water absorption.
- cement content: a higher cement content, resulting in a lower W/C-ratio and a higher strength gives a lower water absorption. This conclusion is valid for the absorption in water and in water containing 3.5% NaCl.
- type of filler: using a limestone filler with a finer grading gives a higher absorption in case of water without chlorides and a lower absorption in water containing chlorides.
- TC in comparison with SCC: the SCC give lower values for absorption than the corresponding TC (same amount and type of cement, same W/C-ratio). This conclusion is valid for the absorption in water and in water containing 3.5% NaCl.

3.2.2 Capillary suction

From the mixes described in section 3.1, cubes 150 x 150 x 150mm were made. These concrete cubes were stored in a climate room at $20^{\circ}\text{C} \pm 2^{\circ}\text{C}$ and more than 90% R.H. At the age of 28 days, these concrete cubes were stored for minimum 2 and maximum 3 weeks (the tests for capillary suction were started on Monday) at $40^{\circ}\text{C} \pm 5^{\circ}\text{C}$ and $40 \pm 3\%$ R.H. The test was performed in an environment at $20^{\circ}\text{C} \pm 3^{\circ}\text{C}$ and $60 \pm 3\%$ R.H. Then, the cubes were placed on stable supports in water, so that the water level is 5 ± 1 mm above the lower face of the specimen. Before the test and after 3, 6, 24, 72 and 168 hours the mass of the specimen is determined as well as the height of capillary rise (at the four sides of the cube in the middle).

These tests were carried out on three specimens for each concrete mix. This procedure is also carried out in water containing 3.5% by mass NaCl in order to verify if there is any difference. The results for the mass increase in water are given in Figure 1. In Table 4 the results are given of the mass increase after 24 hours in water and in water containing 3.5% NaCl. Also the height of capillary rise after 24 hours in these two cases is given. The measurements on the other moments follow the same trend.

From these results, the following conclusions can be made:

- water in comparison with water containing 3.5% NaCl: there is no distinct trend comparing these results.
- cement type: a cement type with a higher strength (SCC2, SCC3), resulting in a higher concrete strength (using the same W/C-ratio), gives in all cases a better result (decrease of the mass increase and decrease of the height of capillary rise)
- cement content: a higher cement content, resulting in a lower W/C-ratio and a higher strength gives a lower water absorption (lower mass increase and lower height of capillary rise). This conclusion is valid for the absorption in water and in water containing 3.5% NaCl.
- type of filler: using a limestone filler with a finer grading gives a lower mass increase and a lower height of capillary rise in both cases (water with and without chlorides).
- TC in comparison with SCC: the SCC give lower values for the mass increase and the height of capillary rise than the corresponding TC (same amount and type of cement, same W/C-ratio). This conclusion is valid for the absorption in water and in water containing 3.5% NaCl.

- a linear correlation exists between the mass increase and the height of capillary rise in the case of SCC ($R^2 \approx 0.95$ after 24, 72 and 168 hours). This correlation seems not to exist in case of TC. More testing will be carried out to verify this.

Figure 1. Mass increase by capillary suction

Table 4. Results capillary suction after 24 hours

mix	in water		in water containing 3.5% NaCl	
	mass increase (g)	height (mm)	mass increase (g)	height (mm)
SCC1	37	25	40	30
SCC2	28	23	27	23
SCC3	30	20	30	22
SCC4	49	31	44	28
SCC5	23	18	17	23
SCC6	19	17	15	19
SCC7	33	23	34	28
TC1	43	44	43	41
TC2	40	31	46	39

3.2.3 Water permeability

From the mixes described in section 3.1, cubes 150 x 150 x 150mm were made. These concrete cubes were stored in a climate room at $20^{\circ}\text{C} \pm 2^{\circ}\text{C}$ and more than 90% R.H. until the age of 56 days. Then, one core (diameter 80mm, height 25mm) from the center of each cube was taken. Afterwards, these cores were vacuum saturated in water. Then the water permeability test was performed in a testing device as shown in Figure 2. Water is present at the upper side of the specimen, on the lower side there is no water. Hence the pressure head is known and the water permeability can be calculated using the following formula:

$$K = \frac{A_t}{A_s} \frac{d}{t - t_0} \ln \left(\frac{h_0}{h} \right) \quad (1)$$

with K the coefficient of permeability, A_t the cross section of the tube, A_s the cross section of the specimen, d the thickness of the specimen, t the time and t_0 the starting time, h_0 the height of water in the tube at t_0 and h the height of water at time t.

Figure 2. Testing device for water permeability

These tests were performed on three specimens for each concrete mix. In figure 3, the results are given for all mixes except SCC4, SCC7 and TC2 because these tests are not finished yet. In table 5 the value of K after 35 days is given.

Figure 3. Water permeability

Table 5. Test results for water permeability

mix	K (10^{-11} m/s)
SCC1	1.8
SCC2	1.6
SCC3	2.0
SCC4	-
SCC5	1.2
SCC6	1.5
SCC7	-
TC1	1.6
TC2	-

The standard deviation on these test results varies between 1×10^{-12} m/s and 6×10^{-12} m/s, which corresponds with the values given in the literature [14]. In [14], the suggestion is made that only the order of magnitude or at the most the nearest 0.5×10^{-11} m/s should be mentioned. The conclusion is that the tests results obtained show very small differences. Also, all concrete mixes have a low water permeability and this test method is not suitable to compare ‘good’ concrete mixes.

4. MODELLING

4.1 Water absorption by immersion

No modelling was found in the literature for this kind of test. This is due to the differences in conditioning of the specimens before the test, the test conditions: drying at 40°C, 105°C, the duration of the test: a certain number of days or a criterium (e.g. difference in weight less than 0.1% in 24 hours).

For concrete in Belgium the criteria for water absorption, following the test method used in the tests described above, are that the individual result must be smaller than 6.5% and the mean value smaller than 6%. All test results given in Table 3 are good.

4.2 Capillary suction

For capillary suction, most models describing the absorption of water (in mass or in penetration depth) in function of time, suppose the following relation [15,16,17,18]:

$$i = A + S t^{1/2} \quad (2)$$

with t the time and i the penetration height or the increase in mass, S is the sorptivity index. Some authors do not use the term A [19]. It is important to note that most researchers are only measuring in the first hour [15,18,19].

In [18], the equation $i = S t^{1/2}$ for capillary suction is derived from the Darcy’s equation for one dimensional flow in an unsaturated medium. The term A in equation (2) is added for the intercept that is usually found. The origin of this intercept is the filling of open surface porosity on the inflow surface and along the sides of adjacent faces. In Figure 4, the test results of SCC1 are given, together with the two types of modelling of equation (2) obtained by regression.

In [16] it is suggested that the sorptivity value is less than $3 \text{ mm/h}^{0.5}$ based on the requirement that the depth of water penetration in concrete exposed to rain must be smaller than the concrete cover. From the regression analysis using equation (2), the values for S are all between $0.5 \text{ mm/h}^{0.5}$ and $2.5 \text{ mm/h}^{0.5}$.

Figure 4. Test results SCC1, together with two types of modelling

All models described in this section are predicting the progress of the water absorption with time, but none of them are predicting the value of S . In the Model Code 90 [20], a formula is given to predict S in the relationship $i = St^{1/2}$:

$$\ln\left(\frac{S}{S_0}\right) = 0.2 \frac{f_{ck}}{f_{ck0}} \quad (3)$$

with $S_0 = 10^{-4} \text{ m/s}^{0.5}$, f_{ck} the characteristic strength and $f_{ck0} = 10 \text{ MPa}$. In Figure 5, the experimental values and the predicted values based on equation (3) are given.

The predicted and experimental values, given in Figure 5, correspondings very well, giving the correct trend except for TC1, where the difference between the experimental and the predicted value is somewhat larger.

4.3 Water permeability

Two models for the value of K are found in literature: the model in MC90 [20]:

$$\ln\left(\frac{K}{K_0}\right) = -0.7 \frac{f_{ck}}{f_{ck0}} \quad (4)$$

with K_0 is 10^{-10} m/s , f_{ck} the characteristic strength and $f_{ck0} = 10 \text{ MPa}$.; and the model of Wong et al. [21], but this model is only applicable for high hydrostatic pressures, which is not the case in the present study.

The experimental and predicted values are given in table 6.

Figure 5. Experimental and predicted values for S

Table 6. Experimental and predicted values for K

mix	K (10^{-11} m/s)	
	measured	predicted
SCC1	1.8	0.8
SCC2	1.6	0.5
SCC3	2.0	0.4
SCC5	1.2	0.5
SCC6	1.5	0.4
TC1	1.6	1.4

From this table, it can be concluded that the values for the traditional concrete correspond very well. For the values of the SCC, the predicted values are lower than the experimental values.

5. CONCLUSIONS

Self-compacting concrete is a new type of cementitious material with a pore structure different from traditional concrete. This influences the durability and, more particularly, the behaviour with respect to water. In the literature, only a few test results were found concerning this subject and were summarized in this article.

In the Magnel Laboratory for Concrete Research, an experimental programme was carried out with 7 self-compacting concrete mixes and 2 traditional concretes. The type and amount of cement was studied, as was the amount of filler (two types of limestone filler were used). Also a comparison between self-compacting concrete and traditional concrete was made. Results are given for the water absorption by immersion and capillary suction and of the water permeability. These tests were carried out in water and in water containing 3.5 % NaCl. These results are compared with predictions obtained by literature models.

The main conclusion is that the self compacting concrete absorbs less water than traditional concrete.

1. INTRODUCTION

Reinforced concrete is the most commonly used construction material worldwide. In the absence of aggressive media such as chlorides and carbon dioxide, good quality concrete with sufficient cover is all that is needed for the structure to achieve its design life with little or no maintenance. Due to the presence of Ca(OH)_2 in the pores of the cement matrix, the pH has an average value of 12.4 [1]. Under these circumstances a thin oxide layer is formed around the reinforcement helping it to remain uncorroded. Reinforcement corrodes only if the protective layer deteriorates. This may happen either due to the fall of the pH value of the pore solution - if the pH value falls below 11 the protective layer starts cracking, and it deteriorates totally when the pH falls below the value 9 – or due to the great concentrations of chlorides around the steel reinforcement bar. Both phenomena – carbonation and chloride ingress-result in the corrosion of the reinforcement and the reduction of the designed service life of the structure.

High performance concrete mixtures significantly increase the corrosion initiation time. It was reported [2] that the corrosion initiation due to carbonation may be significantly extended when high quality concrete is used in combination with supplementary cementing materials. But even in this case, there finally comes a time at which the corrosion of steel initiates.

As it was reported that in many cases in severe environments even good quality concrete cannot provide sufficient protection, a number of additional corrosion protection systems are marketed to face the problem of corrosion in reinforced concrete. Corrosion inhibitors, coatings at the surface of reinforcing steel or at the surface of concrete, stainless steel and cathodic protection are some of the technologies developed. Among those corrosion protection systems the use of corrosion inhibitors as concrete admixtures is a very popular, easy and a relatively economical method. Calcium-nitrite (CNI)[3,4] and N,N'-dimethylaminoethanol is used as a corrosion-inhibitive admixture in concrete [5,6].

Although its action in inhibiting the corrosion due to chloride ingress is well investigated, there is limited research concerning its behavior against carbonation, especially when the inhibitor is added in blended cement mixtures. This is experimentally investigated in this paper. Mortar mixtures were prepared with portland and blended cements and were exposed to a curing room with 18-23 °C and 50-65% relative humidity and also in outdoor conditions. Carbonation depth and steel rebar loss versus time measurements were taken for a period up to three years for portland and blended mortar mixtures prepared with and without the addition (of inorganic and organic) corrosion inhibitors.

2. MATERIALS AND METHODS

The materials used were four types of cement (type I-35, I-45, blended cement II-35 and II-45). Chemical composition of those materials is presented in Table 1.

Table 1. Chemical composition of the materials used.

Oxide content (%)	Commercial cement I-35	Commercial Blended Cement II-35	Commercial Cement I-45	Commercial Blended Cement II-45
SiO ₂	20,67	22,36	19,64	25,3
Al ₂ O ₃	4,99	6,62	4,62	5,95
Fe ₂ O ₃	3,18	4,08	3,27	4,44
CaO	63,60	56,55	63,59	55,7
MgO	2,79	3,52	1,91	2,98
SO ₃	2,44	2,44	3,03	3,00
Na ₂ O	0,29	0,53	0,38	0,30
K ₂ O	0,37	0,72	0,62	0,57

Mortar mixtures were produced according to DIN 1164 [7] by using EN-196-1 [8] standard sand. The water/cementitious material ratio was equal to 0.45 for each mixture. The ratio cement/sand was equal to 1/3. Two types of corrosion inhibitors were used: One inorganic corrosion inhibitor (ICI) based on Ca(NO₂)₂ and one organic (OCI) based on N,N'-dimethylaminoethanol were added at a dosage of 20 l/m³ of concrete and 4% per weight of cement respectively.

Resistance against carbonation was measured on cylinder (40x100 mm) mortar specimens. Six specimens were produced for each mixture. A 10mm diameter steel rebar was embedded in the middle of four specimens of each mixture produced with class 35 cements. Those specimens were initially cured for 28 days in a curing room with relative humidity $\geq 95\%$ and temperature 20 ± 2 °C. After this period, they were placed in an outdoor locations in Athens (Zografou campus). Carbonation depth was measured at different ages up to three years in two specimens using a phenolphthalein spray indicator. Gravimetric weight loss was measured at the same ages according to the procedure described in [9].

Figure 1. Cylindrical specimens used for carbonation measurements

Using class 45 cements produced additional specimens. Those specimens were cured for three days in a curing room with relative humidity $\geq 95\%$ and temperature 20 ± 2 °C. After this, they were

placed in a carbonation chamber with relative humidity of $60\pm 5\%$, temperature of 20 ± 2 °C and CO_2 concentration of 10%. Carbonation measurements were performed after five weeks.

3. TEST RESULTS

Carbonation measurements performed in outdoor conditions at different ages up to three years, are presented for all mixtures in Figures 1, 2 and 3. From Figure 2 is obvious that specimens with blended cement II-35 have greater carbonation depth than the specimen with I-35 cement. In Figure 3 is shown the carbonation depth of specimens with cement I-35 with and without corrosion inhibitors. The specimens with corrosion inhibitors have smaller carbonation depth in comparison with the specimens without inhibitors. The same event is shown in Figure 4.

Figure 2. Carbonation depth of specimens with cement I-35 and II-35.

Figure 3. Carbonation depth of specimens with cement I-35 (with and without corrosion inhibitors).

Figure 4. Carbonation depth of specimens with cement II-35 (with and without corrosion inhibitors).

Figure 5. Rebars mass loss of specimens with cement I-35 and II-35.

Mass loss of specimens with I-35 and II-35 cement are shown in Figure 5. Difference of corrosion resistance between specimens with I-35 cement and II-35 cement is not shown in this experiment.

Figure 6. Rebars mass loss of specimens with cement I-35 (with and without corrosion inhibitors).

Figure 7. Rebars mass loss of specimens with cement II-35 (with and without corrosion inhibitors).

Mass loss of rebars specimens with and without corrosion inhibitors made with I-35 cement are shown in Figure 6. The presence of both corrosion inhibitors (ICI and OCI) decrease the mass loss of rebars about of 50%. The same phenomenon is observed in the specimens with cement II-35 (Figure 7).

Carbonation measurements performed on class 45 cement mortars placed in the carbonation chamber are presented in Figure 8. It is obvious that specimens with blended cement II-45 have greater carbonation depths than the specimen with I-45 cement. Also the specimens with corrosion inhibitors have smaller carbonation depths in comparison with the specimens without inhibitors.

Figure 8. Carbonation depth of specimens with class 45 cements (with and without corrosion inhibitors) after 5 weeks exposure in carbonation chamber.

4. DISCUSSION

Carbonation depth of blended cement mortars is in general greater than the one of Portland cement mortars. This phenomenon is also mentioned elsewhere [10-11]. Carbonation depth of II-35 cement mixtures is almost equal to the one of the control mixtures with cement I-35 at the age of one year, but it significantly increases at the age of two and three years. This is mainly attributed to the reduction of OH^- caused by the pozzolanic reaction.

Addition of an inorganic corrosion inhibitor (calcium nitrite) slightly decreased the carbonation depth of all mixtures at all times, as it is also reported elsewhere [10,12]. The influence of the inhibitor is very significant in the case of gravimetric weight loss (Figures 6, 7). Although this was quantitatively low in any case, addition of calcium nitrite reduced the weight loss up to 50% for all mixtures. By the presence of $\text{Ca}(\text{NO}_2)_2$ a stable passive layer could be formed on the reinforcement, avoiding all the metastable forms, according to the following reaction [10,12]:

The passive layer of $\gamma\text{-Fe}_2\text{O}_3$ decrease the formation of corrosion products. The rest of Ca^{2+} decrease the reduction of pH of all mortars containing corrosion inhibitors.

Addition of inorganic corrosion inhibitor also decreased the carbonation depth of all mixtures and reduced the gravimetric weight loss [Figures 6, 7]. The smaller carbonation depth observed in N,N'-dimethylaminoethanol specimens could be attributed to the lower water penetration of these mixtures. Further research is needed in order to obtain a clear explanation for this phenomenon. In all cases the addition of OCI, based on N,N'-dimethylaminoethanol, in fresh mortar has a protective effect. The effectiveness of this class of compounds has been shown by means of various experiments [5,6,13,14,15]. Earlier experiments have shown that aminoalcohol chemisorbs from aqueous solution onto oxidized steel surfaces [13].

The thickness and the composition of the absorbate phase, depend upon the composition and the concentration of the aminoalcohols solutions. The absorbate phase is formed, even if chlorides are present [13]. The corrosion inhibition effect is explained by the fact that aminoalcohol displaces,

due to its strong bonding, ionic species from the oxidized steel surface, in particular chlorides, and forms a durable passivating film [14,15].

5. CONCLUSIONS

Mixtures produced with blended cements exhibited greater carbonation depths compared with the control mixtures produced with Portland cements, irrespective of the class (35 or 45) of the cement used.

The addition of both corrosion inhibitors decreased the carbonation depth of all mixtures. However, their influence was stronger in reducing the gravimetric weight loss of steel rebars.

Both corrosion inhibitors offered significant protection against carbonation by reducing the carbonation depth and the gravimetric weight loss up to 50% for all mixtures. According to the results available so far, both inhibitors performed equally against carbonation at the dosages examined.

K. K. Sideris

Dr. of Engineering, Laboratory of Building Materials, Civil Engineering Department, Democritus University of Thrace, P.O. Box 252 Xanthi, 671 00 GREECE
20-5-1969 : Born in Athens, Greece

1992:	M.Sc. in Civil Engineering
1992 - 1994:	Military Service.
1992-1996:	Ph. D. candidate of Democritus University of Thrace
1997-1998:	Research assistant at the laboratory of building materials, Democritus University of Thrace
02/ 1998:	Lecturer at the lab. Of Building Materials, Democritus University of Thrace

PROFESSIONAL EXPERIENCE

I have worked in several construction offices in Athens as a consultant in terms of concrete technology and durability aspects. During my military service, I have worked in the construction of a military airport in Greece (buildings, motorways, shelters etc).

Since 1997 I am teaching several lessons at the civil engineering department in the areas of Building Materials, Concrete Technology and Concrete Durability

My research interests are in the area of cement hydration (emphasized in the hydration of blended cements), concrete technology and concrete durability.

Papers available on request.

DURABILITY OF CEMENT MORTARS IN SIMULATED SEWAGE ENVIRONMENT

ABSTRACT

The corrosion of concrete sewage by the action of sulphuric acid is a worldwide problem both for industrialised and underdeveloped countries. Today there are several ways to repair degraded concrete in the sewage area but often these methods are ineffective or too expensive. In order to make effective cement mortars to repair concrete in sewage, a study was carried out on 3 different renders and a polymer modified mortar. The products were tested using a biogenic simulation chamber and a sulphuric acid immersion test. A comparison between these two techniques was pointed out. The progression of acid attack was followed by X-ray diffraction, B.E.T. specific surface area measurements, EDS and optical microscopy.

1. INTRODUCTION

The degradation of concrete in sewerage is a problem currently studied by many researchers [1,2,3,4,5]. One of the main reasons of such degradation is the sulphuric acid produced by bacterial oxidation of hydrogen sulphide (aerobic oxidation), formed by the anaerobic fermentation of civil and industrial waste-waters. Sulphuric acid has a deleterious effect on concrete structure being the cause of softening and spalling of the hardened cement phases [3,6,7]. Today, in Europe, two are the most important accelerated tests used to evaluate the resistance of cement mortars to sewage conditions. One technique is based on loss mass measurements of samples stored for one year in a chamber where an accelerated bacterial attack is simulated [8]. The other method is based on a residual strength determination of samples immersed for 14 days in a sulphuric acid solution at pH=0 and 70 days at pH=1 [12].

In order to develop cement-based materials resistant to aggressive sewage environment, four different mortars were prepared and tested with the mentioned accelerated methods. A physical-chemical study was carried out by X-ray diffraction, B.E.T., EDS and optical microscopy on mortar specimens dipped in a sulphuric acid solution (pH=0) to clarify the mechanism of acid attack.

2. EXPERIMENTAL

2.1 Specimens Preparation

The mortar composition is reported in Table 1. The components were mixed according to ENV 196/1. The physical-mechanical properties of fresh mortars are reported in Table 2. On the same Table the neutralisation capacity [11] is shown.

Specimens of different sizes (according to the test method) were kept for 24 hours at 20°C and 95% R.H. Therefore the samples were demoulded and cured at 20°C and 95% R.H. for 28 days.

Table 1. Mortar composition

Components	A	B	C	D	Characteristics
Cem.I 42,5 R (according ENV 196/1)	25	-	3	35	CaO=63,8 Al ₂ O ₃ =4,6 SO ₃ =4,0 Fe ₂ O ₃ =1,9 MgO=2,2
CEM III/C (according ENV 196/1)	-	32	-	-	Al ₂ O ₃ =17,0 MgO=11,0 CaO=40,0 SiO ₂ =32
High alumina cement	-	-	27	-	Al ₂ O ₃ =40,0 Fe ₂ O ₃ =16,2 CaO=39,4
Superplasticizer	0,1	0,1	0,1	0,1	Naphthalene based superplasticizers
Normalised sand (according ENV 196/1)	74,9	67,9	64,9	64,9	Silica sand
Water (perceptual on the solid part)	12	15,5	15	-	-
Acrylic latex	-	-	-	19,5	Dry content = 14%

Table 2. Chemical physical properties

Sample	A	B	C	D
Specific gravity (kg/m ³)	2246	2140	2170	2150
Flow test (%-UNI 7044)	57	87	74	70
Compressive strength (MPa- 28 days)	69	30	90	58
Calculated Neutralization Capacity	4,1	5,5	7,6	5,4

2.2 Chemical Sulphuric Acid Corrosion Test

Mortar specimens (40x40x160mm), after demoulding, were cut in two 40x40x80mm parts and cured. At the end of curing period the mortars were divided in three groups. A group was kept in water for 14 days. Another set of samples was dipped in a 1M solution of sulphuric acid (pH=0-10l) for 14 days. The remaining specimens were immersed in a 0,1 M sulphuric acid solution (pH=1-10l). The pH of the solution was computer controlled and kept constant by means of an electrode system interfaced with dosing pumps. When the pH exceeded the threshold value of 0,1 pH unit, the computer started the pumps that added automatically a 5M sulphuric acid solution to establish the initial pH conditions. The mixing of the solution was assured by means of an air pump; the mixing speed was set to avoid a mechanical abrasion of the samples.

The specimens, after acid treatment, were washed. Then their volume and mass change were determined. The reference specimens and the degraded ones were cut into 40mmx40mmx40mm cubes in order to obtain a regular shape. Their compressive strength was measured.

2.3 Biogenic Sulphuric Acid Corrosion

Mortar samples (30mmx30mmx30mm) were prepared as reported previously. At the end of curing period the mortars were subjected to biogenic acid corrosion. The test was performed at the University of Hamburg (Germany). The experimental details are deeply explained elsewhere [8,9]. The mass loss was detected after 2, 4, 6, 8, 10 and 12 months of bacteriological attack.

2.4. Chemical-Morphological Study

Cylindrical specimens (30mmx30mmx30mm) were subjected to chemical sulphuric acid test to analyse the mechanism of mortar degradation, cylindrical specimens (30mmx30mmx30mm) were subjected to chemical sulphuric acid test.

Specific surface area determination by B.E.T. method was carried out before and after acid attack. Sulphuric acid penetration was studied by a selective precipitation of lead sulphate on polished sections of degraded samples. Such salt was subsequently coloured by sodium rodizonate (0,2% water solution). The procedure is summarised below:

- The surface of degraded specimens was treated with a concentrated water solution of lead nitrate

Lead Sulphate is white and cannot be easily detected;

- This compound was coloured by the addition of a water solution of sodium rodizonate

Lead Rodizonate is a red complex which is clearly evident on the material surface.

A SEM (Scanning Electron Microscopy) analysis was also performed on the samples before and after acid corrosion.

Furthermore EDS line scan for SK α , CaK α , SiK α , was carried out on polished sections of the specimens after acid degradation. The study was focused on the border line between the unaltered region and the degraded one.

A set of samples (30mmx30mmx30mm), prepared according to the composition in Table 1 without the use of sand, were analysed by XRD analysis (Philips PW 1830 with Cu K α radiation) before and after acid treatment.

RESULTS

3.1 Durability Test

Mass and compressive strength changes after acid attack are reported in Table 3.

Table 3. Sulphuric acid immersion test

pH=0				
Sample	A	B	C	D
Mass loss %	40	5	10	45
Residual strength (%)	56	77	82	53
Compressive strength MPa (acid/water)	41 / 73	24,6 / 32	76 / 93	32,3 / 61
pH=1				
Sample	A	B	C	D
Mass Increase %	1	5	4	6
Residual strength (%)	69	70	67	68
Compressive strength MPa (acid/water)	56 / 81	25,2 / 36	73 / 109	47,6 / 70

The strength loss is given by a parameter called “Residual resistance” calculated using the following formula:

$$R_r = (R_a \times 100) / R_b \quad (1)$$

Where

R_a = Compressive strength of the specimen after acid attack (average on four specimens);

R_b = Compressive strength of the reference specimen (average on four specimens).

Mass loss was calculated according to the formula:

$$\text{Mass loss} = [(M_f - M_o) / M_f] 100 \quad (2)$$

Where

M_f = Mass before acid attack

M_o = Mass after acid attack

At pH=0, the data reported in Table 3 showed the following order of acid resistance:

High alumina cement mortar > Slag cement mortar > Ordinary Portland cement mortar \approx Polymer modified mortar.

Although these results are in agreement with a large part of published literature [8,10], Fourie [4,5] using hydrochloric acid, showed the higher resistance of a Portland cement system respect to slag and calcium aluminate cement based concretes.

At pH=1, we found a very similar resistance of mortar specimens.

Mass losses of the samples subjected to bacteriological attack are shown in Table 4. Such parameter was calculated as reported for acid immersion test. The order of resistance was:

Slag cement mortar > Polymer modified mortar > High alumina cement mortar > Portland cement mortar.

Table 4. Mass reduction in biogenic chamber

Incubation (week)	A (%)	B (%)	C(%)	D(%)
8	1,4	0	0	0
16	12,2	1,2	4	0,4
24	17,6	3,3	8,5	12,1
32	27,4	3,9	16,6	12,1
40	66,2	3,9	28,8	12,9
48	70,3	6,5	28,9	13,5

3.2 Morphological analysis

The specific surface area measurements are shown in Table 5. A substantial surface area increase was observed due to acid corrosion. Only SEM micrographs of specimens A and C were enclosed in the paper (Figures 2, 3, 4 and 5). In Figure 2 (undamaged part of sample A) a strongly carbonated and compact microstructure appears. Fibrillar C-S-H is not visible. In Figure 3 (corroded part of specimen A) the microstructure is completely changed. It is characterised by many cracks and a lower density. SEM micrographs of specimen C are shown in Figures 4 and 5. Crystals of hydrated calcium aluminates appear. In this case the microstructure was not strongly affected by acid aggression.

Table 5. Specific surface area before and after acid attack

Sample	Before (m^2/g)	After (m^2/g)
A	6,8	14,9
B	11,2	21,1
C	5,9	10,3
D	8,1	10,2

Acid penetration was emphasised by rodizonic acid test. Polished sections of mortar samples before and after acid degradation are presented in Figure 1.

Figure 1. Sodium Rodizonate Test (from the left: A; D; B; C)

Figure 2. Undamaged part of sample A

Figure 3. Degraded part of sample A

Figure 4. Undamaged part of sample C

Figure 5. Degraded part of sample C

3.3 XRD Analysis

The diffraction patterns (E=Ettringite; P=Portlandite; G=Gypsum) are reported in Figures 6,7,8 and 9. Sample A is characterised by a large gypsum formation. Crystals of ettringite are also present. A sensible portlandite reduction occurs.

Acid treatment on slag based cement paste (B) causes gypsum precipitation. Portlandite is not evident.

Gypsum is again the main reaction product in the case of specimen C. A small amount of crystalline ettringite appears.

Figure 6. Specimen A before and after acid attack

Figure 7. Specimen B before and after acid attack

XRD pattern in Figure 8 (sample D) is characterised by a large gypsum formation and portlandite reduction.

Figure 8. Specimen C before and after acid attack

Figure 9. Specimen D before and after acid attack

From these results a substantial gypsum formation is evident in all the specimens. Ettringite is also formed in the case of samples A and C. Portlandite reduction was noted in Portland cement pastes.

3.4 EDS Analysis

From EDS analysis (Figure 10) the following chemical relationship were found toward the undamaged part of the sample:

- 1) Ca/S ratio increase;
- 2) Ca/Si ratio increase.

A similar trend was found on the other mortars. Therefore a single corrosion mechanism could be expected.

Figure 10. EDS Line Scan of Specimen B

3. DISCUSSION

4.1 Durability

The test conditions certainly affect final results. In fact calcium aluminate cement (CAC) mortar was the most resistant in sulphuric acid immersion test at pH 0 and slag mortar showed the highest resistance in bacteriological simulation chamber. Surprisingly at pH=1 all the mortars were corroded in a similar manner. Furthermore Fourie *et al.* [4,5], using hydrochloric acid and dolomite aggregates, outlined that high alumina cement was somewhat less resistant than Portland cement based mixtures. Such results are in contrast with our findings. Several reasons could explain these differences. In the cases studied by Fourie, the reaction between acid and binder is complicated by the high reactivity of dolomite in acidic environment respect to silica type aggregates. Choosing silica sand, we focalised our analysis only on the chemistry of reaction between binder and acid. The higher resistance of Portland cement could be connected to the stronger interfacial bond between hydrated calcium silicates and carbonate based aggregates [13]. Such hypothesis is confirmed by Fourie that observed a very high acid resistance of CAC/Alag mixture - aggregate with similar composition to alumina cement. In fact Alag type aggregates are not attacked by acid and they are able to bond strongly hydrated calcium aluminates [9]. Moreover the reaction product of hydrochloric acid aggression on hardened cement phase is mainly Calcium Chloride which is more soluble than gypsum (that is formed during sulphuric acid attack). Therefore different corrosion kinetics should be expected.

So acid type, pH and experimental procedure strongly influences acid resistance results.

In contrast with previous statements [8], neutralisation capacity alone cannot explain the different performances of mortars subjected to bacteriological and chemical aggression. The volume of acid added to keep the pH constant was very low and no significant differences were noted among the specimens. The kinetics of acid attack is presented in Figure 1. Sulphuric acid penetration in the alumina cement based mortar is very small. On the contrary in the case of slag mortar, it is much deeper. However acid aggression does not cause deleterious damages on these systems. Destructive

effect of acid is more evident for specimens A and D (Portland cement based renders) due to a larger mass reduction.

4.2 Chemical Morphological considerations and mechanism

XRD patterns pointed out that the main reaction product formed during acid degradation is gypsum. A significant specific surface area increase was also noted. Morphology variation is likely connected to gypsum precipitation and C-S-H alteration. Acid corrosion was further emphasised by SEM micrographs. Considering the small amount of ettringite detected during acid corrosion, we suppose that gypsum precipitation is the first cause of mortar degradation.

The involved reaction is:

Calcium hydroxide is provided by: 1)Initial cement hydration; 2)Dissolution of hydrated calcium silicates (Portland cement based mortar) or hydrated calcium aluminates (alumina based mortar).

At pH=0, that is a short time critical condition, the degradation process is governed by kinetics. The experimental results showed higher resistance of mortars with lower amount of portlandite. Therefore at pH=0, portlandite neutralisation is a reaction kinetically faster than the decomposition of hydrated cement phases. At pH=1, for longer immersion time, the degradation process is governed by thermodynamics and all hydrated phase are involved in the reaction (portlandite, hydrated calcium aluminates and hydrated calcium silicates). Afterwards substantial differences among mortars cannot be observed. Previous papers pointed out an increase of sulphuric acid resistance with water cement ratio [3,6]. The rise of water/cement ratio, which is connected to an increase of capillary pores, could balance the mechanical stress arising by gypsum crystallisation. Therefore concrete degradation due to acid attack could be very similar to damaging action of freeze-thaw cycles. The expansion, caused by gypsum crystallisation, could be the main reason of mortar failure.

4. CONCLUSION

The experimental work showed a larger selectivity of sulphuric acid immersion test at pH=0. Mortars resisting such test conditions also gave good results to bacteriological aggression. However, the bacteriological chamber is more similar to reality. Thus, the sulphuric acid immersion test could be a useful and fast experimental procedure to screen mortars before biogenic simulation chamber and field tests.

A mechanism of sulphuric acid degradation at pH=0 was supposed:

- 1) Acid reacts with portlandite to give gypsum;
- 2) Expansive gypsum formation causes internal stress determining mortar failure.

EFFECTS OF PREHYDRATION ON FINENESS CHARACTERIZATION OF GRANULATED BLASTFURNACE SLAG

B. Osbaeck

F.L.Smidt A/S, R&D, Laboratory, Copenhagen, Denmark. E-mail: bjarne.osbaeck@flsmidth.com

ABSTRACT

Like Portland cement clinker, granulated blastfurnace slag to be used as a cementitious material in mortar and concrete is ground to a certain fineness to achieve the reaction potential that is necessary for the desired strength development. Fineness characterisation based on measurement of the specific surface by air permeability is still the most widely used method in the cement and slag grinding industry. During the grinding process minor prehydration of the ground powder can take place even for granulated blastfurnace slag. This small prehydration can influence the results of the fineness measurement and can, when not taken into account, lead to erroneous conclusions e.g. in connection with grinding tests, mill comparisons and materials comparisons. The paper illustrates the character and magnitude of the effects based on analysis of data from a mill comparison test and from laboratory tests.

1. INTRODUCTION

The quality of cements and other cementitious products is judged primarily from their strength development potential as a binder in mortar or concrete. The strength producing potential is a matter of the inherent reactivity of the material(s) used as a basis for production of the cement or cementitious material, and the fineness to which it is ground in the finish grinding mill. Thus in industrial grinding of cements or cementitious materials one or more fineness parameters are used as control figures and indicators for expected strength performance. Also in evaluation of the grindability of different materials a fineness parameter is used to quantify the degree of fineness achieved by the grinding effort and thus becomes a key figure for evaluation.

In the cement industry a specific surface measured by the air permeability method is the most widely used fineness parameter. It is commonly performed according to the method developed by Blaine [1], but a similar method proposed by Lea and Parker [2] is used in some countries. They give similar results. Both methods are fairly simple and quick and give a figure correlated to the specific area and which – most importantly - usually gives a good correlation to the reactivity and strength development potential of the ground product.

However, when comparing e.g. products from different grinding installations one should be careful as the simple correlation to strength does not always hold. This is usually due to differences in particle size distribution of the final products but also other factors such as prehydration during grinding may influence the result. Due to its high reactivity towards water Portland cement is very susceptible to prehydration. But we have experienced that even a material such as granulated blastfurnace slag, though only characterized as latent hydraulic, can be prehydrated to a certain degree during storage and grinding. Furthermore this prehydration, even when very limited in magnitude, can have an influence on the results of fineness measurements and particularly on

measurements of the specific area according to the air permeability method. Evidence of this feature is given in the following case study and from laboratory experiments.

2. COMPARISON OF SLAGS GROUND IN DIFFERENT MILLS

From a production of ground slag where different mills were in use for grinding of the product it was found out that using the same basic slag source one had to grind the slag to a substantially higher specific surface area as measured by air permeability in one mill than in another to achieve the same strength contribution figures of the final products.

To find the reason arrangements were made for comparative grindings using exactly the same slag source (Chemical characteristics in Table 1) .

Table 1. Chemical analyses (%), Modules and Glass content (%) of the slag.

CaO	SiO ₂	Al ₂ O ₃	MgO	Fe ₂ O ₃	Mn ₂ O ₃	TiO ₂	K ₂ O	Na ₂ O	S-total
39.6	35.4	13.2	8.5	0.57	0.60	0.50	0.35	0.26	0.73

CaO / SiO ₂	(CaO + MgO) / SiO ₂	(CaO+MgO+Al ₂ O ₃)/SiO ₂	% Glass (BS 6699)
1.12	1.36	1.73	97

In addition to the two industrial mills in question (referred to in the following as “Mill A” and “Mill B”) tests were also performed in a pilot scale mill (“Mill C”) of the same type as Mill B. From experience it was found that the slag meals from Mill B had to be ground to a Blaine fineness 70-80 m²/kg higher than those of Mill A to achieve the same strength figures in mixes with Portland cement. This difference was also used in the comparative test series. The products from Mill 3 were produced in the same Blaine range as those from Mill B.

Besides using the Blaine method the products were also characterized for fineness using laser diffraction spectrometry (LDS) to get a description of the particle size distribution (PSD). Supplementary fineness characterizations using air jet sieving and air elutriation were also applied.

The laser diffraction spectrometry were performed on Sympatec Helos equipment using wet dispersion in ethanol. The following key data were used from the particle size distribution measurement: the median size (d-50), the n- value according to the Rosin-Rammler-Sperling-Bennett (RRSB) distribution (n) and the calculated specific surface (SSA).

The air jet sieving was performed on an Alpine air jet sieving unit. The 32 µm and 45 µm residues were measured. The air elutriation was performed on an F.L.Smith Flourmeter adjusted to separate at 10µm. The fine fraction thus achieved is designated AEF-10µm (AEF = Air Elutriation Fines). Key fineness results from the applied methods are found in Table 2.

Table 2. Fineness and LOI data on the ground slag samples

Mill	Sample	Blaine (m ² /kg)	SSA (LDS) (m ² /kg)	d50 (LDS) (µm)	n (LDS)	R 32µm (%)	AEF-10µm (%)	W 200 (%)	W 750 (%)
A	1	470	488	9.5	1.07	4.10	62.9	0.06	0.22
A	2	495	529	8.4	1.05	4.10	67.1	0.05	0.22

B	1	531	557	8.1	1.00	6.50	57.9	0.16	0.33
B	2	573	620	7.1	1.00	3.60	63.4	0.18	0.36
C	1	573	570	7.8	1.02	4.30	60.3	0.32	0.61
C	2	565	547	8.1	1.04	5.10	60.2	0.25	0.52
C	3	529	544	8.3	1.03	4.60	59.4	0.14	0.31

Knowing that particularly the Blaine measurement can be sensitive to prehydration of a cementitious material the state of prehydration had to be quantified. As basis for that a thermogravimetric analysis (TGA) of the samples was performed using a Stanton Redcroft thermobalance. The loss on heating up to 750°C in a nitrogen atmosphere (20°C per min.) was recorded. The results for the 8 samples are shown in Figure 1.

Figure 1. Thermogravimetric analysis of the ground slag samples (Cf. Table 1)

The loss occurs continuously over the temperature range, however, with a more pronounced increase up to 200°C. As key parameters the following are used: the cumulative weight loss up to 200°C (W 200) and 750°C (W 750). The values are found in Table 2.

Judged from these measurements it can be seen that the sequence of prehydration levels is as follows: Mill C > Mill B > Mill A. Sample 3 from mill C has lower loss values than the other two samples from that mill and is on the same levels as those from Mill B.

Comparison of the fineness results obtained by different method reveals some interesting features.

Figure 2. Specific surface (Blaine) versus median particle size (LDS)

Figure 2 shows the measured specific surface by the Blaine method plotted against the median particle size determined by laser diffraction. Both methods show Mill B and C products as being finer than Mill A products but there is a clear indication that at the same fineness level quantified by the d-50 value the Blaine value will follow the sequence Mill C > Mill B > Mill A, i.e. the same

sequence as for the prehydration level. Even the sample 3 from Mill C falls similarly as the Mill B samples just as for the prehydration values.

Since the spread of the PSD as indicated by the RRSB-n-values is not completely identical for the different mill products, differences in the Blaine values could be influenced by this factor. However, if we use a specific surface calculated from the whole PSD (SSA (LDS)) instead of the median particle size (d-50) we still see the same pattern (Cf. Figure 3).

Figure 3. Specific surface (Blaine) versus specific surface (SSA) calculated from the PSD.

If we use the air elutriation fines (AEF-10 μ m) as fineness parameter we see a different situation (Cf. Figure 4).

Figure 4. Specific surface (Blaine) versus air elutriation fines below 10 μ m (AEF-10 μ m).

Judged from *this* fineness parameter the samples from Mill B and C are not generally finer than those from Mill A, and the Blaine sequence at equal AEF-10 μ m is similar but more accentuated than in the other comparisons.

From the comparisons above there seems to be a clear indication of the phenomenon that prehydration of slag the powder gives rise to an increased specific surface as measured by the air permeability method (Blaine method).

For quantification of the indicated effect regression analyses have been made on the present data expressing the measured Blaine value as a function of an alternative fineness parameter and the weight losses as measured by TGA. Regression models based on 200°C losses (W 200) are found in Table 3 and those on 750°C losses (W 750) in Table 4.

Table 3. Regression models. Blaine as a function of an alternative fineness parameter and 200°C loss.

Regres.	Model	r
(1.1)	Blaine = $-29.9 * d_{50} + 232 * W_{200} + 740$ (3.6) (35)	0.993
(1.2)	Blaine = $0.60 * SSA(LDS) + 264 * W_{200} + 157$ (0.13) (58)	0.980
(1.3)	Blaine = $3.8 * AEF_{10} + 466 * W_{200} + 740$ (2.8) (86)	0.924

Table 4. Regression models. Blaine as a function of alternative fineness parameter and 750°C loss.

Regres.	Model	r
(2.1)	Blaine = $-32.1 * d_{50} + 141 * W_{750} + 745$ (4.0) (35)	0.991
(2.2)	Blaine = $0.66 * SSA(LDS) + 164 * W_{750} + 106$ (0.11) (32)	0.984
(2.3)	Blaine = $2.6 * AEF_{10} + 286 * W_{750} + 267$ (3.5) (70)	0.876

The regressions turn out with high multiple correlation coefficients (r) and the individual regression coefficients (apart from those of AEF-10) are highly statistically significant (cf. the standard errors in the parenthesis below the regression coefficients).

There is a fairly large difference in magnitude between the specific effects of prehydration based on models with LDS parameters (d_{50} and SSA) as alternative fineness parameters and those obtained with AEF-10 as fineness parameter. This could be due to experimental errors or other non-recognized reasons, but it could also be a result of an effect of prehydration even on the LDS results.

Regression models expressing the selected *LDS fineness parameters* as a function of AEF-10 and the selected TGA losses turn out as shown in Table 5.

Table 5. Regression models. LDS parameters as a function of AEF-10 μ m and TGA losses.

Regres.	Model	r
(3.1)	$d_{50}(LDS) = -0.14 * AEF_{10} - 7.9 * W_{200} + 18.1$ (0.08) (2.9)	0.816
(3.2)	$d_{50}(LDS) = -0.12 * AEF_{10} - 4.7 * W_{750} + 17.1$ (0.10) (2.0)	0.746
(4.1)	$SSA(LDS) = 4.2 * AEF_{10} + 321 * W_{200} + 328$ (4.5) (138)	0.726
(4.2)	$SSA(LDS) = 3.2 * AEF_{10} + 181 * W_{750} + 282$ (4.9) (100)	0.636

Though the correlations are not impressive the regression coefficients for the loss values (W-values) are still generally statistically significant. This is an indication of a possible effect; however, a causal correlation still has to be demonstrated.

3. TESTING EFFECTS OF PREHYDRATION ON FINENESS RESULTS.

In order to verify the indicated effects of prehydration on Blaine fineness and possibly other fineness parameters, laboratory tests have been initiated with the aim of forcing a prehydration on slag powder and measuring the effect on fineness parameters. The first experiments performed have been based on simple treatments of a slag powder of low initial prehydration ($W_{200}=0.14\%$; $W_{750}=0.30\%$) ground in a laboratory ball mill to a Blaine fineness of $480 \text{ m}^2/\text{kg}$.

One type of treatment was to expose a bed of slag powder to air at 100%RH for a short period of time. This did not give any significant prehydration of the slag meal. However, direct mixing with water at room temperature and at 100°C followed by drying did. At present only preliminary results are available but they do indicate an effect on Blaine to support the findings of the mill products comparison presented above.

Figures 5 and 6 show the measured Blaine values as a function of weight losses up to 200°C (W_{200}) and 750°C (W_{750}). A marked effect is indicated on the Blaine as results of the prehydration, although these experiments show a higher prehydration level than measured in the mill comparison case.

Figure 5. Specific surface (Blaine) versus TGA weight loss (25-200°C) on a ground slag sample submitted to different kinds of forced prehydration

Figure 6. Specific surface (Blaine) versus TGA weight loss (25-750 °C) on a ground slag sample submitted to different kinds of forced prehydration

Estimates of the specific effects of prehydration on Blaine using the data above give the following approximate figures: + 160 m^2/kg per percent. W_{200} and +70 m^2/kg per percent. W_{750} . If one takes the four data at highest W-level only the figures are: +190 m^2/kg per percent. W_{200} and

+120 m²/kg per percent. W750, i.e. values approaching those estimated from the mill comparison data. Characterization of fineness by laser diffraction was also performed but no conclusive results were obtained.

4. DISCUSSION

The background for prehydration of slag is that a major part of slag used for cement and concrete has been granulated (rapidly cooled) by water and thus delivered and stored with a moisture content of typically up to 15%. During the storage of this product a certain amount of prehydration will take place. When grinding the slag it can be dried in a special drier before grinding. This is normally done in connection with grinding in a ball mill. When a vertical roller mill is used the drying is usually performed in the mill itself i.e. in combination with the grinding. Thus there will be a difference in the character of contact with water and water vapour dependent on the grinding procedure and equipment used and this can give rise to differences in the prehydration level of the ground products even if the raw slag used is the same. In the example above the A samples are from a ball mill using predried slag whereas the B and C samples are from vertical roller mills with combined drying and grinding.

Returning to the results of the present investigation it may seem surprising that a minute prehydration of a material should have such a marked effect on the measured Blaine fineness as indicated in the present study. But considering that the Blaine surface is measured by the resistance to an air flow through a packed bed of powder it could be argued, that a formation of hydrates on the surface of the particles could increase the resistance to the air flow and thus the resulting Blaine value. For ground slag particles where the surfaces in general are much smoother than those of ground Portland cement clinker particles due to the glassy character of the slag, the effect of such hydrate formations on the surface could be more pronounced.

To pursue the matter the samples from the mill product comparison have been investigated by scanning electron microscopy. This investigation revealed that distinct formations of hydrates were present on the surfaces of all samples even on the samples of lowest prehydration.

Figure 7 shows the surface of a particle from sample A-2 viewed under large magnification. Formations of hydrates on the otherwise smoothly looking surface are clearly visible.

Figure 7. Scanning electron micrograph of surface of slag particle (Sample A-2) .
(1 μ m bar indicated on the graph)

Particles from the B and C-series with a higher prehydration level in general had less clean surfaces and the hydrates formed on the surfaces seemed to be larger (Cf. Figure 8). On both micrographs small slag particles adhering to the surface are also visible but in general easy to distinguish from the tabular or rod-like hydrate formations.

The hydrate formations might also be able to influence the PSD measurements by laser diffraction since this technique is based on deflection of light by particles, but this has to be studied further.

The influence on the Blaine measurement results also deserves further investigations, but it is the opinion of the author that the data presented in this paper do indicate an influence of even small levels of prehydration.

Figure 8. Scanning electron micrograph of surface of slag particle (Sample C-3) .
(1 μm bar indicated on the graph)

The magnitude of the effect is probably variable dependent on how the prehydration has taken place, so the quantifications attempted in the present investigation should only be considered as indicative of the order of magnitude that can prevail.

A standard measurement of loss-on-ignition on slag will not always be sufficient to reveal the state of prehydration of a slag powder since the measurement is disturbed by oxidations of constituents in a reduced state of oxidation. But a thermogravimetical analysis performed in nitrogen seems to be a useful technique to reveal even small levels of prehydration.

The present paper has concentrated on the issue of the influence of prehydration of slag on the results of different fineness characterization methods. Another question is how prehydration may influence the reactivity of the slag when used a cementitious constituent. Investigations on this matter are taking place as well in our laboratory.

5. CONCLUSIONS

Prehydration of slag powder occurring during grinding seems to be able to give rise to increased values of the specific surface measured by the air permeability method (Blaine) even at small levels of prehydration. This is important to remember when comparing the performance of different mills and different materials, and when evaluating product performance with reference to fineness.

Indications were found to a possible effect of prehydration on the particle size distribution measured by laser diffraction spectrometry as well, but this needs further investigation.

The state of prehydration of slag, even at small levels of prehydration, can be measured by thermogravimetric analysis in nitrogen atmosphere.

ABSTRACT

An Integrated Particle Kinetics Model (IPKM) has been developed to simulate the evolution of cement microstructure during hydration. This model is not discretized (based on pixels), so that features can be represented over several orders of magnitude of length. The capillary pore space is characterized by an analytical transformation into a network of cylindrical tubes, which allows a wide range of pore sizes to be described without resolution limits. The water permeability of the obtained network is then calculated by applying Darcy and Poiseuille laws.

1. INTRODUCTION

Empirical knowledge and experimental data on cement-based materials are well developed; nevertheless some phenomena are not well understood. Simulation in the field of cement-based materials can bring a better understanding and help to link microstructure with properties.

Based on a continuum approach, we have implemented an Integrated Particle Kinetics Model, (IPKM) for three-dimensional simulation of the evolution of tricalcium silicate (C_3S) microstructure during hydration [1,2,3]. This model considers spherical cement grains and hydrates. The model is vectorial because all the solid phases are described by a position and a radius. The hydration rate of each grain is controlled by three mechanisms in competition and depends on time, the radius of the anhydrous core and the thickness of hydrates.

In this paper the following aspects are presented: the microstructure formation, the hydration kinetics, the characterization of the pore space and the permeability calculations. Some numerical examples of pore size distributions and permeabilities are discussed. A general discussion of the model and perspectives are presented in conclusion.

2. MICROSTRUCTURE FORMATION

At the present stage of development the phase C_3S is considered because it is the main component of Portland cement and its hydration has been extensively studied. The particle-size distribution is similar to that of commercial cements in the range 1–60 μm . (At present limitations of computing power on the number of particles mean that particles below 1 μm in size are not considered.). The particles are placed at random in the computational volume at the desired water to cement ratio down to $w/c = 0.4$.

Two hydration products are formed, calcium silicate hydrate (C-S-H) and calcium hydroxide (CH). The relative reaction volumes are shown in equation (1).

The C-S-H grows on C_3S grains and the CH in the pore space. The C-S-H composition is considered constant during hydration and the “inner C-S-H” the same as the “outer C-S-H”. A schematic representation of the different solid phases is shown in Figure 1.

Figure 1. Schematic representation of the solid phases. r is the original anhydrous grain radius, r_{in} the radius of the remaining anhydrous core, r_{out} the radius of the C-S-H and $r_{out} - r_{in}$ the thickness of C-S-H.

The number of CH grains is a function of time and the number of C_3S grains (equation (2)).

$$n(t) = n_{\max} (1 - \exp^{-at}) \quad (2)$$

where: $n(t)$ is the number of CH grains at time t , n_{\max} is its maximum ($t=\infty$), a is a constant calculated from experimental data.

There is a random precipitation of small quantities of CH on the existing CH grains until the necessary amount given by the equation (1) is reached.

3. HYDRATION KINETICS

In this simulation the evolution of hydration is controlled by three different mechanisms, nucleation and growth, phase-boundary reaction and diffusion. The corresponding kinetics are described by equations (3)-(5), proposed in [4].

Nucleation and growth of products :

$$(-\ln(1 - \alpha))^{1/3} = K_1 t \quad (3)$$

Phase-boundary reaction :

$$1 - (1 - \alpha)^{1/3} = \frac{K_2 t}{R_0} \quad (4)$$

Diffusion :

$$1 - (1 - \alpha)^{1/3} = \frac{\sqrt{K_3 t}}{R_0} \quad (5)$$

where α is the degree of hydration of the considered particle, R_0 its original radius, t the hydration time and K_1 , K_2 and K_3 are parameters calculated through cement heat generation curves.

For spherical particles, the equations (3)-(5) can be re-formulated by replacing the degree of hydration by the rate of advancement of the reaction front dr_{in}/dt (equations. (6)-(8)).

$$dr_{in}(t) = -K_1^3 R_0 t^2 \text{Exp}(-K_1^3 t^3 / 3) dt \quad (6)$$

$$dr_{in}(t) = -K_2 dt \quad (7)$$

$$dr_{in}(t) = \frac{-\sqrt{K_3}}{2\sqrt{t}} dt \quad (8)$$

Since the third mechanism represented by equation (8) does not consider the thickness of the diffusion layer explicitly, we have replaced it by equation (9).

$$dr_{in}(t) = -\frac{K_3 dt}{r_{out} - r_{in}} \quad (9)$$

The rate of reaction (hydration) of each grain depends on the time, the original radius of the anhydrous core and the thickness of C-S-H. The passage from one kinetic regime to another occurs when two hydration rates become equal. Depending on original grain size, hydration may progress through the three mechanisms or only through the first and the third ones. A schematic representation of the three hydration kinetics for a single particle is shown in Figure 2. In this example the hydration of the considered grain is controlled by three mechanisms and the passage from the first mechanism to second one occurs in point A and from the second one to the third one in point B.

Figure 2. Schematic representation of the variation of three kinetic curves 1, 2, 3 with passage points from one mechanism to another one (points A and B).

After interparticle contacts take place, due to the increase of grain sizes, the hydration rate is diminished to take into account the effect of the diminution of the available space for the deposition of the C-S-H and the decrease of the overall amount of water to continue the hydration reaction (equation (10)).

$$(dr_{in}^i(t))' = dr_{in}^i(t) \times \left(\frac{\text{surface free}}{\text{surface total}} \right)^i \times \left(1 - \frac{\alpha v}{\rho w_0 + \alpha} \right) \quad (10)$$

v is the ratio between the products volumes (C-S-H + CH) and the reactant volume (C_3S), ρ is the density of cement and w_0 the water-to-cement ratio.

4. CHARACTERIZATION OF PORE SPACE

To characterize the pore space, a pore center is defined as a local maximum of the distance to the grains and a neck center (boundary between two pores) is defined as a local minimum of this distance. The pore centers are calculated analytically from algorithms developed in the field of molecular biology [5]. Extension of these algorithms, pore centers are defined as the center of a tangent sphere to four grains that can be placed without overlapping other grains. The pore network is represented by tubes linking adjacent pore centers and has a radius depending on the neck.

In Figure 3, a 2D illustration of two pore centers and one cylinder is presented. At each step of hydration the program controls the existence of pore centers and necks throughout the pore system and constructs the network of cylindrical tubes.

Figure 3. 2D schematic representation of two pores and one cylinder. The black circles represent cement particles.

The effective radius of a cylinder is the hydraulic radius of the neck; this value is defined by the equation (11).

$$R = \frac{2 * \text{area}}{\text{perimeter}} \quad (11)$$

This radius is equivalent to that of a circle the neck is circular.

5. PERMEABILITY CALCULATIONS

According to the Hagen-Poiseuille law, the flux q in a cylindrical tube of hydraulic conductivity g is given by equation (12):

$$q = \frac{g}{\mu} \Delta p \quad (12)$$

where: μ is the viscosity of fluid and Δp is the pressure difference between the two tube extremities.

The hydraulic conductivity is defined by equation (13) and the flux may be written by equation (14):

$$g = \frac{\pi r^4}{8l} \quad (13)$$

$$q = \frac{\pi r^4}{8l} \frac{\Delta p}{\mu} \quad (14)$$

To calculate the permeability, the principle of mass conservation is applied to each node i (tube extremity) of the network by equalizing the fluid flows that may enter or leave through the tubes connecting neighboring nodes j to the node i . By applying a Gauss-Seidel iterative method with

over-relaxation (equation (15)) all the nodal pressures are calculated. The flux direction can be chosen in one of the three directions.

$$p_i = \beta \frac{\sum_j g_{ij} p_j}{\sum_j g_{ij}} + (1 - \beta) p_i \quad (15)$$

p_i is the pressure at the node i and g_{ij} is the conductivity of the tube connecting nodes i and j , β is the over-relaxation parameter.

The over-relaxation considers the previous value to calculate the new one, β is between 1 and 2 and its optimal value, which permits the final solution to be found most rapidly, depends on the geometry.

At a given surface, by summing the fluids entering or leaving the surfaces exposed to the macroscopic pressure gradient ΔP and applying Darcy's law given by the equation (16), the permeability coefficient K can be calculated.

$$Q = K \frac{A}{\mu L} \Delta P \quad (16)$$

where: Q is the macroscopic flow passing through the surface of area A and a length of L .

6. EXAMPLES: PORE SIZE DISTRIBUTIONS AND PERMEABILITY

The influence of particle size distributions (psd) on the pore size distribution of hydrated C_3S paste was studied through numerical simulation. Table 1 presents the size characteristics of four psds considered in this study. The cumulative weight distributions of the grains are also given in Figure 4. In this work the computational volume considered is $100\mu m \times 100\mu m \times 100\mu m$ and the water-to-cement ratio 0.42. We have simulated only the hydration of these four coarse cements D1, D2, D3 and D4 and examined their pore distribution.

Table 1. Size characteristics of the four psds considered in comparison with that of real cement: number of particles, specific surface, minimum and maximum radii

	Number of particles	Specific surface (cm^2/g)	ϕ_{max} (μm)	ϕ_{min} (μm)
D1	191	1058	40.4	10.9
D2	932	1597	40.4	5
D3	2556	1976	40.4	2.95
D4	4182	2085	40.4	2
real	110000	3585	40.4	0.5

Figure 4. The four particle size distributions in comparison with a that of a real cement

The results before and after hydration for the pore size characteristics are given in Table 2. It presents the number of particles, cylinders, the minimum and maximum radii for the four cements. The reached hydration degree is around 0.95 and the porosity around 7 % for the four cements.

Table 2. The number of grains and cylinders, the maximum and minimum radii are presented for the four cements, before and after hydration. The hydration degrees at the end of simulation are around 0.95 for the four different cements, which gives a porosity around 7%.

	Number of grains	Number of cylinders	R_{\max} (μm)	R_{\min} (μm)
D1 before	191	2398	6.93	0.96
D2 before	932	11275	5.18	0.44
D3 before	2556	30662	4.01	0.24
D4 before	4182	49321	3.82	0.18
D1 after	229	1067	4.93	0.0039
D2 after	1118	3728	3.60	0.0011
D3 after	3067	11550	3.19	0.00045
D4 after	5018	16572	2.79	0.00023

Table 3. Number of cylinders smaller than the given size for the four cements before hydration

Radius in μm	D1 before	D2 before	D3 before	D4 before
10	2398	11275	30662	49321
5	2119	11275	30662	49321
2	125	4277	22350	42257
1	1	299	3158	8483
0.5		3	141	532
0.2				2

Table 4. Number of cylinders smaller than the given size for the four cements after hydration

5	1067	3728	11550	16572
2	693	3200	11216	16382
1	316	1667	6847	11178
0.5	135	631	2903	4711
0.2	45	213	861	1420
0.1	20	91	355	637
0.05	7	43	146	314
0.02	3	16	46	100
0.01	3	6	31	50
0.005	2	2	9	23
0.002		2	2	70
0.001			1	6
0.0005			1	6

The number of cylinders as a function of size is shown in Tables 3 and 4, before and after hydration respectively.

For the permeability calculations, only the three coarsest particle size distributions were considered, due to the time and memory necessary for the calculations. To obtain lower porosities than can be by complete hydration, we have also dilated the solid structure by increasing all particle radii by the same amount. The permeability results for hydration are shown in Figure 5 compared with experimental results for C_3S pastes [6], and those for dilation of the solid structure are shown in Figure 6.

Figure 5. Experimental and calculated permeabilities during hydration. The specific surfaces are $1058 \text{ cm}^2/\text{g}$ for D1, $1597 \text{ cm}^2/\text{g}$ for D2, $1976 \text{ cm}^2/\text{g}$ for D3 and $3200 \text{ cm}^2/\text{g}$ for the real cement.

Figure 6. Calculated permeabilities for dilation of the solid structure

7. DISCUSSION

The particle size distributions for the simulation are coarser than real ones due to the limitations of calculation with a large number of particles. The number of grains increases considerably as smaller particles are taken into account (Table 1) and the calculation time is proportional to the square of this number. After hydration, this number of grains increases because grains of calcium hydroxide are created in the pore space. The number of cylinders is much greater than the number of particles. After hydration, of course, many pores and necks disappear because the pore space is reduced.

Regarding the cylinder sizes, the pore size distributions become finer during hydration (Tables 1-3) and the minimum values after hydration are around a nanometer. This analytical transformation of the pore space into a network of cylindrical tubes allows pores down to this nanometric size to be characterised, which avoids resolution problems and allows pertinent values for small pores to be considered.

The calculated permeabilities deviate considerably from the experimental values (Figure 5) but the main reason for this is that the specific surfaces are much smaller than in real cement. Another reason is that shrinkage responsible for the closure of small pores is neglected at this stage. During the simulation of hydration some problems arise due to changes in the pore connectivity as some pores are removed whereas others are created in the vicinity of these disappearing pores. When the structure is dilated such problems are avoided, indeed, the pore centers do not change position, decrease in size and then disappear progressively without creating other pores.

The percolation threshold of the porosity is found to be around 3 % (Figure 6), which is in agreement with the case of monosize spheres packing with overlapping [7]. The percolation threshold calculated for different models depends strongly on the type of structure and on the resolution of pixel based models: for sites in regular lattices the value is 15.4% [8], in the NIST model, results depend on pixel size (resolution), this value being 22 % for pixels of 1 μm , 17 % for pixels of 0.5 μm and 12 % for pixels of 0.25 μm [9].

8. CONCLUSION AND PERSPECTIVES

The model presented here allows the pore structure developed during hydration to be simulated. However, at present this IKPM model is still limited in several respects. Firstly, only C_3S and spherical solid phases are considered. It is intended in the future to introduce the other constituents of cement and their hydration products. The use of spheres is clearly an approximation of the real shapes of cement grains, but is necessary in a vectorial-based model and it is felt that the advantages of this approach outweigh the limitations. It is not so obvious that the shape has a strong influence on the microstructure and properties, but this point will be further explored by comparison with experimental results. The major advantage of such a “continuum” approach is that there is no lower limit on the pore size which can be represented, which opens up the possibility of studying shrinkage forces which arise during partial desaturation of the pores, as in drying or autogeneous shrinkage.

Concerning the hydration kinetics, the formula can be calibrated against experimental data. The parameters can be related to the particle size distribution and water-to-cement ratio in order to quantify the influence of these factors.

At present the major limitation is the difficulty in considering small particles due to the fact they are very numerous. The calculation time is proportional to the square of the number of particles and

this number increases enormously even when the minimum diameter is decreased by a small amount. The limit is actually around 2 μm when the computational volume is 100 μm *100 μm *100 μm . It may be possible to tackle this limit by imaging a different treatment of the small particles that react very quickly or by a multilevel.

ABSTRACT

The transition zone between Portland cement paste and aggregate is the weakest region of the concrete which strongly influences strength, permeability and durability. It is commonly known that durability of alkali-activated slag mortars and concrete is very high. Very dense microstructure with very low content of the capillary pores is the main reason for the very high durability of AASC.

Ground granulated blast furnace slag activated by water glass was used for mortar preparation. Ordinary Portland cement mortars were used as reference samples. Tested mortars were cured in water and in a magnesium chloride solution respectively.

Diffusion coefficients of chloride ions and strength of the mortars were determined. Microscope observations with EDS microanalyses were also carried out.

Scanning electron microscope (SEM), X-ray diffraction, microporosity tests were used to investigate the interface between paste and sand.

The results show significantly lower diffusion coefficients and much denser interfacial zones between paste and quartz sand for alkali-activated slag mortars than for OPC mortars.

1. INTRODUCTION

It is generally accepted that alkali-activated slag cement, which consists of ground granulated slag and an alkaline activator, may exhibit higher strength, denser microstructure, and better durability than Portland cement [2-4].

It is commonly accepted that binding materials containing blast furnace slag are more resistant to the action of aggressive solutions. A good example is the resistance to chlorides. Impermeability decreases the chloride ions' diffusion coefficient in slag cement pastes. It is also important that some of the diffused chlorides become bound in the cement paste. Slag binder pastes show a higher chloride binding capability compared to OPC paste [5-7]. It reaches 1% of the cement mass.

Similar conclusions apply to the high chemical resistance of alkali-activated slag binding materials - products of hydrating these materials show lower dissolvability, which makes their durability higher than in case of products of hydrating Portland cement. The dissolvability of high alkali products of hydrating Portland cement, $\text{Ca}(\text{OH})_2$, C_2SH_2 , C_3AH_6 remains at the level of 0.3 - 0.5 g/l, whereas the dissolvability of low alkali lime hydrosilicates and hydrogarnets (main products of

hydrating AASC binders) remains in the range 0.035 - 0.05 g/l, and the dissolvability of carbonates and alkali aluminum silicates is even lower [8].

The interfacial zone between cement paste and aggregate in all concretes is the weakest region that controls permeability and durability. In the case of Portland cement concrete this interfacial zone is characterized by the prevalence of calcium hydroxide and higher porosity. The thickness of this zone in OPC concretes ranges from 50 to 100 μm [9].

There are only a few studies [9, 10, 11] where the transition zone in alkali-activated slag concretes have been investigated. Contrary to OPC mortars, in AASC mortars, dense and uniform transition zone was observed. The formation of the dense and uniform transition zone in alkali - activated slag mortars can be attributed to several factors such as the water reducing function of alkaline activators, the high initial concentration of $[\text{SiO}_4]^{4-}$ in the pore solution and increased dissolution of quartz in a high pH medium [9].

The objective of the study was to examine the properties of AASC mortars cured in MgCl_2 solution.

Comparative research on the diffusion of the chloride ions and the resistance to corrosion of AASC mortars and OPC mortars was carried out. Phase composition of the pastes and microscope observations were also carried out. Additionally, observations of paste-aggregate transition zones in 27 year old AASC concrete were conducted.

2. EXPERIMENTATION

2.1 Raw materials

The following materials were used in the research: granulated blast furnace slag, ordinary Portland cement, water glass, quartz sand and 27 year old AASC concrete.

2.1.1 Granulated blast furnace slag

A pelletized Polish blast furnace slag (BFS) was used in the research. The characteristics of the granulated blast furnace slag are given in Table 1. An XRD and microscopic analysis indicated that the slag consists mainly of glassy phase (ca. 85%) with some crystalline melilites. BFS was ground in ball mill to the specific surface ca. 400 m^2/kg .

2.1.2 Ordinary Portland Cement

A typical commercial ordinary Portland cement CEM I 32.5R (according to the European standard EN 197-1) was used in this study as a reference binder [1]. The chemical and some physical properties of the Portland cement are also given in Table 1.

Table 1. Chemical composition and physical properties of BFS and OPC.

Material	Chemical composition [mass %]							Specific gravity [kg/m^3]	Blaine Fineness [m^2/kg]
	CaO	SiO ₂	Al ₂ O ₃	MgO	Fe ₂ O ₃	MnO	Na ₂ Oeq		
Granulated Blast Furnace Slag	43.76	39.38	6.13	8.25	0.35	0.47	1.09	2940	405
Ordinary Portland Cement	64.00	21.20	5.04	2.21	2.54	n.d.	0.78	3120	315

2.1.3 Water glass

Sodium water glass was used as the activator of the slag binder. Numerous previous studies have indicated that beside Na_2CO_3 , water glass is the best activator for Polish granulated blast furnace slag [4, 6]. The silicate modulus of the water glass was 1.5.

2.1.4 Sand

Standardized quartz sand 0 - 2 mm was used in mortar preparation.

2.1.5 AASC concrete

The 100mm diameter cylinders were cut off from the 27 year old alkali - activated slag concrete. It was AASC concrete activated with Na_2CO_3 (6% of the slag mass) containing sand-gravel mix as the aggregate. The mean compressive strength of the AASC concrete after 27 years of curing was 43.2 MPa.

2.2 Preparation of mortars

The BFS and OPC, sand, water glass and water were used in mortars preparation. In alkali - activated slag mortar water glass was dissolved in the mixing water first and then mixed with the slag and sand. Constant water to binder ratio of 0.45 was used. The composition of mortars is presented in Table 2.

Table 2. Composition of the mortars

Mortar	Ingredients [g]				w/b
	Portland Cement	Slag	Water glass	Sand	
AASC	-	450	67.5	1350	0.45
OPC	450	-	-	1350	0.45

The fresh mortars were cast in 25x25x100 mm bars and plates of 80 mm in diameter and approx. 10 mm in thickness. Some pastes without sand ($w/b=0.27$) were also prepared for XRD analysis of hydration products. All the mortars and pastes were preliminarily cured for 28 days in water (temp. 20 +/- 1°C).

2.3 Corrosion solution

The subject of the research was the effect of MgCl_2 solution on the described mortars. A solution with the concentration of 293g $\text{MgCl}_2/\text{dm}^3$ was used in the examination of diffusion and resistance to corrosion.

2.4 Examination of chloride diffusion through mortar plates

Prepared mortar rings (diameter 80 mm, thickness 10 mm) after 28 days of preliminary curing were used in diffusion measurements. The apparatus for measuring chloride diffusion through mortars consisted of two chambers, between which a plate made of the mortar was placed. The mortar plate was tightened with rubber gasket and silicon glue. The whole assembly was put together with screws located symmetrically around the mortar plate. The first chamber was filled with MgCl_2 the solution, whereas the second chamber was filled with saturated $\text{Ca}(\text{OH})_2$ solution.

After 90, 120 and 180 days, a sample was taken from the chamber filled with the calcium hydroxide solution for chloride content analysis. Chloride content in the samples was determined by Mohr's method [12]. On the basis of the results of chloride ion concentrations in diffusion solutions, effective CL^- ion diffusion coefficients were calculated.

2.5 Sample durability tests

After 28 days of initial curing samples were moved to the corrosion environment. Tests on bars taken from chloride solutions and water (reference samples) were carried out after 28, 90, 180 and 365 days of curing.

2.6 Powder X-Ray Diffraction (XRD) Analysis

Powder XRD analysis was performed on OPC and AASC pastes after 28 days of hydration. The phases were identified from the characteristic peak database of the Powder Diffraction File of the Joint Committee on Powder Diffraction Standards.

2.7 Microporosity measurements

The microporosity of the mortars was determined by means of mercury porosimetry. The total porosity in the range of 4 to 7500 nm as well as average pore radius was measured. The samples were tested after 365 days of water curing.

2.8 Scanning Electron Microscope (SEM) Observations

The samples in the form of rectangular plates, with dimensions 2,5 x 1 x 1 cm, were cut using a diamond-wheel saw. They were mechanically abraded under kerosene with silicon carbide paper (up to 1200 grit No.). After polishing with diamond paste to a 1µm finish, the samples were ultrasonically cleaned with alcohol.

A careful attempt was made to monitor the development of the structures, morphologies and chemistry of samples formed under different conditions of experiments using scanning electron microscopy (SEM) with the backscattering electron image (BSE) mode together with energy dispersive X-ray spectroscopy (EDS) analysis.

2.9 Environmental Scanning Electron Microscope (ESEM) Observations

Pieces of 27 year old AASC concrete were used for ESEM observations. Microanalysis of the different interfacial zones (paste - aggregate) was also carried out.

3. EXPERIMENTAL RESULTS

3.1 Effective diffusion coefficients

The calculated “effective” chloride diffusion coefficients are presented in Table 3 and Figure 1.

Table 3. Values of “effective” diffusion coefficients of Cl ions.

Type of mortar	Time [days]	„Effective” diffusion coefficient [m^2/s] • 10^{-12}
AASC	0-90	2.20
	90-120	2.35
	120-180	2.48
OPC	0-90	21.21
	90-120	24.18
	120-180	31.17

It is well visible that “effective” diffusion coefficient of Cl ions for AASC mortar is much lower than for OPC. It confirms also the results of previous work [4, 6, 7] where the positive influence of granulated blast furnace slag on the chloride resistance of the mortars and concretes was observed.

Figure 1. Values of “effective” diffusion coefficients of Cl ions.

3.2 Durability in MgCl₂ solution

The results of flexural and compressive strength measurements are presented in Table 4.

Table 4. Results of flexural and compressive strength tests.

Environment	Flexural/Compressive strength [MPa]					
	3 d	28 d	28+28 d	28+90 d	28+180 d	28+365 d
AASC						
Water	7.90	10.90	13.20	14.10	14.60	14.70
	24.90	46.80	63.90	70.40	77.20	80.30
MgCl ₂	-	-	12.90	13.80	13.70	13.60
	-	-	62.40	66.95	69.45	66.90
OPC						
Water	8.30	14.40	11.60	11.70	11.80	11.85
	21.20	41.80	43.70	44.90	49.60	52.10
MgCl ₂	-	-	12.10	6.90	3.20	0.00
	-	-	39.40	21.48	15.05	0.00

OPC mortars cured in the MgCl₂ solution showed clear corrosion changes after ca. 180 days. A substantial swell could be seen at the ends and along edges of the bars. After 180 days of curing significant reduction of the strength was noted (~ 50%). After one year the samples were completely destroyed. On the other hand AASC mortars confirmed very high resistance to the MgCl₂ action.

3.3 XRD Analysis of Hydration Products

For better understanding of the microstructural properties of the AASC mortars and concretes, the phase composition of the paste was determined. The XRD patterns of the AASC paste and OPC paste after 28 days of water curing are presented in Figure 2.

Figure 2. XRD patterns of OPC and AASC pastes after 28 days of curing.

The hydration products in OPC paste are typical: C-S-H phase, portlandite and ettringite. In AASC paste amorphous C-S-H phase is dominating the hydration product. Traces of hydrogarnets (HG) were also detected.

3.4 Microporosity

The microporosity of the mortars after 365 days of water curing is presented in Table 5 and Figure 3.

Table 5. Porosity of the mortars.

Type of mortar	Total porosity [mm ³ /g]	Average pore radius [nm]
AASC	12.6	4
OPC	28.5	28

Figure 3. Pore size distribution.

It is very clear that the porosity of the AASC mortar is less than half of the porosity of the OPC mortar. The average pore radius for AASC mortar is also very low, which means that small gel pores dominate this mortar.

3.5 SEM observations

Morphologies of the mortar samples and the transition zone between Portland cement paste/quartz sand and alkali-activated slag cement/quartz sand after the corrosion test in MgCl_2 solution are shown in Figures 4-8. SEM observations were conducted for both 1 mm regions: saturated $\text{Ca}(\text{OH})_2$ solution / mortar and MgCl_2 solution / mortar. In the case of Portland cement – $\text{Ca}(\text{OH})_2$ contact region the material was dense without cracks and pores. On the other hand in the case of Portland cement mortar after reaction in MgCl_2 solution, the samples were completely corroded (see Table 4). Many cracks have been observed in the analysed region of the OPC (Figure 4). Contrary to the $\text{Ca}(\text{OH})_2$ solution – mortar region, the interfacial zone between Portland cement paste and quartz sand in these samples was characterized by many regions rich in Al and Cl (Figure 5).

Figure 4. Microstructure of OPC mortar in the contact with MgCl_2 solution (1 year of exposure)

Figure 5. X-ray map in the region shown in Figure 4.

Figure 6(a) and 6(b) shows the surface morphology of AASC mortar in the contact region with $\text{Ca}(\text{OH})_2$ solution. It can be seen that this material exhibits dense microstructure without cracks and excellent adhesion between paste and aggregate. It has also been observed that the paste/aggregate contact layer is very compact. It corresponds very well with the results presented in Table 4 (very low porosity of the AASC mortars cured in water). On the other hand in the case of AASC mortars after corrosion in MgCl_2 solution, the progress of corrosion and a large number of cracks in the outer part of the samples were observed. Figure 8 shows the X-ray maps of this region indicating strong accumulation of Mg and Cl in this zone (ca. 800 μm distance from ASSC mortar vicinity – Fig.7a). It appears that in the presence of Mg^{2+} ions the replacement between these ions and Ca ions in C-S-H phase takes place. But, it is very evident that even after one year of corrosive exposure the development of corroded zone was limited and much smaller than for OPC mortar. Contrary to the OPC samples, no enrichment in Al, and Cl on the surface of the sand grains was observed.

Figure 6. Microstructure of AASC mortar in the contact with $\text{Ca}(\text{OH})_2$ solution (1 year of exposure); (a) magnification 50x, (b) magnification 400x

Figure 7. Microstructure of AASC mortar in contact with MgCl_2 solution (1 year of exposure); (a) magnification 50x, (b) magnification 400x

Figure 8. X-ray map in the region shown in Figure 7a.

3.6 ESEM observations

Generally, compact C-S-H phase was detected as a main product in 27 year old AASC paste. Some quantities of CaCO_3 and thomsonite were also present. The microstructure is highly densified with no microcracks. The interfacial zone between paste and gravel is very dense and even traces of interaction paste - grain were found (Figure 9.).

Figure 9. Interfacial zone grain - AASC paste (ESEM + EDS).

4. CONCLUSIONS

This study has investigated the resistance of alkali - activated slag mortar to the action of MgCl_2 solution. The “effective” diffusion coefficients of chloride ions in AASC mortar and OPC mortar were determined. The phase composition of the pastes, interfacial zone paste - aggregate in the mortars and 27 year old AASC concrete was also investigated.

The following conclusions can be drawn based on the experimental results:

- (1) The “effective” diffusion coefficients of Cl ions in AASC mortars are lower by a class compared to OPC mortars.
- (2) Durability of AASC mortars to the action of highly concentrated MgCl_2 solution is significantly higher than ordinary Portland cement mortars.
- (3) The phase composition of the AASC paste, low porosity and very dense interfacial zone paste - aggregate are the main reasons for the very high durability of AASC mortars. The absence of portlandite and the low crystallinity of the C-S-H phase in these pastes form the dense and impermeable microstructure of the mortars and concretes.
- (4) In the presence of Mg^{2+} ions in the aggressive medium the replacement between these ions and Ca^{2+} in C-S-H phase takes place. But, even after one year the development of the corroded zone is very limited.
- (5) ESEM observations of 27 year old AASC concrete confirmed that interfacial zone paste - gravel is very dense with no microcracks. The observations confirm also Shi hypotheses that the presence of alkalis in AASC paste markedly increases the dissolution rate of quartz [9]. The surface dissolution of sand grains will enhance the bonding between quartz and alkali - activated slag paste.

EFFECT OF SILICA FUME ADMIXTURE ON THE PROPERTIES OF FLY ASH CEMENTS

Zbigniew Giergiczny

Górażdze Cement S.A., Technical University of Opole, Poland.

E-mail: zbigniew.giergiczny@gorazdze.pl

ABSTRACT

In this work the silica fume addition to fly ash cement was studied. Silica fume of high pozzolanic activity was considered as a good supplement of low-calcium fly ash. The progress of the reaction between fly ash and calcium hydroxide was investigated, as well as the rate of the process occurring in the system fly ash – silica fume – calcium hydroxide was analyzed. A significantly higher calcium hydroxide consumption in the presence of active microsilica was found using the thermogravimetric method. In this reaction the calcium silicate hydrates are preferentially produced.

The beneficial influence of silica fume addition on the strength of fly ash cement mortars should be attributed to its very high pozzolanic activity and fineness, giving a filler effect – small SF particles enter the space between cement grains. The “excess” gel-like C-S-H produced in the pozzolanic reaction can thus fill the pores in hardened paste and consequently the total porosity decreases. The mean pore diameter is also reduced.

This low calcium hydroxide content together with reduced porosity allows the assumption of a significantly higher corrosion resistance of these materials in an aggressive environment. The examination of mortars stored for a long time in sulphate solutions (MgSO_4 , H_2SO_4), and in saturated sodium chloride confirmed this.

1. INTRODUCTION

Fly ashes are commonly used in cement and concrete production, because of their ability to react with alkalis, mainly calcium hydroxide evolved during the hydrolysis of calcium silicates from cement clinker. The hydrated calcium silicates and aluminates are thus produced. This fly ash property is known as pozzolanic activity [1], [2], [3].

Cements and concretes produced with fly ash show low heat of hydration, lower shrinkage, better workability, high corrosion resistance and fairly good strength at later ages. The negative feature revealed in building practice, attributed to the presence of fly ash in cementitious materials is low strength development, as compared to the cements from standard group CEM I, as well as very poor strength development at low temperatures. This is attributed to the retarded pozzolanic process, strongly affecting the physical and mechanical characteristics of hardened fly ash composites.

There is no one opinion about the start of pozzolanic reaction between the glassy fly ash substance and calcium hydroxide. It seems however, that this is determined by the activity of the pozzolan. Therefore some operations, such as very fine grinding, grain size separation, alkali activation, chemical additives or thermal treatment are used to improve the pozzolanic properties [5], [6]. In this work the ways of modification of fly ash cement mechanical properties by silica fume are

presented. Silica fume, formed as a by-product from ferrosilicon alloy metallurgy, is known for its high pozzolanic activity and can be used as as supplement of poorly pozzolanic fly ash, modifying the hardening process at early ages.

The following studies were carried out in this work:

- kinetics of fly ash – $\text{Ca}(\text{OH})_2$ pozzolanic reaction,
- effect of silica fume on the properties of fly ash cement.

2. MATERIALS

The samples of cements were prepared in laboratory from commercial Portland cement, fly ash and silica fume. The chemical composition of the materials used is given in Table 1.

Table1. Chemical composition of materials

Material	Percentage of component in wt. %									
	l.o.i.	SiO_2	Al_2O_3	Fe_2O_3	CaO	CaO_f	MgO	SO_3	Na_2O	K_2O
PFA	1,9	50,8	23,9	8,6	3,6	0,2	2,8	0,8	0,8	2,9
SF	0,1	91,4	1,24	3,4	0,4	---	---	---	0,63	1,6

Silica fume – a by-product from ferrosilicon metallurgy is formed as a result of reduction of quartz by carbon in an electric furnace and consists mainly of amorphous silica. The XRD pattern of silica fume is shown in Figure 1.

Figure 1. XRD pattern of fly ash

Fly ash, originating from black coal combustion reveals, apart from glassy phase, some amounts of quartz, mullite and haematite, as main crystalline components. The XRD pattern of fly ash is shown in Figure 2.

Cement was produced from Portland cement clinker of the following phase composition (calculated by Bogue method): C_3S – 57,5%; C_2S – 19,2%; C_3A – 9,8%; C_4AF – 6,7%; CaSO_4 – 1,5% and natural gypsum added as 4,0%.

Figure 2. XRD pattern of silica fume

3. KINETICS OF FLY ASH – $\text{Ca}(\text{OH})_2$ POZZOLANIC REACTION

Two cementitious mixtures were produced to follow the course of the reaction between the fly ash admixture with silica fume and calcium hydroxide:

- 1) Mixture I – 70% PFA and 30% $\text{Ca}(\text{OH})_2$ (in wt. %)
- 2) Mixture II – 10g SF added to 100g of mixture I.

The mixtures were hydrated at water to solid ratio 0,6. The pastes thus produced were stored in sealed containers. The hydration was stopped after 1, 3, 7, 14, 28, 90 and 180 days respectively; the dried samples were investigated using differential thermal analysis, thermogravimetry and X-ray diffraction. In Figure 3, the DTA curves for mixtures I and II given above are plotted.

Figure 3. DTA curves of hydrated mixtures

From the set of DTA results it is evident that $\text{Ca}(\text{OH})_2$ consumption in the mixtures with silica fume is significantly accelerated. The $\text{Ca}(\text{OH})_2$ decomposition peaks in the temperature range of $475 - 490^\circ$ are reduced and the endothermic peak in the range of $120 - 130^\circ \text{C}$ increases with time. The latter one corresponds to the decomposition of gel-like pozzolanic reaction product. At 180-day hydration there is no calcium hydroxide in the sample admixture with silica fume – all $\text{Ca}(\text{OH})_2$ was consumed by active fly ash and silica fume components. These results have been also confirmed by XRD studies where the $\text{Ca}(\text{OH})_2$ and C-S-H peaks show the same trends (see Figure. 4).

The amount of $\text{Ca}(\text{OH})_2$ consumed in the pozzolanic reaction, calculated based on TG data, is shown in Figure 5.

Figure 4. XRD patterns after 180 days hydration
1- mixture II (with silica fume), 2- mixture I

As is evident from DTA curves (see Figure 3) as well as from the data shown in Figures 4 and 5, the silica fume admixture plays a role of active supplement to the fly ash of low pozzolanic activity within the first days. The calcium silicate hydrates are mainly produced in this early reaction.

4. EFFECT OF SILICA FUME ON THE PROPERTIES OF FLY ASH CEMENT

4.1. Properties of fly ash cements tested with silica fume

The fly ash cements were produced by simultaneous grinding of clinker, fly ash and gypsum. The composition and properties of cements are shown in Table 2.

Table 2. Composition and properties of fly ash cements

Sample code	Composition of cements, wt. %			Density g/cm^3	Specific surface, m^2/kg
	Clinker	PFA	Gypsum		
Cement "0"	96	---	4	3,07	311,2
Cement 1	81	15	4	2,94	304,8
Cement 2	66	30	4	2,85	321,2
Cement 3	46	50	4	2,77	327,0

Figure 5. Rate of Ca(OH)_2 consumption in pozzolanic reaction.

Silica fume was added at 5 and 10% by mass of cement (mixing was done in a laboratory mill). The mortars were produced following the EN 196 standard. The compressive strength was tested on 4x4x16 cm bars following the procedure given in EN 196.

The results of the compressive strength tests are given in Table 3.

Table 3. Compressive strength of fly ash cements

Sample code	SF content in wt. %	Compressive strength in MPa at age			
		3 days	7 days	28 days	90 days
Cement 1	---	20,6	27,5	38,0	52,0
Cement 1	5	21,0	30,5	51,9	60,1
Cement 1	10	22,7	33,2	52,3	61,3
Cement 2	---	17,7	22,5	34,7	49,3
Cement 2	5	21,7	28,8	51,5	60,1
Cement 2	10	22,6	30,1	49,6	59,9
Cement 3	---	8,3	14,0	23,5	41,5
Cement 3	5	13,7	20,2	37,2	50,3
Cement 3	10	14,7	24,5	43,1	53,7

In Table 4 the total porosities and mean pore radii for 90-day matured paste produced using cement 1 (1% PFA) with or without the added 5% of silica fume are given. Both values decreased with silica addition and this is important from the durability point of view.

Table 4. Results of porosity measurements

Sample	Total porosity cm^3/g	Mean pore radius, nm
Cement 1(15% PFA)	0,2797	38; 650
Cement 1(15%PFA + 5%SF)	0,2478	4,8; 38

The durability of fly ash and silica fume containing mortars was also tested. For this purpose the following investigations were carried out:

- the mortars were stored in a sulphate aggressive environment,
- the mortars were produced using saturated NaCl solution and stored in such a solution (testing for possible use of mixed cementitious materials in some special works).

Sulphate resistance. This was evaluated based on the reduction of compressive strength for mortars stored in two different solutions:

- sulphuric acid of SO_4^{2-} concentration - 4800 mg/dm^3 ,
- magnesium sulphate solution of Mg^{2+} concentration – 3000 mg/dm^3 .

The samples of mortars were put into the aggressive solution after 28-day maturing in standard conditions, in water. The observations were carried out within 2 years, for cement 2 and 3 admixture with 10% SF. The compressive strength of mortars is shown in Table 5.

Table 5. Compressive strength of mortars cured in different liquid media

Type of cement	Liquid environment	Compressive strength in MPa at age			
		90 days	180 days	360 days	720 days
Cement “0” No admixture	Water	53,6	55,9	60,1	60,3
	H_2SO_4	53,6	49,3	42,7	40,7
	MgSO_4	53,9	52,1	39,5	37,6
Cement 2 30% PFA	Water	51,7	60,9	64,3	64,0
	H_2SO_4	54,4	59,7	62,9	58,8
	MgSO_4	52,7	56,7	55,5	55,0
Cement 2 30% PFA 10% SF	Water	57,3	61,8	62,3	63,9
	H_2SO_4	54,4	61,0	61,8	63,7
	MgSO_4	52,7	57,0	51,6	51,0
Cement 3 50% PFA	Water	31,2	37,0	42,0	42,1
	H_2SO_4	34,2	39,1	45,3	39,0
	MgSO_4	31,2	40,7	43,4	38,5
Cement 3 50% PFA 10% SF	Water	45,6	47,2	48,0	48,0
	H_2SO_4	45,5	47,0	48,4	45,6
	MgSO_4	40,6	40,3	34,5	31,4

As is evident from the data given in Table 6, the fly ash admixture is one way of improving sulphate resistance, while the silica fume addition brings about the modification of mechanical properties. The sulphate resistance, which is very good in H_2SO_4 solution, decreases significantly in MgSO_4 . It should be derived from the mechanism of reaction between MgSO_4 and hydrated paste, where the decomposition of amorphous C-S-H occurs, apart from gypsum formation. Magnesium hydroxide and silica produced in this process have no cementitious properties [6]. The reactions of MgSO_4 with hydration products can be written as follows:

Therefore in case of mortars produced from cements with fly ash and silica fume, at low calcium hydroxide content and very high amounts of C-S-H, the compressive strength decrease is the consequence of a detrimental MgSO_4 effect on gel-like C-S-H stability.

4.2 Properties of fly ash cements produced and stored using NaCl solutions

The studies were carried out for cement without admixture (cement “0”), cement 2 (30% PFA) and cement 2 modified with silica fume. The cement pastes were produced with NaCl solution of concentration 310 g NaCl/dm^3 . After 2-day hardening the mortars were stored in a NaCl saturated solution. The compressive strength tests showed the differences between the “neat” cement and the pozzolanic cements. Cements with pozzolanic admixtures show continuous strength development, while cement without admixture does not. Additionally, cement with fly ash and silica fume exhibits very high strength after prolonged storage - 90 days and more, when the strength decrease is observed for mortar without pozzolanic admixture (Figure 6). This mortar reveals, on visual examination, some surface cracks being the results of swelling.

The following features were noticed during the DTA and XRD investigations (see Figures 7 and 8):

- in hardened cement paste produced from Portland cement, calcium chloroaluminate $3\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot\text{CaCl}_2\cdot 10\text{H}_2\text{O}$ and calcium hydroxide $\text{Ca}(\text{OH})_2$ are detected,
- in cement – fly ash paste modified with silica fume there is no $\text{Ca}(\text{OH})_2$ peak; the small $3\text{CaO}\cdot\text{Al}_2\text{O}_3\cdot\text{CaCl}_2\cdot 10\text{H}_2\text{O}$ peak is detectable after 90 days curing; a significant amount of C-S-H is noticeable.

Such a situation can be attributed to the high ability of C-S-H formed preferentially in the presence of fly ash (and silica fume) to incorporate the chlorine ions. Another reason is presumably related to the change of concentrations in the liquid phase in the presence of pozzolanic - siliceous admixtures.

5. DISCUSSION

Huge amounts of fly ash – a by-product of high fineness and pozzolanic activity are produced in those countries, where black coal is basic source of energy. Fly ashes are commonly used in cement and concrete manufacturing. A main feature related to siliceous fly ash's (denoted in EN 197-1

standard as “V”) practical implementation in cement, particularly when a higher admixture content is taken into account, is prolonged setting and low strength development (within the first 28 days), as compared to Portland cement CEM I of the same class. This may be improved by use of silica fume modifying admixture.

Silica fume is a very active pozzolanic material, quickly consuming the calcium hydroxide with the formation of calcium silicate hydrates (see Figure 5), revealing its activity at earlier ages, when fly ash is still relatively inert. Fly ash cement with silica fume shows higher compressive strength at all ages (see Table 3) and the differences are greater for higher fly ash contents (30 and 50% respectively). This advantageous influence of silica fume on fly ash cement strength can be attributed to the high pozzolanic activity of microsilica. In pozzolanic reaction the calcium silicate hydrates are produced as a main product, as confirmed in DTA measurements (see Figures 3 and 4). Additional C-S-H is distributed in pores, thus reducing the total porosities of pastes (Table 4). The mean pore radius decreases also. The fineness of fly ash and silica fume fill the empty spaces in the hardened system. This affects also the microstructure, which becomes more dense.

Hardened cement – fly ash – silica fume materials show low calcium hydroxide content and together with reduced porosity this strongly improves their corrosion resistance. The tests of cement – fly ash – silica fume mortars stored in sulphuric acid solution showed the stability of strength parameters (Table 5). On the other hand, in a MgSO_4 solution at later ages, the mortars exhibit reduction of strength and some destructive changes, this being the consequence of interaction between Mg^{2+} ions and C-S-H.

The fly ash and fly ash-silica fume cements show very good properties in the saturated NaCl solution (see Figure 6), while Portland cement mortars reveal destruction after a time (swelling, cracks). These results demonstrate the suitability of using fly ash and mixed pozzolanic materials in underground works in salt mines, in drilling and other “extreme” conditions.

6. CONCLUSIONS

1. Silica fume is a mineral additive complementing pozzolanic activity low calcium fly ashes.
2. Introducing silica fume as a component of fly ash cements improves their compressive strength in all examined hardening periods.
3. The hardened cement – fly ash paste with silica fume admixture shows lower content of $\text{Ca}(\text{OH})_2$ and lower porosity, which is interesting, as it improves resistance to aggressive media.

Serrano Galvache, s/n,28033, Madrid, Spain.

ABSTRACT

This research intends to verify the XRD and Le Chatelier (L-A) experiments. For this purpose, 28 cements consisting of 7 Portland cements and 21 blended cements containing 20,30 and 40% metakaolin (M pozzolan) have been submitted to the L-A test for two years. With these cements, L-A specimens were manufactured. The parameter *Diameter Growth Rate*, $V_{c\phi} (= \Delta\phi (\%)/\text{day})$ was not measured but it was obtained by dividing the $\Delta\phi(\%)$ measured by the relevant age. Other complementary determinations were: chemical analysis, XDA patterns and SEM of ettringites and specific properties of some cements tested. The results have shown that:

(a₁) The formation rate of the ettringite resulting from reactive alumina, Al_2O_3^- , present in M pozzolan, is considerably higher than the formation rate of ettringite from C_3A and much higher than ettringite from C_4AF , both present in OPC. These ettringites have been named: "rapid formation"(ett-rf), "slow formation" (ett-lf) and "very slow formation"(ett-vlf) ettringites, respectively.

(b₁) The size of the **ett-rf** crystals is considerably smaller than the size of the **ett-lf** ones (in accordance with the aforementioned conclusion).

On the other hand, these results have also shown that:

(a₂) Pozzolanic reactions derived from the reactive alumina, Al_2O_3^- , present in M pozzolan, for a gypsum and water environment -L-A specimens- take place during the first 28 days – and even, during the first 7 days. This occurred for most POZC prepared with this M pozzolan (metakaolin), and **ett-rf** and **ett-lf** were the reaction products in all cases.

(b₂) **Ett-rf** and **ett-lf** formation, does not take place independently from one another, but interdependently or in a joint way or interactive way. That means that both ettringites appear, to a greater or lesser extent, when dealing with gypsum and water environments. Nevertheless, the reaction products are closer to **ett-rf** than to **ett-lf**, when more M pozzolan is added (40%) and vice versa(20%).

Keywords: Gypsum Attack, Portland Cements, Metakaolin, Ettringites, Formation rates, Kinetics, Sizes.

1. INTRODUCTION

The Le Chatelier-Ansttet (L-A) test (1) has been used in some European countries (2) (3) (4) (5) (6) as an accelerated test to predict cement behaviour against gypsum attack. However it was used here, mainly, to show differences between the ettringite formed from reactive alumina (tetra- or penta-

coordinated alumina), $\text{Al}_2\text{O}_3^{\text{r}}$ (7), which is present in M pozzolan (from now on "**ett-rf**"), and the ettringite from C_3A and C_4AF , both present in OPC (from now on "**ett-lf**" and "**ett-vlf**", respectively). These differences will be shown later on.

Researchers' disagreement regarding the influence of pozzolans on ettringite kinetochemistry led us to use the Le Chatelier-Anstet (L-A) test (indirect or relative parameter $V_{\text{co}} = \Delta\emptyset(\%)/\text{day}$) in order to confirm phase formations previously obtained (8) (9).

On the other hand, experimental results also have shown that the L-A specimen overall dimensions change during water diffusion and chemical reactions(10), and in a recent international meeting on sulphate attack(11), other related effects were pointed out. Moreover Santhanam et al.(12) lately expressed dissatisfaction because of the fact that sulphate attack, that was given so much importance some years ago, has lost interest for researchers, and pleaded for setting up again the investigation to determine the service life of concrete foundations that have been attacked by sulphates. For this purpose, reagent substances and reaction products formed and possibly involved when pozzolanic additions are in contact with Portland cement attacked by gypsum, should be known first, as well as their respective morphologies, sizes, formation rates, inter-reaction or inter-connection during formation, technological consequences and other possible effects.

For all these reasons, the same experiments were carried out once again, but new indirect parameters and reasonings had to be considered to confirm that the formation rate of rapid formation ettringites (from reactive alumina present in M pozzolan), must be greater than the formation rate of slow formation ettringites (from C_3A present in OPC), and consequently, their different sizes, as well. This indirect or relative parameter has been **Diameter Growth Rate, V_{co}** , ($= \Delta\emptyset(\%)/\text{day}$) as well as pozzolanic reactions derived from the reactive alumina $\text{Al}_2\text{O}_3^{\text{r}}$, present in M pozzolan for a gypsum and water environment - L-A specimens - taking place through the 28 days – and even as early as during the first 7 days. This occurred for most POZC prepared with this M pozzolan; **ett-rf** and **ett-lf** were the reaction products in all cases. Further their respective inter-relation or inter-connection during formation will be shown. For that purpose L-A specimens(1), manufactured with cement paste partially hydrated plus gypsum (ratio 1:2), were used.

2. OBJECTIVES

The main objectives of this research are the following:

1. To prove through the L-A test that the formation rate of ett-rf($V_{\text{f}} \text{ ett-rf}$) is higher than the formation rate of ett-lf($V_{\text{f}} \text{ ett-lf}$) and than the $V_{\text{f}} \text{ ett-vlf}$ (semi-quantitative or comparative analysis). Therefore:

$$V_{\text{f}} \text{ ett-rf} \text{ is } > V_{\text{f}} \text{ ett-lf} \text{ is } > V_{\text{f}} \text{ ett-vlf}$$

2. To confirm that **ett-rf** crystals are smaller than **ett-lf** ones, as well as to find a conclusive explanation for both of them.

3. To determine whether the greatest amount of pozzolanic reactions for the $\text{Al}_2\text{O}_3^{\text{r}}$ present in M pozzolan, take place in L-A specimens during the first 28 days, and sometimes as early as 7 days, for most POZC tested.

4. To determine whether there is any relation or not between **ett-rf** and **ett-lf** and/or **ett-vlf** during their formation in gypsum and water environments.

3. EXPERIMENTAL

3.1 The starting materials used for this research are shown in Table 1:

In accordance with Eitel's ternary diagram(15), the following materials have been chosen:

1. Four OPC -P-1, P-2, P-3 and P-5 (=P-n°)- and three SRPC -PY-1,PY-4 and PY-6 (=PY-n°).
2. Metakaolin prepared using kaolin (with ≈ 50% quartz content); calcination at 750°C.
3. Gypsum natural stone (with a high CaSO₄.2H₂O content) used as aggressive media.

3.2 The operating procedure

First of all, 21 POZC specimens, with ratios 80%/20%, 70%/30% and 60%/40% (%P-n°/%M or %PY-n°/%M ratios), were prepared with 7 Portland cements -4 OPC and 3 SRPC- and M pozzolan. Secondly, all these POZC were analysed by the Frattini test (16) in order to confirm their pozzolanic characteristics at 7 and 28 days (later on related to sulphate attack) (Figure 1).

Figure 1. Frattini test of the 21 POZC

Thirdly, mechanical strengths (flexural and compressive strength) (17) and setting time (18) were determined (Table 2). Lastly, each POZC and each PC, were submitted to the L-A test(1). In it, the cement is firstly ground to make it pass through a sieve of approximately an 88 μm opening (a No. 170 sieve), and then the ground cement, 100.0 g, is used to make a 0.50 water-cement ratio paste, which will be allowed to harden for several weeks (usually 2), and then crushed into 5 mm size and dried at 40°C. Gypsum, 50.0 (as \approx 50 percent of the dried set cement) is added, and the mixture is ground to pass through a sieve of approximately 212 μm opening (a No. 70 sieve). Six percent of distilled water by weight of solids is added, and the dampened paste is placed in an 80 x 30 cylindrical mould, and compressed under a pressure of 196 Pa/minute. The cylinder is placed on filter paper kept damp by allowing the ends to be dipped in water and covered with a bell jar to make an air-tight joint. The diameter was measured at 24h, 7 days, 28 days, 90 days or even later, according to the purpose. Thus, firstly, the direct parameter, $\Delta\theta(\%)$, was measured (the maximum expansion acceptable is 1.25% at 28 days – physical requirement(15)(16) -, and secondly, the indirect or relative parameter, $V_{co} = \Delta\theta(\%)/\text{day}$, was calculated dividing the $\Delta\theta(\%)$ by the relevant age.

TABLE 2.- Mechanical strengths and times of setting from OPC, P-1, P-2, SRPC PY-6 and their POZC with M pozzolan.

CEMENTS	Mechanical strengths, MS(cement mortar type: EN 196-1)(13)				Setting Times (h, m)(14)

PY-6/M 70/30	9.5	10.4	57.2	68.4	5h 45m	7h 35m	1h 50m
PY-6/M 60/40	7.3	8.1	54.3	54.6	6h 15m	8h 10m	1h 55m
NOTE: The rest of the cements (OPC, SRPC and their POZC) reached MS and TS values of similar order.							

Other complementary determinations were: chemical analysis of the cementing materials used(Table 1), XDA patterns(Figures 3, 4 and 5) and SEM analysis of ettringites (Figures 6 and 7).

4. RESULTS

V_{c0} values are shown in Figures 2 (a), (b), (c), (d), (e), (f) and (g). For discussion and interpretation, the curves shown in this Figure 2 were grouped according to their similarity to a Gauss curve (mainly, its right and/or left branch).

Fig.2- Parameter : Diameter Growth Rate, $V_c\phi$

Specimens : 80 mm ϕ x 30mm h.

Pastes : Le Chatelier - Anstett (2)

Cements : 4 OPC (P-n²), 3 SRPC (PY-n²) and 21 POZ C

Pozzolan : M

4.1 Observations

4.1.1 (A) Plain OPC -4- and plain SRPC -3-:

Origin, evolution and development of $V_c\phi$ values for the 7 PC tested -4 OPC and 3 SRPC- generally can be compared to a Gauss curve or, at least, to its right branch. These branches have a negative

slope and reach very small values, decreasing to zero in all cases, for a given age. Accordingly, the areas defined by plain PC curves are proportional to their C_3A content (in %).

NOTE: In these figures (Figure 2), no initial point has been represented since it would correspond to the specimens manufacture, thus, zero days. Therefore, the initial point of 1 day, V_{c01d} , should be considered linked by an imaginary line to the day 0 point, V_{c00d} . This imaginary line must be considered as well the left branch of the Gauss curve.

**Fig. 3. - XRD of the L-A specimens. SRPC: PY-1, PY-4 and PY-6.
Age: 2 years**

4.1.2 (B) POZC -21-:

1. In all L-A specimens for the 21 POZC, the origin, the evolution and the development of V_{c0} values have shown, at the end of the test, a decrease from age 1 day down to zero in all cases. This decrease was sometimes preceded by an increase. It is necessary to emphasize that no matter which of the 21 POZC is considered, since the highest V_{c0} values were always reached during the first 28 days, and most times, during the first 24 hours. This increase up to its respective highest V_{c0} value is generally

followed by a rapid and sharp decrease, sharper than the one for its plain OPC=P-n° or its SRPC=PY-n°, Figures 2(a), (b), (c), (d), (e), (f), (g), and the more M pozzolan (its $\text{Al}_2\text{O}_3^{\text{r}}$) was added, the highest the $\text{C}_3\text{A}(\%)$ content the OPC had.

In short, $\text{Vc}\theta$ diminished faster for any family of POZC than for its plain PC P-n° or PY-n°, and even faster as the addition of M pozzolan is higher. This decrease began after the maximum $\text{Vc}\theta$ value, which was normally reached at the age of 1 to 7 days. Besides, the bigger the $\text{C}_3\text{A}(\%)$ content was for PC, P-n° or PY-n°, the higher the maximum $\text{Vc}\theta$ value was for its POZC.

2. At age 1 day, $\text{Vc}\theta$ values generally increased as the amount of M pozzolan increased for all OPC (=P-n°) or SRPC (=PY-n°) considered. For this reason, $\text{Vc}\theta$ values satisfied the following order:

$$< \text{Vc}\theta < \text{P-n}^\circ \text{ or PY-n}^\circ / \text{M } 100/00 < 80/20 < 70/30 < 60/40, \text{ at 1 day} \quad [1].$$

Hence, relation [1] is a consequence of the direct chemical effect derived from the physical substitution of PC by M pozzolan. But after 7 days, until the age of 28 days and up, the opposite order took place:

$$> \text{Vc}\theta > \text{P-n}^\circ \text{ or PY-n}^\circ / \text{M } 100/00 > 80/20 > 70/30 > 60/40, \text{ from 28 to 730 days} \quad [2].$$

Furthermore, $\text{Vc}\theta$ magnitude order was much smaller after 7 days, decreasing as the M pozzolan amount increased in every case, and sometimes with the opposite sign.

3. $\text{Vc}\theta$ value for any plain OPC (=P-n°) or SRPC (=PY-n°) tested, was only a direct consequence of its daily $\Delta\theta$; this is due to the formation of **ett-If** (Figure 3). Nevertheless, when M pozzolan was added, its $\text{Vc}\theta$ values increased proportionally, and specially, at early test ages.

The main cause must be once again, the $\text{Al}_2\text{O}_3^{\text{r}}$ present in M pozzolan, when transformed into **ettr-rf** due to its pozzolanic activity for a gypsum and water environment -L-A specimens- (Figures 4 and 5).

5. DISCUSSION AND INTERPRETATION

The aim of kinetic-chemistry is to study the evolution of chemical system(s) in terms of time. Kinetic chemistry deals particularly with measurement and interpretation of reaction rates which are to be defined as $\mathbf{R}=\mathbf{dX}/\mathbf{dt}$ [3]. For a reaction that takes place in a solid-liquid interface -as it occurs with ettringites-, if the interface area is not known, different definitions for the intensive "rate" should be used, such as: $\mathbf{R}=(1/\mathbf{W})(\mathbf{dX}/\mathbf{dt})$ [4] or $\mathbf{r}=(1/\mathbf{V}')(\mathbf{dX}/\mathbf{dt})$ [5], where \mathbf{W} and \mathbf{V}' are weight and volume of the solid particles dispersed in the fluid phase. Nevertheless, $\text{Vc}\theta$ was considered representative enough for our objective, since:

- \mathbf{W} and \mathbf{V}' parameters as well as the parameters for the corresponding reaction products formed (in this research, ettringites from different origins: $\text{Al}_2\text{O}_3^{\text{r}}$, C_3A and C_4AF , respectively) are very difficult to separate and quantify exactly;

- the reaction rate has to be proportional to the derivative of the reaction advance versus time, in such a way that it does not matter which of the expressions [4] or [5] is used;

- the reaction development of ettringite formation can be represented by the daily "Total" specimen increase or by its greatest size; the evolution through time of the diameter growth, the **Diameter Growth Rate**= $\Delta\theta(\%)/\text{day} = \text{Vc}\theta$, is represented for L-A specimens (Figure 2).

5.1 From observations (B) 1 and 2

According to observations (B)1 and (B)2, the bigger/lower the negative slope of the V_{c0} curve is, the bigger/lower the correspondent positive slope must be. This positive slope corresponds to the first 24 hours. These observations allow the following reasoning: considering first only plain PC(OPC=P-n° and SRPC=PY-n°) curves, it can be seen that the maximum V_{c0} value for 1 day, $V_{c0_{1d}}$ increases with PC C_3A content (%). According to this, for the P-1 specimen to reach the same $V_{c0_{1d}}$ value than the P-1/M 60/40 specimen, C_3A (%) content of OPC P-1 should have been $\approx 91.72\%$, that is to say, this OPC should have been an expansive S type clinker(19), but it was not. Thence, the reason why 60% of OPC P-1 with 40% of M pozzolan, have given rise to 1 day higher $V_{c0_{1d}}$ value than plain OPC P-1, is once again the M pozzolan (40%) forming **ett-rf**(8)(9). See Figures 4 and 5.

Figure 4. L-A specimens. XRD of the POZC:PY-6/M 60/40

a) partially hydrated according to the L-A test

b) L-A specimens. Age: 7 days

However, the most interesting thing of this reasoning is that the total area defined by OPC P-1 curve would correspond to the formation of 64.60 g of **ett-lf** from the C_3A present in OPC P-1(14.11%), whereas the corresponding areas for PY-4/M 60/40 and/or PY-6/M 60/40 curves, would match at the most with the formation of 55.23 g of **ett-rf**, mainly from Al_2O_3 present in M pozzolan (23.11%), assuming that all is reactive, and if all is not reactive, which probably would be the case(8)(9), it would still be better for the final conclusion of this reasoning. Nevertheless, both areas ratio is at the most $\approx 1:10$. Here, it can be said once again(8)(9), that a great paradox can be seen(8)(9) between

behaviours (V_{c0} values v time) and theoretical stoichiometric calculations(8)(9), but behaviours holding priority.

Figure 5. L-A specimens. XRD of the POZC:PY-4/M 80/20, 70/30 and 60/40
a) partially hydrated according to the L-A test
b) L-A specimens. a) + Gypsum + H₂O Age: 7 days

Therefore, the only possible explanation of such remarkable paradox is that the reactive alumina, $Al_2O_3^{r-}$ of M pozzolan reacting to form ettringite, must be notably higher than C_3A from the OPC P-1. For this reason, the M pozzolan would form the ettringite much faster than that of the C_3A from OPC, although the quantity formed in the first case is a bit greater than in the second. For this, it can be said that such a notable reactivity of the $Al_2O_3^{r-}$ could be found in the physical-chemistry ideal state for this process. The C_3A would be an opposite case, let's say, the non-ideal, or at least, a less ideal form from the same results. Consequently, it can also be said that the formation rate of its ettringite markedly decreases, thus, the C_3A will form it more slowly, and therefore, the C_4AF will be still much slower in forming it. That is to say,

$$V_f \text{ ett-rf must be } > V_f \text{ ett-lf is } > V_f \text{ ett-vlf} \quad [3]$$

But nevertheless, it could be envisaged that $V_f \text{ ett-rf is } = V_f \text{ ett-lf}$ and their common value would be the $V_f \text{ ett-lf}$: With this supposition, whatever POZC family is considered, their curve should be their respective OPC curve. Let's say, P-n° or PY-n°/M 80/20,70/30 and 60/40 curves should be the same that their respective plain P-n° or PY-n° curve. On the contrary, this behaviour has not happened but the behaviours or classifications (Eqs. [1] and [2]) have been achieved.

Both groups of curves were achieved by drawing V_{c0} versus time and all V_{c0} values were due to the ettringites' expansion. On the other hand, the ettringite formation from C_3A present in OPC was

verified by a previous paper(8). Likewise, it was also shown that M pozzolan forms ettringite as well during their exposure to the same sulfate bearing solution(from gypsum)(8), for instance, in L-A specimens, see Figures 4(b) and 5(b).

To sum up, when comparative analysis was made between PY-6/M 60/40 and PY-4/M 60/40 curves with P-1 curve, areas, shapes and developments were different, and when made between P-1/M 80/20,70/30 and 60/40 curves with P-1 curve, were different as well. Besides, the more different the curves have been, the more OPC P-1 was replaced by M pozzolan and vice versa, or in other way, the greater the amount of M pozzolan added was, the earlier and greater high V_{c0} values were. Consequently, the initial supposition seems to be incorrect. Hence, or V_f **ett-rf** is $< V_f$ **ett-lf**, or V_f **ett-rf** is $> V_f$ **ett-lf**. But V_f **ett-rf** cannot be $< V_f$ **ett-lf** for the following reasons:

1^a.- If the two groups of curves obtained for both compared cases, are very different, the cause that gave rise to them is also very different. And if V_{c0} value of POZC P-1/M 60/40 - 14.46% -, is greater than V_{c0} value of OPC P-1 -1.62% -, or in other way, that 8.466% C_3A (= 14.11%x0.6) with M pozzolan (40%) brings about more V_{c0} than 14.11% C_3A (from plain OPC P-1), the cause is the M pozzolan when converted in **ett-rf** (Figures 4(b) and 5(b)) by means of its high pozzolanic activity at early ages (Fratini test(16) at 2 days: results,

- with gypsum(%SO₃ content = 7.0): [CaO]_{2d} = 44.50 mM/l and [OH⁻]_{2d} = 5.45 mM/l, (**ett-rf** was formed, Figures 4(b) and 5(b)), and
- without gypsum: [CaO]_{2d} = 35.00 mM/l and [OH⁻]_{2d} = 2.15 mM/l;

that is, both cements satisfied the Fratini test at 2 days).

2^a.- For this reason, the curves shown in Figures 2(a), (f) and (g) are needed: Even though the amounts of ettringite obtained for each case through theoretical stoichiometric calculations are relatively similar, their respective areas - defined by OPC P-1 curve and PY-4/M 60/40 and PY-6/M 60/40 curves- are completely different, and in addition, its shapes and developments as well. Consequently, their respective formation rates will be completely different, as well as their technological consequences once again, as well. For instance:

- $V_{c0_{1d}}$ and VNP_{1d} values raised at 1 day: OPC P-1 were quite lesser than POZC P-1/M 60/40 ($V_{c0_{1d}}$ values, see Figure 2(a): 1.62(%) /day against 14.46%/day) and VNP_{1d} , 14.25 mm against 34.30 mm), and
- $V_{c0_{7,28d}}$ and $VNP_{7,28d}$ values rised at 7 and 28 days: OPC P-1 were $V_{c0_{7,28d}}$ also less than POZC PY-4/M 60/40 and PY-6/M 60/40, see Figure 2(a), (f) and (g): at 7 and 28 days, 0.52%/day and 0.17%/day against 0.54%/day and 0.32%/day, and 0.73%/day and 0.66%/day, respectively, and $VNP_{7,28d}$ higher than POZC PY-4/M 60/40 and PY-6/M 60/40 (at 7 and 28 days, 23.8 mm and 26.4 mm against 0.00 mm, 0.00 mm, 0.00 mm and 17.0 mm, respectively).

This shows that formation rate of ettringite from reactive alumina $Al_2O_3^r$ present in M pozzolan, would turn out to be significantly higher than formation rate of ettringite from C_3A (origin of PC), and as a result and according to the Von Weimarn's and Garrido's set patterns(20)(21), **ett-rf** would have to be a much smaller size than the **ett-lf**, as it occurred in this research, see Figures 6(a) and (b) and 7(a) and (b). Von Weimarn and Garrido demonstrated that precipitation rate for a salt is directly proportional to the super-saturation grade and inversely proportional to its solubility. Besides, the set pattern of Von Weimarn(20) and Garrido(21) underlines that the more insoluble a salt is (and so the ettringite solubility varies between 0.255 and 0.024 g ett/l for water solutions with $Ca(OH)_2$ content between 0.056 and 1.08 g CaO/l while $Ca(OH)_2$ solubility in water is 1.2 g CaO/l at 18°C) the more

difficult is to produce a slow precipitation and to form big and well shaped crystals as occurred in this research, see Figures 6 and 7.

Figure 6. Ettringites of rapid formation, ett-rf

Figure 7. Ettringites of slow formation, ett-lf

Hence, according to Von Weimarn's and Garrido's set patterns, if reagents are mixed in such a way that high super-saturation takes place -as usually happens for the reactive alumina $\text{Al}_2\text{O}_3^{\text{r}}$ present in some pozzolans - fast precipitation occurs and it results in a gelatinous precipitate. This creates small crystals which are quickly formed (**ett-rf**, in this case). In contrast, if the precipitating agent is slowly added in a diluted solution - as is required for the C_3A present in OPC- there is slow super-saturation, and a precipitate constituted by macro crystals slowly appears (**ett-lf**, in this case). This means that initial rate of precipitation is proportional to $[(Q-S)/S]$, where Q is total concentration of the substance that precipitates, S is concentration of the solution in balance with the precipitate, and finally, $Q-S$ is the super- saturation when the precipitation starts. Summing up, the particle size of the precipitate decreases (**ett-rf**, in this case) when the concentration of the reagent substances increases (M pozzolan or its reactive alumina, $\text{Al}_2\text{O}_3^{\text{r}}$, in this case); and on the contrary, if crystalline precipitate (great and well-formed crystals) is preferred $[(Q-S)/S]$, the concentration has to be as small as possible(OPC or its C_3A , in this case).

On the other hand and according to Garrido, crystals that result from weak super-saturation are the same as those resulting from that vapour phase gives rise (that is to say, without solvent) to smaller crystals and growth rates correspond to faces that have an electric field. However, an inversion of the growth order is originated when the growth is performed with strong super-saturation, and the faces with strong electric field have a minimum growth rate. This inversion can be explained taking into account that when solution is strongly super-saturated, ions in solution and dipoles assume a different

configuration than when the solution corresponds to saturation. In contact with crystal-solution a different phenomenon occurs. As the solution is poorer in solvent with strong super-saturation, it must result in dissolution. This is easier to obtain in reticular surfaces with a weak electric field, which makes these surfaces increase their growth rate, which will be able to exceed the rate of the surface with strong electric field. The higher the super-saturation grade (it brings about the change of faces), the stronger the solvent-crystal link is, and the salt solubility will also be lower (the ettringite is insoluble enough). Hence, there is a very marked interaction between solvent and crystal, and the **F** forms, which have appeared in balance stage, may be replaced by **S** or **K** forms.

3^a.- At 1 day,

- POZC PY-4/M 60/40 and PY-6/M 60/40, V_{c01d} values: 0.63%/day and 0.62%/day, respectively,
- OPC P-1, V_{c01d} value: 1.62%/day, being 60% = 0.972%/day and 40% = 0.648%/day, and
- POZC P-1/M 60/40, V_{c01d} value:
 - theoretical value: $0.972\%/day + (0.63\%/day + 0.62\%/day)/2 = 1.597\%/day$, which is greater than 0.972%/day, and
 - real value: 14.46%/day, but $14.46\%/day - 0.972\%/day = 13.488\%/day$, which is greater than 0.972%/day, and than 1.62%/day, properly, that is to say, in any case, V_{c01d} of POZC P-1/M 60/40 is greater than V_{c01d} of OPC P-1; but according to results obtained, real values prevailed.

From these results, reasons and foundations, many questions about morphology and size differences of ettringites that Mehta brought up (22) can be now explained in detail.

When V_{c0xd} is 0.00(%) /day after reaching the maximum value, the ettringite formation reaction is finished. Accordingly, it can be seen in Figure 2 that for all cements considered, most of the area defined by the curves correspond to ages from 0 to 28 days. Besides, if there is M pozzolan in L-A specimen, the larger the amount of M pozzolan present, the sooner the zero value is reached. This proves that:

1st. The greatest amount of pozzolanic reactions forming ettringite from the reactive alumina, $Al_2O_3^{r-}$, present in M pozzolan, takes place during the first 28 days.

2nd. The bigger the amount of M pozzolan added to the SRPC=PY-n° is, the sooner this reaction takes place -7 days.

3rd. The bigger the C_3A amount present in OPC or SRPC, the sooner this reaction takes place.

5.2 From observation (B) 3:

It can be proved that formation of **ett-rf** and **ett-lf** in L-A specimens does not take place independently from one another, but inter-dependently or in a joint or interactive way for the closer the $Al_2O_3^{r-}$ and C_3A particles were, the more inter-dependent this formation is. This situation of maximum proximity from each other would be achieved for maximum addition of M pozzolan and OPC with high C_3A content (%), as also happened in this research for POZC specimens, P-1/M 60/40 and P-2/M 70/30 and 60/40, see Figures (a) and (b). Thus, and in order to verify this hypothesis, it can be said that,

- when these OPC, P-1 and P-2 were present in a big amount (ratios 70/30 and 80/20, respectively), or
- when these OPC were replaced by other OPC or SRPC with small C_3A content(%) (this is the case of the P-31(7.63% C_3A), P-5(6.83% C_3A) and PY-1(3.83% C_3A)),

V_{co} maximum value should have been reached after 1 day -at the age of 7 days in this case or even later- by their 60/40, 70/30 or even 80/20 POZC, which once again happened in this research for such POZC, see Figures 2(a), (b), (c), (d) and (e).

Therefore, when C₃A content was zero -case of PY-4/M and PY-6/M families-, the **V_{co}** would reach the maximum value after 7 days, which in this research was reached at the age of 28 days, see Figures 2(e) -ratio 60/40 – 2(f) and 2(g).

6. CONCLUSIONS

Through interpretation and discussion of the **V_{co}** values, the following conclusions were reached:

L-A test - parameter: **V_{co}** -, has finally proved that:

- The V_f of ettringite from the Al₂O₃^F present in M pozzolan, or **ett-rf**, is considerably higher than the V_f of the ettringite from the C₃A present in OPC, or **ett-lf**, and even higher than the ettringite from C₄AF, or **ett-vlf**, which is according to conclusions and proposals from references (8)(9).
- The **ett-rf** has a much smaller size than the **ett-lf**. This is a direct consequence of the conclusion above.

The pozzolanic reactions from Al₂O₃^F present in M pozzolan in a gypsum and water environment -L-A specimens-, formed **ett-rf** and took place all through the 28 days, starting early during the first 7 days in most of the cases studied, and the larger the content in C₃A was for the PC, the sooner those reactions finished.

The combined formation of the **ett-rf** and **ett-lf** in L-A specimens, did not take place independently from one another, but they were more or less inter-dependent or in a joint or interactive way, and the reaction products are closer to **ett-rf** than **ett-lf** when more M pozzolan is added (40%), and vice versa(20%).

ABSTRACT

Chloride penetration into concrete may lead to the corrosion of reinforcement, which is recognized to be the main cause of the lack of durability of reinforced concrete. In recent years, the chloride ingress in concrete is being studied by the measurement of the so-called chloride Diffusion Coefficient which is being used for predicting the service life. However, in the calculation of the diffusion coefficient of chlorides through concrete there are several points that there need explicit recognition of their limitations and a critical analysis. In this paper, these points are undertaken from an experimental (considering 4 different types of concrete and 2 types of mortar with different kind of binders in steady and non steady tests) and theoretical (sensitivity analysis) point of view. As a result, it can be said that the D_{ns} values cannot be used simplistically for comparing concretes without been referred to the surface concentration and to binding capacity while the D_s values represent the transport ability in a reliable way. However, if the D_s is used for service life prediction, the binding ability and the resulting surface concentration in the real environment will have to be taken into account.

1. INTRODUCTION

One of the main concerns about service life of reinforced concrete is related to corrosion of reinforcements. This distress is responsible of very expensive repairs to maintain the function, safety and aesthetics of the structure. Therefore, the calculation of the time until depassivation of the rebars is becoming an urgent need due to the engineering demand of prediction of the service life of concrete structures. The service life of the rebars is composed of two periods [1]: initiation and propagation. The most widely used methodology for determining the initiation period consists on the calculation of the diffusion coefficient of the chlorides and then using it to extrapolate to longer periods using the Fick's second law.

However, in the calculation of the diffusion coefficient of chlorides through concrete there are several points that there need explicit recognition of their limitations and a critical analysis. As a first point, in the calculation of the diffusion coefficient of chlorides through concrete it is often neglected that at least two kind of coefficients can be obtained: one of them from steady state experiments using the so-called diffusion or migration cell [2-7], or by measuring the resistivity, and the other from non-stationary experiments [8, 10]. These coefficients are called in literature reversibly as effective, D_{eff} , or apparent, D_{app} . In order to avoid any confusion, in present paper they will be named as D_s = stationary value of diffusion coefficient and D_{ns} = non-stationary value. Concerning the meaning of these two coefficients, D_s tries to characterize the transport itself, assuming that the flux of chlorides is constant in time. On the other hand, D_{ns} takes into account not only the transport, but also the binding of chlorides with cement phases, and therefore it is used for predicting purposes.

As a second point, different experimental conditions in non steady state conditions lead to different diffusion coefficients [11,12,13], which makes the problem of obtaining realistic values of D_{ns} very difficult to be solved. In addition, it has been noticed that D_{ns} varies in function of the surface chloride concentration, and in function of the time. Regarding C_s , it will depend not only on the concrete composition, but also on the external concentration, which in many situations will be so unpredictable as the weather is. With respect to the time law of evolution of D_{ns} , it differs with the type of cement [14] and other circumstances still not well known, probably related to the evolution in the binding ability, which is the third point to take into account [15,16].

Taking this in mind, a comparative exercise of these coefficients as well as the possibility of using them for prediction purposes, or as input parameters for service life models, needs a critical analysis considering different types of concretes and binders, which is the objective of this paper. So, in this contribution some experimental results, as an illustration of the extensive discussion on the key points described above, for different types of concretes and binders at different times, are presented.

2. EXPERIMENTAL

2.1 Materials and procedures

In order to cover in this study a wide range of conditions, several types of cementitious matrix (4 different types of concrete and 2 types of mortar) with different kind of binders have been used. The design of the different mixes are detailed in table 1.

Table 1. Mixes of the materials used.

label	1	2	3	4	5	6
Type of matrix	C	C	C	C	M	M
Cement	I-42.5 R/SR	I-42.5 R/SR	I-42.5 R/SR	I-42.5 R/SR	IV-B/32.5 SR/BC	IV-B/32.5 SR/BC
Addition	none	140 (FA)	36 (SF)	140 (FA) 36 (SF)	FA (as part of the cement)	FA (as part of the cement)
w/c	0.45	0.45	0.45	0.45	0.37	0.49
cement (Kg/m ³)	400	260	364	224	708.3	
Cement + sand	-----	-----	-----	-----	-----	1948
sand (Kg/m ³)	911	911	911	925	1239.4	-----
Gravel (Kg/m ³)	949	949	949	885	-----	-----
Remarks: C: Concrete, M: Mortar, FA: Fly ash, SF: Silica Fume						

All the specimens were cylindrical of 75 mm in diameter and 150 mm in high. They were demoulded after 24 hours of being cast and were cured during 28 days in a humid chamber (95% HR). After this period, the porosity of each mix was evaluated by mercury porosimetry and two specimens of every mix were tested to determine the D_s , (by migration tests) according to the procedure in [17], and the D_{ns} (by diffusion tests with different durations of the exposure to the chloride solution) according to [18]. The rest of specimens were sealed. One year later, two specimens of every dosage were removed from storage, their porosity measured and the coefficients analysed. Some other specimens kept sealed for two years more and at the age of three years they were tested to determine the D_s .

Prior to the tests, the specimens were pre-treated for saturation under vacuum following the standard ASTM C1202-91. The experimental conditions of the tests were:

2.1.1 Migration tests

Distilled water was introduced in the compartment where the anode was placed (anolyte), while the cathodic compartment was filled with a solution 1 M NaCl. The voltage drop applied was of 12 V DC.

Black steel bars were used as electrodes. Periodically during the experiment, Cl^- concentration in the anodic compartment was monitored to know the flux of chlorides.

2.1.2 Diffusion tests

Sealed specimens in a ponding device full of a solution 1 M of NaCl. After different periods of exposure, the chloride profiles were measured by milling the surface of the specimen, exposed to the chloride solution, layer by layer and analysing the powdered samples obtained. From these profiles, the D_{ns} were calculated by fitting to the Fick's second law.

3. RESULTS

The steady state diffusion coefficients, calculated according the procedure and equations given in [17], are presented in Figure 1, where it can be seen that for concrete mixes (1 to 4) there is not a noticeable decrease in the values obtained as the age of the matrixes increases. As long as the mortars are concerned, a more pronounced decrease has been produced.

Figure 1. Steady state chloride diffusion coefficients obtained for the 6 mixes after curing in humid chamber for 28 days and after 1 and 3 years sealed.

The non-steady state diffusion coefficients calculated after milling the specimens and analysis the chloride content according the procedure and equations given in [18], are given in table 2 and in Figure 2. In table 2, the diffusion coefficients as well as the surface concentration and the correlation of the fitting to the Fick's second law are given.

From Figure 2, it can be deduced that the data corresponding to concrete dosages (1 to 4) can be correlated (in function of the duration of the test) all together, independently of having been exposed to the chloride solution after curing for 28 days or after one year sealed. Therefore, for these concretes, it seems that there is not a significant influence in the delay of exposure to chlorides in the coefficient obtained. It can be also noticed that for the dosage 1, cast with OPC low in aluminates, there is not a decrease in the diffusion coefficient as long as the test or age of the specimens increases. The case of mortars is different (dosages 5 and 6) as there is a difference depending on the delay to the exposure to chlorides which, in addition, does not follow the same trend for the two mixes studied. The temporal evolutions of the coefficients given in table 2 have been fitted to potential equations. The factors encountered and the correlation coefficient are given in table 3. In the case of mortars only the data obtained after one year have been used in the fitting. From data of table 3 it can be deduced that the decreasing slope is different depending on the type of mix and binder (parameter b), and that a general rule can not be established.

Table 2. D_{ns} diffusion coefficients, surface concentration and correlation of the fitting to the Fick's second law for the different mixes and conditions

Curing		28 days	28 days	28 days	1 year	1 year	1 year	1 year
Duration of the test		3 months	1 year	2 years	3 months	1 year	1.5 year	2 years
1	D_{ns}	21.0 E-8	----	----	32.2 E-8	57.9 E-8	22 E-8	48.6 E-8

5	1E-8	0.4929	0.980
6	1E-8	0.6914	0.922

Figure 2. D_{ns} for different time of exposure to chlorides and at different delay in exposing them.

4. DISCUSSION

From the comparison of the two types of coefficients obtained, it could be said that the D_s is a more “reliable” coefficient, as provided that the material does not change, the values that are obtained are quite consequent and the scatter among them is reasonable (see Figure 1). This is due to the fact that it only accounts for the porous network of the material. So, it does not depend on so many parameters as the D_{ns} . The differences among these two kind of coefficients can be illustrated by depicting them in function of the porosity of the matrix (Figure 3 (a-b)).

Figure 3. (a-b) a) D_s and b) D_{ns} in function of the porosity (% vol) of the cementitious matrix.

Figure 3, which includes the data for 28 days and after 1 year, shows very clearly that there is a relationship between the porosity and the steady state diffusion coefficient. However, there is no sign of relationship when trying to correlate with the D_{ns} . This is due to the fact that the D_{ns} depends on several factors, which are going to be analysed as follows:

4.1 Influence of time

The evolution of D_s with time was shown in Figure 1 and that of D_{ns} in Figure 2. In both cases, the D values either remain nearly constant or decrease with time, although the trends are not consistent with the cement type, as D_s remains almost constant in the four concrete mixes, while D_{ns} only does in the OPC-low C3A concrete. For the rest of the concretes, there is not a general trend to be established.

4.2 Influence of C_s

In present experiments, the C_s is different due to the mixes being different in spite of the fact that the external concentrations of the testing solutions are the same. Again porosity and binding ability influence the C_s values obtained. In the case of D_s values, their calculation is based in the external solution concentration and therefore, it could be deduced that they are independent of C_s . However, it has been demonstrated [18] that the D_s increase as the external concentration decrease. That is to say, as more diluted is the external solution, higher is the D_s value.

In order to understand the influence of C_s , in Figure 4 (a-d) several examples have been plotted. Figure 4-a shows the experimental C_s for the different concretes and binders tested. Figure 4-b illustrates that for the same C_s , the lower D_{ns} , the lower is the concentration of chlorides at a certain distance from the surface. Figure 4-c shows the profiles for the same D_{ns} but with 3 different C_s , where the deduction indicates that very different concentration of chlorides can be found at the same distance, lower as lower is the C_s , for the same D_{ns} . Finally, in Figure 4-d an extreme example is shown. In this case, a lower D_{ns} with higher C_s gives higher chloride concentration values until 9 mm depth. These examples

indicate that a value of D_{ns} not referred or standardized to a C_s value is certainly misleading from the point of view of the onset of reinforcement corrosion.

4.3 Influence of binding ability

The influence of binding in the values of D_s and D_{ns} can be studied by using the equation (1) given in [19], assuming a linear binding.

$$\frac{D_s}{D_{ns}} = \varepsilon + (1 - \varepsilon) \frac{C_s}{Cl} = \varepsilon + (1 - \varepsilon) \gamma \quad (1)$$

ε is the volumetric fraction of pores and C_s and Cl are the concentrations (mol/cm^3) in the solid and liquid respectively. The ratio among these variables is γ .

Taking into account that D_s can be considered as dependent on the porosity (Figure 3-a), using the correlation obtained in present research this variable is put in function of the other and equation (1) can be plotted as in Figure 5, where the three-dimensional map showing the D_{ns} in function of D_s and C_s/Cl (γ).

Figure 4. (a-d): Influence of C_s : a) experimental C_s for the different concretes and binders tested. B-d) Profiles of chlorides obtained, according to the second Fick's law, after 50 years for : b) different D_{ns} and the same C_s , c) the same D_{ns} and three different C_s , and d) different D_{ns} and different C_s .

Figure 5. Three-dimensional plot of equation 1, giving D_{ns} in function of D_s and C_s/Cl .

From equation 1 and Figure 5, it can be deduced that if: a) $C_s < Cl$, $D_s < D_{ns}$; b) $C_s = Cl$, $D_s = D_{ns}$ and c) $C_s > Cl$, $D_s > D_{ns}$. That is to say, the relation D_s/D_{ns} is determined by the binding ability.

As an example illustrating the influence of binding of chlorides with solid phases, the resulting profiles after 50 years of exposure to chlorides are depicted in Figure 6-a considering that they correspond to different concretes with the same capillary net or resistivity, which means the same D_s ($3E-8$ cm²/s in this example), but having different binders and therefore different binding abilities.

For the same C_s , the Figure illustrates a logical trend that indicates that the chloride concentration is smaller at a certain depth as binding ability is higher, which deals to smaller D_{ns} values. However, again the trend might not be logical if instead of a constant C_s , the binding ability means also different C_s values. Let us consider two different γ values. For example 1) $\gamma=0$ and 2) $\gamma=0.5$. Assuming an external concentration of 0.5 M and so the same concentration in the pore solution of the most external layer of the concrete, for the same D_s (the same porosity) the C_s would result in 0.09% for $\gamma=0$ and $C_s=0.43$ for $\gamma=0.5$. Figure 6-b depicts the resulting profiles indicating that a higher γ would be negative because it would allow higher chloride concentrations at the same depth, that is, that higher amounts of chlorides will be found near the reinforcement in spite of the lower D_{ns} and higher binding ability.

This allows the deductions that the total amount of chlorides can be a misleading parameter and that the free amount of chloride ions in the pore solution has to be determined, and that it seems that the C_s is a very influencing parameter on the risk of reinforcement corrosion.

Figure 6. Profile of chlorides obtained, according to the second Fick's law, after 50 years for concretes with the same D_s but different binding ability (γ) and therefore, different D_{ns} : a) without considering the influence of binding on C_s and b) considering the influence of binding on the C_s .

5. CONCLUSIONS

The main conclusions that have been drawn out from the results of present paper are:

- 1) The D_{ns} values cannot be used simplistically for comparing concretes without been referred to the surface concentration and to binding capacity. The D_{ns} values alone are misleading regarding the prediction of the onset of reinforcement corrosion.
- 2) The D_s values seem to be less misleading as they represent the connectivity of pores (transport capacity). However, binding and the resulting surface concentration in the real environment have to be accounted for the sake of service life prediction.

Marta M^a Castellote

The Author is a Doctor in Industrial Chemistry. She has been working in the Institute of Construction Science "Eduardo Torroja" (IETcc) from October 1993. She was awarded with the special distinction of the University of Zaragoza (Spain) for her PhD, in 1997. Her research has been mainly focussed in the application of electrical fields to concrete, for the characterisation of the ionic transport through concrete, as well as for decontamination purposes. In addition, she is working in the application of Advanced Techniques (Synchrotron Radiation and Neutron Diffraction) in the characterisation of solid cementitious materials.

RESEARCH ON A NEW KIND OF MINERAL ADDITIVE OF CONCRETE: FINE POWDER OF STEEL-MAKING SLAG

Yimin Chen, Hongtao Zhang, Zhen Lin, Suihua Guo and Wensheng Zhang

China Building Materials Academy, Beijing 100024; Email: chenym1@163.com

ABSTRACT

This paper gives the experiment results on a new kind of mineral additive made from steel-making slag. Experiment results show that the fine powder of steel-making slag may used to produce concrete with strength grade from C20 to C60. It can replace from 10% to 50% of cement in concrete and the best amount of replacement is between 20% to 25%. It can be used in plastic concrete and flowing concrete. The effect of fine powder of steel-making slag on strength and workability of concrete is similar to other mineral additives.

Keywords: fine powder of steel-making slag, concrete, mineral admixture

1. INTRODUCTION

Mineral additives, as a component part of concrete, play an increasingly important role in concrete. It not only decreases the cost of concrete but also improves the performance of concrete. High quality mineral additives, i.e. powder of blast furnace slag, 1st grade fly ash, silica fume, have become a necessary part of high performance concrete. In recent years, nearly all high strength concrete and high performance concrete contain part of fine powder of blast furnace slag or 1st grade fly ash.

Steel-making slag is the waste in steel production and its annual amount in China is more than 10 million tons. Steel-making slag has been used in cement as mineral additive[1] for more than 30 years and in China. There is a national standard for cement containing steel-making slag [2]. But only a little research on it as a concrete additive has been done[3], and it has not been successfully and widely used because its properties were not good enough; it is too difficult to be ground, its composition is changeable, it is not sufficiently reactive and not stable volume. This paper gives excellent results of powder of steel-making slag as an active mineral additive of concrete.

2. MATERIALS

Steel-making slag was taken from two steel corporations: one from Beijing (B) and the other from Wuhan (W). They were ground to finer than $400\text{m}^2/\text{kg}$ and became active mineral additives for concrete. Their chemical compositions are listed in Table 1. The ratio of $\text{CaO}/(\text{SiO}_2+\text{P}_2\text{O}_5)$ must be higher than 2.0 for high reactivity. The content of iron is less than 1% and free CaO is limited to less than 5% for the necessary of soundness. Autoclave testing shows that the soundness of cement with as high as 45% fine powder of steel-making slag is still good enough.

Three kinds of cement were used: 525 Portland cement P.525, 525 ordinary Portland cement (P.O.525) which containing less than 15% mineral additive, 425 ordinary Portland cement (P.O.425) which containing about 15% mineral additive. Table 2 lists the properties of cement. Four

kinds of commercial water-reducer, FDN, JSP-IV, HH-2, JYD-3, were used. Fine aggregate was sand and coarse aggregate was 5-25mm stone.

Table 1. Chemical compositions, specific gravity and specific area of steel-making slag powder

Chemical compositions (wt%)												Sp. gravity	Sp. area
No.	Loss	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	P ₂ O ₅	R ₂ O	TiO ₂	Fe	g/cm ³	m ² /kg
B	0.79	15.28	5.31	18.55	43.15	12.39	0.10	0.92	0.06	1.06	0.68	3.17	460
W	1.65	11.22	0.94	22.45	43.13	6.63	0.19	2.33	0.10	--	0.56	3.12	459

Table 2. Properties of cement

No.	Specific area m ² /kg	Water requirement of normal consistency %	Soundness	Setting time (h : min)		Compressive strength (MPa)			Flexural strength (MPa)		
				initial	final	3d	7d	28d	3d	7d	28d
P.525	323	27.6	Pass	3:15	4:35	5.2	-	9.0	34.7	-	61.5
P.O.525	335	27.3	Pass	4:13	5:38	6.0	7.9	9.2	33.2	48.1	61.8
P.O.425	310	26.7	Pass	4:18	5:50	4.0	5.6	7.1	26.4	38.7	49.8

3. EXPERIMENT RESULTS OF PLASTIC CONCRETE

Table 3 lists compositions, slump and strength grade of plastic concrete made from P.525 cement, in which 10~50% cement is replaced by W steel-making slag powder. The water/binding materials is 0.32 and the slump of concrete varies from 60mm to 80mm. FDN is high effective water-reducer, polymethylene naphthalene sulfonate. Figure1 gives the relationship between strength.

Table 3. Composition, slump and strength grade of plastic concrete

No.	Composition(kg/m ³)						W/B	Slump (mm)	Strength grade
	Cement	Steel-making slag	Water	Sand	Stone	FDN			
1-1	520	0	190	626	1113	3.6	0.32	78	C60
1-2	468	52	190	626	1113	3.6	0.32	75	C60
1-3	416	104	190	626	1113	3.6	0.32	72	C60
1-4	364	156	190	626	1113	3.6	0.32	70	C55
1-5	312	208	190	626	1113	3.6	0.32	68	C55
1-6	260	260	190	626	1113	3.6	0.32	60	C45

Figure 1. Concrete strength vs amount of steel-making slag powder replacing cement

It is shown that the strength of concrete did not obviously change when 10% or 20% cement is replaced by steel-making slag powder and the strength grade remains C60. When 30% to 50% cement is replaced, concrete strength decreases with the increasing of steel-making slag powder added. The early strength decreases more obviously than the long-term strength, which indicated that steel-making slag powder helps concrete strength increasing with time.

4. EXPERIMENT RESULTS OF FLOWING CONCRETE

4.1 Concrete adding 15%~35% steel-making slag powder from Beijing

Table 4 lists concrete composition with 10% to 35% steel-making slag powder from Beijing. In the compositions binding material (cement and mineral admixture) is 514kg/m^3 and the ratio of water/(cement + mineral additive) is 0.37. P.O.525 cement is used and from 10% to 35% of cement is replaced by steel-making slag powder. Slump of concrete is about 220mm.

Figure 2. gives the relationship of concrete strength with the amount of steel-making slag powder. Strength of the four samples at 28 day are higher than 55MPa. Between 15% to 25%, with steel-making slag powder increasing the concrete strength at 7 day does nearly not change and at 28 day gradually increases. When adding 25% steel-making slag powder, the strength of concrete reaches the highest one. When 35% cement is replaced by steel-making slag powder, 7 day strength of concrete decreases obviously and 28-day strength is similar to that with 15% steel-making slag powder. So, in this case, suitable content of steel-making slag powder as mineral admixture will improve concrete strength, especially the long term strength, and optimum amount is 25%. Even if 35% cement is replaced by steel-making slag powder, 28-day strength can be as high as that containing 15% steel-making slag powder.

Table 4. Composition and strength concrete with 15% to 35% steel-making slag powder

No.	Steel-making slag	Composition(kg/m^3)						Strength (MPa)	
		Cement	Steel slag	Water	Sand	Stone	JSP-IV	7d	28d
ZH-1	15%	437	77	190	681	1065	9.3	50.7	55.4
ZH-2	20%	411	103	190	681	1065	9.3	49.1	58.3
ZH-3	25%	385	129	190	681	1065	9.3	51.0	63.0
ZH-4	30%	360	154	190	681	1065	9.3	47.7	58.1
ZH-5	35%	334	180	190	681	1065	9.3	41.6	55.6

Figure 2. Effect of content of steel-making slag powder from Beijing to concrete strength

4.2 Concrete containing 30% steel-making slag powder from Beijing

In Table 5, concrete is made from 70% P.O.525 cement and 30% steel-making slag powder from Beijing. The water/ binding materials ratio changes during 0.35 and 0.47 and binding materials content changes during 550 kg/m³ and 385 kg/m³. Figure 3 shows that concrete strength increases with the increase of amount of binding materials containing 30% steel-making slag powder and with the decrease of water/binding material ratio, which is same to the regular pattern of concrete strength.

The strength grade of concrete in Table 5 locates in C30 to C40. When cement amount is 269kg/m³, steel-making slag powder is 116 kg/m³ and water/binding material is 0.47, concrete strength grade is C30. When cement is 291kg/m³, steel-making slag powder is 124 kg/m³ and water/binding material is 0.44, concrete strength grade is C35. When cement is 311kg/m³ and 353kg/m³, steel-making slag powder is 142kg/m³ and 152kg/m³, and water/binding material is 0.35 and 0.41, concrete strength grade is C40.

Table 5. Composition and strength of concrete with 30% steel-making slag powder and various amounts of binding materials and water/binding material ratio

No	W/B	Composition (kg/m ³)						Bind Material (kg/m ³)	Slump (mm)	Strength (MPa)	
		Cement	Steel slag	Water	Sand	Stone	HH-2			7d	28d
8-1	0.35	353	152	166	687	1031	15.15	505	210	44.0	52.1
8-2	0.38	333	142	171	715	1030	14.25	475	220	37.7	49.9
8-3	0.41	311	134	173	745	1028	13.35	445	230	34.4	49.6
8-4	0.44	291	124	174	775	1028	12.45	415	220	32.0	44.0
8-5	0.47	269	116	173	807	1027	11.55	385	210	30.1	37.8

Amount of P.O.525 cement and steel-making slag powder (kg/m³)

Figure 3. Concrete strength made from P.O.525 vs amount of binding materials with 30% steel-making slag powder

In the composition of concrete in Table 6, binding material is also combined with 30% steel-making slag powder from Beijing and 70% P.O.425 cement. The amount of cement and steel-making slag powder is between 510 kg/m³ and 340kg/m³. Water/binding ratio is between 0.375 and 0.55. Figure 4 is the curves of concrete strength to amount of cement and steel-making slag powder.

The data shows the same regularity with the concrete adding other mineral admixtures and with Table 5 and Figure 3. Concrete strength grade is between C20 to C40. By comparing Table 5 and Table 6, it can be observed that, in the case adding 30% steel-making slag powder from Beijing, the

influence of water/binding material ratio on the strength of concrete is stronger than that of cement strength.

Table 6. Composition and strength of concrete made from 70% P.O.425 cement and 30% steel-making slag powder from Beijing

No.	W/B	Composition (kg/m ³)						Slump (mm)	Strength (MPa)		
		Cement	Steel slag	Water	Sand	Stone	JYD-3		3d	7d	28d
11-1	0.55	238	102	187	991	897	10.2	185	11.6	23.0	31.8
11-2	0.49	266	114	187	915	933	11.4	210	12.4	26.8	40.4
11-3	0.45	294	126	187	841	967	12.6	195	15.5	31.6	43.1
11-4	0.41	328	138	188	769	998	13.8	200	19.4	34.9	50.5
11-5	0.37	357	153	190	695	1020	15.3	205	25.1	40.5	51.9

Figure 4. Strength of concrete made from 70% P.O.425 cement and 30% steel-making slag powder from Beijing vs amount of binding materials

4.3 Concrete containing 25% steel-making slag powder from Wuhan

Table 7 lists the composition of concrete made by 75% P.O.525 cement and 25% steel-making slag powder from Wuhan. Table 8 lists their slump and strength testing results. Figure 5 gives the relationship between concrete strength and amount of binding materials. In these compositions, water-reducer, FDN, is the pure polymethylene naphthalene sulfonate and does not contain set-retarding component, so the slump loss after 60 minutes may be a lot. From the results it is indicated that adding steel-making slag powder can effectively improve concrete workability. The strength grade is between C25 and C55, which is in the reasonable range.

Table 7. Composition of concrete with 25% steel-making slag powder from Wuhan

No.	Binding material (kg/m ³)	W/B	Composition (kg/m ³)					
			Cement	Steel-making slag powder	Sand	Stone	Water	FDN
12-1	582	0.33	436	146	582	1036	192	4.1
12-2	488	0.39	366	122	634	1083	190	3.4
12-3	386	0.48	289	97	677	1104	185	2.7
12-4	286	0.61	215	71	721	1124	174	2.0

Table 8. Slump and strength of concrete with 25% steel-making slag powder

No.	Binding material (kg/m ³)	Steel-making slag powder (%)	Slump (mm)		Strength(Mpa)			Strength grade
			Initial	60min	7d	28d	90d	
12-1	582	25	216	188	49.4	62.1	70.8	C55
12-2	488	25	210	176	45.6	53.3	66.2	C45
12-3	386	25	204	160	34.2	46.9	52.7	C40
12-4	286	25	198	144	21.7	31.8	39.4	C25

Figure 5. Concrete strength made from 75% P.O.525 cement and 25% steel-making slag powder from Wuhan vs amount of binding materials

5. CONCLUSIONS

- (1) After being ground to finer than 400m²/kg, fine powder of steel-making slag can be used as a mineral additive for concrete. It is suitable for both plastic concrete and flowing concrete.
- (2) Fine powder of steel-making slag can be used in C20 to C60 grade concrete to replace cement from 10% to 50%. In some cases, its benefits are to improve concrete properties, and the optimum addition is 20% to 25%.
- (3) The regularity of the effect of steel-making slag powder on concrete strength is similar to other mineral additives. It contributes to increasing long term strength of concrete and is favorable for decreasing the slump loss of concrete.

ABSTRACT

This paper describes the stabilisation of a ferro-vanadium waste in various ways. In each case a combination of the ferro-vanadium waste together with fly ash was employed for this purpose. The methods investigated ranged from physical encapsulation in different matrices to high temperature immobilisation in solid products.

Keywords: stabilisation/solidification, fly ash, environmental, ferro-vanadium waste.

1. INTRODUCTION

Fly ash produced from coal combustion possesses many physical and chemical properties that make it eminently suitable for use in the cement and concrete industries. The combination of fly ash and cement with hazardous waste offers a number of novel ways to treat side product streams from several industries. These treatments are based on the solidification, immobilisation and encapsulation of wastes through various physical, thermal and chemical mechanisms. South Africa is a major producer of various ferro-alloy raw materials, for example ferro-chrome, ferro-silicon and ferro-vanadium, to name but a few. These industries produce a number of waste products that can be potentially harmful to the environment and require treatment or controlled land filling to minimise their harmful effects.

It is well known that fly ash can be utilised as a component of raw meal in cement production [1]. Wastes combined with fly ash can be used as one option to immobilise harmful elements originating from the waste, after thermal treatment. However, a pre-requisite for this route of treatment, is that the burnability of the cement raw mix not be compromised by the addition of any foreign material added to it.

A further thermal treatment that renders waste harmless or at least decreases interaction with the environment is sintering with fly ash. Using this method it is possible to create useful products from the process, for example lightweight aggregates and ceramic filters/tiles (Kruger R, private communication).

The pozzolanicity of fly ash offers another route for the treatment of wastes. Together with a suitable activator, like lime, it can be mixed with the waste to harden in a solid cementitious matrix. In this way the potentially harmful elements present in the waste can be incorporated in a durable matrix, which can present both a physical as well as chemical barrier against its contact with the environment.

The addition of fly ash to concrete offers many potential advantages in different applications of concrete. Should the concrete be used to encapsulate waste of some form or another, the well-documented ability of fly ash to adsorb heavy metal elements [2], that can potentially be present in an untreated waste, would certainly enhance the effectiveness of this proposed treatment option. In addition, the greater durability imparted by the fly ash to the final concrete element [3] would further contribute to a reduced risk of potential leaching.

The current work will describe the application of all the above-mentioned options to utilise fly ash to render a waste from a South African ferro-vanadium producer less harmful to the environment.

2. EXPERIMENTAL PROCEDURE

Industrial materials were used in this investigation. Their compositions were measured by XRF analysis following the standard method used in the XRD & XRF laboratory of the University of Pretoria, as adapted from H. Bennett and G. Oliver's proposed methods and are given in Table 1.

Table 1. Chemical composition of the materials used in the investigation.

%	PPCLIME	LETHABO FA	WASTE
SiO ₂	0.37	52.59	2.71
TiO ₂	<0.01	1.68	11.96
Al ₂ O ₃	0.20	34.59	3.70
Fe ₂ O ₃	<0.01	3.15	75.91
MnO	0.71	0.04	0.35
MgO	1.13	1.06	0.98
CaO	71.57	4.08	0.56
Na ₂ O	<0.03	0.17	2.10
K ₂ O	<0.01	0.60	<0.01
P ₂ O ₅	<0.01	0.28	<0.01
Cr ₂ O ₃	<0.01	0.04	0.27
V ₂ O ₅	<0.01	0.04	0.45
LOI	25.42	0.57	0.07
Total:	99.43	98.99	96.96

2.1 Immobilisation

A typical cement raw mix was compiled with various amounts of ferro-vanadium waste and fly ash in addition to the usual limestone and clay components. The burnability of these mixes was evaluated according to the F.L. Schmidt method[5] by measuring the residual amount of free lime[6] at various clinkering temperatures. For the production of cement clinker, an LSF (lime saturation factor) value of 95 was selected, together with a SR (silica ratio) of 2.7. Since the coal used to fire cement kilns result in a fly ash incorporation of typically 1.9 – 3.5% in the clinkers, 2.0% of the Lethabo fly ash was incorporated into all the cement raw meal mixtures investigated.

Ferro-vanadium waste additions varied between 0.5 to 2.0% by mass. The effects of the waste incorporation on the burnability of the clinkers are summarised in Table 2.

2.2 Solidification

For the thermal encapsulation of the waste, various proportions of fly ash and ferro-vanadium wastes were nodulised and then heated at different temperatures to form sintered lightweight aggregates. For lack of suitable apparatus to measure the abrasion resistance of the material manufactured, two crude in-house tests have been developed to determine the robustness of the lightweight aggregates produced in this way. In the first instance the materials were dropped 20 times from a standard height of 1.5 m onto a ceramic tiled concrete floor. If it did not break, it was considered tough enough for practical use and application. In the second test, 100 g of sintered nodules was stirred at 300 rpm in a steel container on a magnetic stirrer for 30 minutes and the mass of powdered material produced in this period measured by sieving it through a 1mm screen. The mass of powder passing the screen was expressed as a percentage of the original mass of material used. Sintered material producing less than 2.5% powder was considered suitable for use as lightweight aggregate. The mixtures used, clinkering temperatures investigated and the results obtained, are summarised in Table 3 and Figure 1.

2.3 Encapsulation

In an attempt to render the ferro-vanadium waste less exposed to the environment, encapsulation in various lime-fly ash mixtures, as well as in concrete mixtures were attempted. In the case of the lime-fly ash mixtures, curing after stripping from the moulds after one day was done at 45 °C, while in the case of concrete normal water curing was performed. Strength measurements after various time intervals were performed according to standard test methods [7]. The mixtures used and results obtained in each case, are summarised in Tables 4 and 5, as well as in Figures 2 and 3.

3. RESULTS AND DISCUSSION

From the results in Table 2, it can be seen that an increasing clinkering temperature leads to a decrease in the residual free lime present. This indicates that the phase forming reactions have been more complete at the higher temperatures than at the lower ones. In similar laboratory studies with normal production raw meal, lower free lime contents are normally encountered at all the clinkering temperatures investigated. The burnability of the raw meal containing waste should thus be optimised further before it can be considered for possible plant application. This can be accomplished by simultaneous adjustments to the LSF and SR to ensure the optimum amounts of silicate materials available to combine with the lime from the calcined limestone in the raw meal. Furthermore, an increase of the waste content at the same clinkering temperature increase the amount of free lime remaining unreacted. From this it can be concluded that the amount of waste in the raw mix should preferably be limited to no more than 1% and the clinkering temperature should preferably not be less than 1450°C.

Table 2. Burnability of various clinkers incorporation fly ash and ferro-vanadium waste.

Clinkering Temperature (°C)	% Ferro-vanadium waste	Residual Free CaO (%)
1350	0.5	11.8
1350	1.0	12.2
1350	1.5	13.0
1350	2.0	13.9
1250	0.5	19.2
1300	0.5	12.3
1350	0.5	11.8
1400	0.5	11.2
1450	0.5	10.2

The results presented in Table 3 and Figure 1 indicate that, by increasing the percentage waste in the lightweight aggregate by 10%, one saves some money on the raw materials used, but requires an additional 100°C thermal energy to achieve about the same degree of durability. The durability of the lightweight aggregate is a function of both the composition as well as the sintering temperature. In the lime-fly ash mixtures reasonable strengths for handling purposes can only be achieved if the amount of lime is at least 24% of the total mixture, i.e. roughly one quarter of the final mix.

Table 3. Mixes used for lightweight aggregate production.

% Fly ash	% Ferro-vanadium waste	Sintering temperature (°C)	“Drop – test” durability	% Powder
80	20	850	Friable and brittle	9.5
		900	Break after dropping twice	6.4
		950	Break after dropping 5-7 x	3.9
		1000	Break after dropping 14-17 x	1.8
		1050	Durable – doesn’t break	0.5
		1100	Durable – doesn’t break	0.3
90	10	850	Break after dropping 6-8x	3.6
		900	Break after dropping 15-18 x	1.3
		950	Durable – doesn’t break	0.2
		1000	Durable – doesn’t break	0.08
		1050	Durable – doesn’t break	0.02
		1100	Durable – doesn’t break	0.01

Figure 1. Durability of sintered lightweight aggregates

The compositions of the various lime-fly ash mixtures are given below in Table 4, while Figure 2 schematically represents the strength at various ages. The compositions of the concrete mixtures used in the investigation are given in Table 5. The strength obtained in each case is graphically represented in Figure 3.

Figure 2. Strength developments in lime-fly ash-waste mixes

Figure 3. Compressive strengths of various concrete mixtures

The final strengths of all the concrete mixes were satisfactory for practical applications and the substitution of cement with a combination of fly ash and ferro-vanadium waste can result in a sizeable saving for the final mixture without compromising its performance. Table 6 indicates that the best possible savings can be achieved by encapsulating the ferro-vanadium waste with a combination of cement and fly ash. One will obviously have to assess the potential amount of leaching in each of the cases investigated before a final verdict can be given on the best treatment option future. This is currently under investigation in our laboratories.

Table 6. Economic comparison of various methods of treatment.

Treatment Method	Normal raw materials costs (R/ton; R/m³)	Raw materials costs with waste (R/ton; R/m³)	% Savings
Sintering as lightweight aggregate (20% vs 10 %)	R 45-00	R 43-00	4.4%
Immobilisation in cement clinker	R 80-00	R 78-50	1.9
Encapsulation in lime-fly ash (M1)	R 100-00	R 97-50	2.5
Encapsulation in concrete (A vs F)	R 300-00	R 280-00	6.7

In an effort to establish whether any chemical interactions have occurred between the solidified waste and the solid matrix, spectroscopic techniques have been used to study some of the lime/fly ash/ ferro-vanadium waste samples prepared. Infrared spectra of the processed samples dispersed in KBr pellets were recorded at Pretoria University; in general, all samples yielded very similar spectra, and no trend was observed. Only one sharp band was observed: it was in the 3640 wave number region and is indicative of a hydroxyl group. The remaining broad bands are in the 1400 and 1100 wave number region and consist of several closely overlapped bands, which have not yet been deconvoluted and hence not identified. A typical example of the spectra obtained is shown in Figure 4. The most striking observation is that there are hardly any changes in the spectra of the various samples.

The FT-Raman spectra were recorded at UNISA; no sample preparation was necessary. Unfortunately the feature that is common to cement samples in general was also observed with the present samples: an excessive amount of fluorescence. The samples were illuminated with only a few mW of laser power (1064 nm wavelength). The broad fluorescence band was centered at about 2000 wave numbers; it was possible to observe some broad band in the 750 wave number region, which varied in intensity from sample to sample - but no trend was evident. A few samples exhibited broad bands in the 1100 wave number region - again with no observable trend. A typical example of the spectra obtained is shown in Figure 5. It should be noted that intensity variations are common for Raman spectra, where the observed scatter is a function of the orientation and size of the crystallites.

When the Raman spectra were recorded at low temperature, the fluorescence was reduced, the observed broad bands sharpened considerably, and additional bands could be observed in the 1100 and 1400 wave number region. Further low temperature studies of cement-related compounds may be of interest.

Figure 4. Typical IR spectra of a lime - fly ash – waste mixture

Figure 5. Typical Raman Spectra of a lime – fly ash – waste mixture

4. CONCLUSIONS

The following conclusions can be drawn from this investigation:

1. Increasing the percentage waste in the lightweight aggregate by 10% saves some money on the raw materials used, but requires an additional 100 °C thermal energy to achieve about the same degree of durability.
2. The durability of the lightweight aggregate is a function of both the composition as well as the sintering temperature.
3. In the lime-fly ash mixtures reasonable strengths for handling purposes can only be achieved if the amount of lime is at least 24% of the total mixture, i.e. roughly one quarter of the final mix.
4. The final strengths of all the concrete mixes were satisfactory for practical applications and the substitution of cement with a combination of fly ash and ferro-vanadium waste can result in a sizeable saving for the final mixture without compromising its performance.
5. The best possible savings can be achieved by encapsulating the ferro-vanadium waste with a combination of cement and fly ash. One will obviously have to assess the potential amount of leaching in each of the cases investigated before a final verdict can be given on the best treatment option future.
6. Spectroscopic techniques applied were not able to detect any interaction between the solid matrix used and the incorporated ferro-vanadium waste.
7. Incorporation of ferro-vanadium waste into a variety of solid matrices can successfully treat it and a reasonable savings can be achieved in the cost of the products produced. Leaching tests are currently underway to assess the success of incorporation of the Fe-V waste in various solid matrices.

ACKNOWLEDGEMENTS

Pretoria Portland Cement (PPC) is gratefully acknowledged for supplying the materials used in this investigation, while ESCOM (Electricity Supply Commission) and the NRF (National Research Foundation) kindly provided financial assistance. Students R. Komane, E. Ngobeni, J. Pretorius and C. Smith helped with the practical tests performed during the investigation.

ABSTRACT

Raw materials in cement manufacturing normally have varying chemical compositions and require regular analyses for plant control purposes. This is achieved by using several analytical instruments and methods. The values obtained for the major elements Ca, Si, Al and Fe are used to calculate the Lime Saturation Factor (LSF), Silica Ratio (SR) and Alumina Modulus (AM). These plant control parameters are used in production to regulate the mixing and blending of various raw meal components used in cement manufacture and to operate the plant optimally. It goes without saying that errors in these parameters not only influence the quality of the cement produced, but also have a major effect on the cost of production of cement clinker through their influence on the energy consumption and residence time in the kiln.

A fact seldom appreciated by plant operators and production managers, is that all analytical measurements suffer from inherent uncertainties. Whatever the source of error, it affects both the precision as well as accuracy of results obtained. This inevitably leads to varying analytical results obtained on samples with a constant composition. It can be especially severe in cases where only one analysis is performed on a sample at any particular time for quality or plant control purposes.

This paper investigated the effect of normal statistical variations in analytical results obtained in the main elements of interest in cement raw meal on the production costs of cement clinker. It was found that a combination of simultaneous variations in the concentrations of Ca, Si, Al and Fe can lower or increase the production costs of clinker by as much as 13% in some cases. The lowest percentage of variation in production costs was around 5%. If considered over a period of a year, these variations can amount to a significant sum of money.

1. INTRODUCTION

In a cement plant, professionals (usually engineers) in charge of the quarry, raw mix preparation, refractory procurement and kiln operations are sometimes poorly versed in chemistry, while most of the professionals (usually chemists) working in the laboratory are not very familiar with kiln and plant operations. The result is a technical gap that could cost the plant millions of Rands per year in unnecessary refractory repairs, kiln upsets and clinker quality problems.

A cement kiln can in fact be considered as a chemical reactor in which a series of complicated reactions take place. Just like any other reactor, it will only give optimum output in terms of cost and product quality if the feed is of as constant a composition as possible. In the cement industry, three plant

parameters are used to control the manufacturing process, namely [1]:

$$\text{LSF} = \text{CaO}/(2.8 \text{ SiO}_2 + 1.2 \text{ Al}_2\text{O}_3 + 0.65 \text{ Fe}_2\text{O}_3) \quad (1)$$

$$\text{SR} = \text{SiO}_2/(\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3) \quad (2)$$

$$\text{AM} = \text{Al}_2\text{O}_3/\text{Fe}_2\text{O}_3 \quad (3)$$

where LSF = lime saturation factor

SR = silica ratio

AM = alumina modulus

These three values are used to control both the raw material feed as well as the clinker (product) quality.

In order to understand the importance of the LSF, SR and AM, it is necessary to briefly state their influence on clinker quality and plant operation conditions. The tendency in a plant is to operate close to a LSF value of 100% to optimise the amount of alite or C_3S , which is responsible for the early strength of cement, and the grindability, which is related to the amount of C_3S , of the clinker. In practice the LSF is usually kept between 92% and 98%. If the LSF is above 99%, the raw mix could become hard to burn, which could result in more fuel usage and incomplete CaO reaction with the other components in the raw mix. If the LSF drops below 90%, refractory brick may be washed out or infiltrated with clinker melt and ring formation is enhanced.

The normal range for SR is 2-3. High SR reduces the amount of coating, produces dusty clinker and reduces clinker burnability. Low SR operational values lead to similar problems as those already mentioned with low LSF values. For most Portland cements, the AM varies between 1.5 and 2.5. The higher the AM, the higher the viscosity of the melt. High AM clinkers have a high heat of hydration, high reactivity and a tendency to high early strength, while low AM clinkers are usually hard to grind.

It is generally accepted that kiln feed composition is under control and constant if the LSF remains within ± 0.2 of the target value [2]. However, this will depend on the variation of chemical analyses with regard to the elemental oxides required to calculate the control parameters. This in turn will be affected by, amongst others, plant conditions like process feed conditions and variations in the raw materials, as well as instrumental measurement accuracy, calibration stability and statistical variations normally encountered in the collection of analytical data. A fact often forgotten is that a XRF spectrometer (or an ICP spectrometer used in some cases), measures element concentration, which is then converted to the equivalent oxide content with computer calculations performed as part of the analysis program. This means that a small error or change in an elemental concentration has a much larger effect in the expressed elemental oxide content.

The purpose of this paper is not to explore sources of possible determinate or indeterminate errors that can have an effect on the reported values of analytes, but to point out the effect that such errors or normal statistical variations in measurements can have on the calculation of the plant control parameters and subsequently the cost of production of cement clinker.

2. EXPERIMENTAL PROCEDURE

It is generally accepted [3] that measurements display a statistical variance in the form of a Gaussian distribution. In simple terms it translates to the observation that the larger the number of measurements conducted, the larger is the precision of the mean value of all the measurements. From XRF measurements conducted over a number of years [4], it was established that the precision of the values

used for the LSF, SR and AM in South African cement clinkers varies as follows:

CaO : 0.2 - 0.8
 SiO₂ : 0.2 - 0.6
 Fe₂O₃ : 0.1 - 0.5
 Al₂O₃ : 0.2 - 0.4

For the purpose of this investigation, the average of the variations, i.e. the standard deviations of the mean values, were calculated and used.

It should be borne in mind that the measured values are further influenced by the number of repetitions on each sample, the number of samples prepared and measured for a particular determination, counting times on the XRF spectrometer, stability of the instrument, calibration accuracy and sample collection and preparation errors. Taking all this into account, the variations in the precision of measured values mentioned above are not only reasonable, but also fairly small.

The approach followed in this investigation was to calculate the variations in the LSF, SR and AM if a high, low and average value of each specific elemental oxide was used in the relevant formulas. Furthermore, it was assumed that if only average values were used in each case, that the production cost of a ton of clinker was R100. The change in the relevant parameter (LSF, SR or AM) that occurred when higher or lower values than the average of the specific elemental oxides were used, then resulted in a change from the standard (assumed) production cost. Because the latter value was R100/tonne, changes could easily be recognised as percentages.

It was furthermore assumed that the raw meal was a two-component mixture of limestone and clay in a ratio of 90 %:10 %. The composition of the limestone and clay used in this exercise was obtained from a real operational plant [5] and is given in Table 1 below, while Table 2 gives the raw meal composition made up from limestone and clay combined in the said 90%:10% ratio. It also indicates the variation in the different values of each specific elemental oxide used in the formulae calculations.

Table 1. The composition of raw materials, Limestone and Clay.

Compound	%Limestone	%Clay
SiO ₂	8.06	66.83
Al ₂ O ₃	1.93	10.28
Fe ₂ O ₃	1.66	4.00
Mn ₂ O ₃	0.07	0.07
CaO	48.48	5.41
MgO	0.38	1.26
LOI	38.53	7.39
Total	99.11	95.24

Table 2. The percent of compounds used to calculate the SR and AM feed compositions

Compound	Low	Average	High
SiO ₂	13.14	13.64	14.14
Al ₂ O ₃	2.52	2.72	2.92
Fe ₂ O ₃	1.68	1.88	2.08
CaO	43.89	44.39	44.89

The approach taken meant that for the two elemental oxides used in the calculation of the AM at three values for each one, nine different combinations (3²) are possible. Similarly, for the SR (3³) 27 and for

the LSF (3^4) 81 possible combinations could be calculated. A spreadsheet was set up on Excel to do the necessary calculations and manipulation of the data.

3. RESULTS AND DISCUSSION

The design of a suitable mix is a fairly simple procedure, when only two raw materials are to be used. Most plants employ computer programs to calculate new mix compositions and designs, because it becomes a lot more complicated when three or four different raw materials are employed.

One can present the three parameters LSF, SR and AM as a three-dimensional combination with the x-axis being the SR, the y-axis the AM and the z-axis the LSF. For a two-component mix, which will be used in this paper, the model can be presented as follows in Figure 1:

Figure 1. A two-component mix solution region diagram

Raw material, A has a higher LSF than the mix (e.g. the limestone), while material B (the clay), has a lower LSF than the final mix. A large number of mixes can be made between A and B and their LSF values will follow the line AB in Figure 1. This line is called the “solution region”. If the LSF value is set at the plant, point P is obtained in the plane for that particular LSF and no other combinations of A and B will satisfy the set LSF requirement. This action then also fixes the SR and AM values. There is a particular cost associated with point P for the raw meal and thus the subsequent clinker production, and analytical variations and inaccuracies in the values used to calculate any of these production parameters (LSF, SR and AM) will have an effect on such costs. The subsequent discussion will illustrate the magnitude and cost implications of such variations.

The simplest case of possible changes in AM will be considered first and the demonstration then expanded to the more complicated cases of SR and eventually the LSF.

When the average values of Fe_2O_3 (1.88 %) and Al_2O_3 (2.72) in Table 2 were used to calculate the AM of the raw meal investigated, a value of 1.45 was obtained. For comparison purposes it was assumed that the cost of clinker produced from such a raw meal mixture was R100/tonne, and that changes in the AM because of higher or lower values of Fe_2O_3 and Al_2O_3 change the cost of the clinker in a directly proportional manner. Table 3 below illustrates the situation when changes in the elemental oxide concentrations due to analytical measurements occur. It also illustrates how the setpoint value of 1.45 (close to the preferred value of 1.50) can drift and change with uncertainties in the measured analytical determinations.

Table 3. Changes in calculated AM with corresponding changes in the comprising elemental oxides

AM variation	Production Cost (R/tonne)	Fe ₂ O ₃ concentration			Al ₂ O ₃ concentration		
		High	Average	Low	High	Average	Low
1.45	100.00		X			X	
1.31	90.38		X		X		
1.62	111.90		X				X
1.55	107.35	X				X	
1.40	97.03	X			X		
1.74	120.31	X					X
1.34	92.65			X		X	
1.21	83.74			X	X		
1.50	103.68			X			X

The values tabulated in Table 3 indicate that even if the CaO and SiO₂ concentrations stay constant, normal analytical variations in the measurement of Fe₂O₃ and Al₂O₃ concentrations could result in the AM drifting out of the acceptable level of change for plant control purposes (set AM [1.45] ∇ 0.2) on at least two occasions. Furthermore, the cost can decrease by more than 16% and increase by as much as 20.3% in such cases. One can of course argue that many measurements on the same raw meal or the same sample many times over make such a scenario unlikely. However, normal practice on a production plant where a single sample is taken once every two hours (or at even longer time intervals) and only run once through the analysing instrument makes it quite likely that the scenarios identified above can occur, with significant implications for the production costs of the clinker.

Table 4 summarizes the calculated values for the change in setpoint SR of 2.97 (which is <3) and production costs when the various combinations of changes in the measured elemental oxide concentrations were taken into account. From the results presented in Table 4, it can be deduced that the lowest cost production occurs when the SiO₂ value is at its lowest, with Al₂O₃ and Fe₂O₃ at their highest possible values in the variation. The percentage reduction in production costs is less dramatic than in the case when only the AM is considered and amounts to just 12%. In contrast with this, the increase observed when the SiO₂ value is at its highest and both Fe₂O₃ and Al₂O₃ have their lowest values respectively, is about 13.5%. However, normal analytical variations in the measurement of SiO₂, Fe₂O₃ and Al₂O₃ concentrations now result in the SR value being out of the acceptable level of change for plant control purposes (set SR [2.97] ∇ 0.2) on at least six occasions, compared to the previous two occasions when only the AM was considered.

A similar analysis exercise in the case of the LSF variations that can possibly be encountered, indicates that the lowest production cost of R94-94/tonne, or 5.06% lower than the baseline, can be achieved with the CaO value at its lowest, and SiO₂, Al₂O₃ and Fe₂O₃ all at their highest possible variations. A very similar increase of 5.5% in the production cost above the baseline value is produced when the CaO value is at its highest possible variation, and the rest all at their lowest possible values.

Table 4. Changes in calculated SR with corresponding changes in the comprising elemental oxides

SR variation	Production cost (R/tonne)	SiO ₂ concentration			Fe ₂ O ₃ concentration			Al ₂ O ₃ concentration		
		High	Aver	Low	High	Aver	Low	High	Aver	Low
3.13	105.51			X			X			X
2.99	100.71			X		X				X
2.86	96.33			X	X					X
2.99	100.71			X			X		X	
2.86	96.33			X		X			X	
2.74	92.32			X	X				X	
2.86	96.33			X			X	X		
2.74	92.32			X		X		X		
2.63	88.63			X	X			X		
3.25	109.52		X				X			X
3.10	104.55		X			X				X
2.97	100.00		X		X					X
3.10	104.55		X				X		X	
2.97	100.00		X			X			X	
2.84	95.83		X		X				X	
2.97	100.00		X				X	X		
2.84	95.83		X			X		X		
2.73	92.00		X		X			X		
3.37	113.54	X					X			X
3.21	108.38	X				X				X
3.07	103.67	X			X					X
3.21	108.38	X					X		X	
3.07	103.67	X				X			X	
2.95	99.35	X			X				X	
3.07	103.67	X					X	X		
2.95	99.35	X				X		X		
2.83	95.37	X			X			X		

It therefore seems that a plant controlled on LSF and SR parameters can experience production cost variations ranging from 5 to 12 % below the baseline costs to between 5.5 to 13.5% above the baseline costs. For a plant producing 1 million tonnes of clinker a year this variation can result in an average of R8.5 million savings or R9.5 million loss. Figures like these emphasize the importance of statistical quality control and proper analytical control in no uncertain terms.

4. CONCLUSIONS

The possible variations in analytical results and continued imprecision of chemical analyses can lead to potentially significant losses in the production costs of clinker in a cement plant, as well as problems with the control of plant operational parameters within specified limits of variation.

ABSTRACT

Curing is a very important factor influencing the strength development observed in mortars and concrete. For this reason the curing conditions in standard test procedures are very carefully specified and controlled. In practical applications steam curing is often employed to accelerate the strength development of mortar or concrete. In this sense it is widely used in the precasting of concrete products to ensure sufficient early strengths in casts to allow fast stripping and turn-around times of the available moulds. A common practice in this industry is to use steam curing at a temperature of approximately 80 °C to allow a production cycle of 24 hours for cast concrete products.

This paper investigated the use of microwave heating instead of normal and steam curing on the strength development of cement mortars. Intermittent heating, continuous heating, the effect of various w:c ratios and the behaviour of different types of cement were some of the variables investigated. Although it might sound like a far-fetched idea, it should be borne in mind that bricks in the brickmaking industry are already treated in large enough “microwave chambers” for drying and firing purposes. Should this type of technology be promising and easily manageable, there is no reason why such an approach cannot replace traditional steam curing in precast concrete in future.

1. INTRODUCTION

Accelerated curing in the concrete industry is no foreign phenomenon and is frequently applied in the production of prefabricated components. The medium normally used to affect such accelerated curing is steam, heated to a temperature of approximately 80°C. Steam curing usually takes place in steps in a confined space and the moulds containing cast concrete undergo a stepped temperature increase over a period of about 1 hour until the desired temperature is reached. After approximately 14 hours, the temperature is decreased again in a stepwise fashion until demoulding can begin. The whole process lasts about 24h and the purpose of such accelerated curing is to produce components with a sufficient strength for handling purposes in as short a time as possible.

Microwave energy is new technology application to drying, calcining, curing and manufacturing processes requiring thermal processing. Heating by microwave energy is based on the excitation of a molecular dipole at its resonant frequency. At 2.45 GHz, which is near the resonant rotational frequency of a liquid water molecule, the change in electrical field direction causes oscillation of the molecule, which exerts a torque on the molecule, whose resulting violent motion results in instant heating. The amount of heat generated in a material is directly proportional to the square of the electric field, the frequency and the loss factor [1].

This is expressed as the power absorbed per unit volume of material exposed to the energy:

$$P = 27.8 \times 10^{-12} E^2 f \epsilon_r''$$

Where: f = frequency in Hz

E = rms local field intensity in V/m, and

ϵ_r'' = relative dielectric loss factor

For a given frequency and field intensity, the relative dielectric loss factor is the dominant variable in determining the microwave power absorbed and therefore the resulting temperature rise in the material.

In a conventional gas or electric furnace, an object is warmed gradually by convection or radiation as heat penetrates from the outside inwards. Microwave energy, by contrast, is cold and heat is only produced when the microwave energy is absorbed by the sample. Since microwaves easily penetrate materials (with the exception of metals) they can be directed and uniformly absorbed throughout the entire volume of an object. This volumetric heating effect causes a material to heat up evenly and rapidly. Since the loss factor for cement is significantly lower than for water, the power absorbed in the water is much greater than that in the cement (and aggregates in the case of concrete) at a given power output and frequency. The power absorbed in the mixture is essentially concentrated in the water areas and decreases as evaporation nears completion, thus limiting the tendency to overheating.

The capabilities of microwave energy have opened up new opportunities in chemistry, materials science and other areas [2]. In the construction industry these include drying of gypsum [1], sample preparation for analyses [3, 4], curing of concrete [5] and syntheses of ceramics [6]. Very novel work is also done at the Materials Research Laboratory of Pennsylvania State University by various researchers on the manufacturing of different types of cement using microwave technology [6 - 10]. This paper will describe the effect of microwave irradiation on the strength development of cement mortars.

2. EXPERIENTIAL PROCEDURE

Mortars were made from OPC (ordinary Portland cement) and an OPC-fly ash mixture (82.5%: 17.5%) with standard sand in a ratio of 1:3. Different w/c ratios varying from 0.4 to 0.6 were used. The moulds used were standard ISO-moulds with dimensions of 40 x 40 x 160 mm and were constructed from PVC (polyvinylchloride).

After mixing the mortars in a Hobart mixer according to standard procedures [11], the PVC moulds were half-filled, vibrated for 1 minute on a vibrating table and then filled completely before another minute's final vibrating. The moulds were then covered with polypropylene and left to stand for 2 hours. After initial setting has taken place, the moulds were heated in a commercial microwave oven (Sharp Model) at 170 W for various time periods. The heating cycles were performed with either continuous or intermittent heating times varying between 1 minute to 20 minutes for continuous curing and 2.5 minutes to 5 minutes in the case of intermittent curing. In the latter case half an hour standing time was allowed between the intermittent heating intervals of one minute at a time.

Twenty-four hours after completion of heat curing, the moulds were stripped and the samples placed in a water bath for normal water curing until compressive strength tests were carried out on a Farnell press.

3. RESULTS AND DISCUSSION

Table 1 represents a summary of the results obtained when OPC and sand mixtures with a w/c ratio of 0.45 were heated continuously for varying time intervals and tested after 24 hours (1day).

Table 1. Compressive strength of cement mortars at 1 day after continuous microwave curing.

Curing Time (Minutes)	Compressive strength (MPa)
2.5	5.9
5.0	7.8
7.5	3.7
10.0	3.1
15.0	1.7
20.0	0.9

The highest strengths were obtained after short heating times, with 5 minutes' heat curing giving the best strength development. During continuous heating a certain amount of steam was evolved and a number of fine cracks were observed in the mortars. It increased with increased heating time and is probably the cause of the decrease in compressive strength observed with the longer microwave heating times.

Table 2 gives a summary of the results obtained when cement mortars with varying w/c ratios were microwave cured for 2.5 and 5 minutes intermittently at 170 W power output before normal water curing for different lengths of time.

Table 2. The effect of initial microwave curing on cement mortars with varying w/c ratios.

Microwave heating time (min)	Curing Time (Days)	Compressive strength (MPa) at a w/c ratio of		
		0.4	0.5	0.6
5.0	1	3.1	6.0	8.7
	7	10.2	8.8	13.2
	14	14.8	32.8	26.6
	28	22.7	40.6	35.2
2.5	1	3.1	5.1	5.2
	7	10.4	13.1	16.7
	14	13.3	18.7	22.5
	28	18.8	31.3	38.3

For the 2.5 minute intermittent microwave curing the highest strength obtained after 1 day was lower than in the case of continuous microwave heating followed by a day's water curing. The maximum compressive strength obtained after 28 days was in the mortar with a 0.6 w/c ratio. This is in contrast to the situation when 5 minutes of intermittent microwave curing was employed before the onset of the normal water curing. In the latter instance, the mortars with a 0.5 w/c ratio developed the highest compressive strength after 28 days.

For this particular mortar, the strength after one day was also higher than when continuous microwave heating was applied. No steam evolved from the moulds when the intermittent microwave-heating

mode was employed. It was noticed that the temperature of the exposed surface increased, but no visible cracks were observed after the microwave heating stage. It seems that the optimum strength development requires a balance between the amount of heat developed in the mortar during microwave heating and the w/c ratio. The former effect (heat development in the mortar) will be closely associated with the mode of heating (intermittent or continuous) and the time it was applied.

Figure 1. Comparison of achieved compressive strength for OPC mortars that were heated intermittently and continuously.

Figure 1 illustrates the difference in compressive strengths for OPC mortars with a w/c ratio of 0.6 that were microwave heated for 2.5 minutes intermittently and continuously, respectively. It seems that the intermittently heated mortars display a trend of having higher compressive strengths after additional water curing than the ones subjected to continuous heating before water curing.

The results obtained when the OPC-fly ash blend mortars were microwave cured continuously for different time intervals are given in Table 3.

Table 3. Compressive strengths of OPC-fly ash mortars microwave cured continuously at 170W

Microwave heating time (min)	Curing time (days)	Compressive strengths (MPa) at a w/c	
		0.5	0.6
2.5	1	4.9	4.7
	7	11.5	12.6
	14	18.9	21.6
	21	27.3	22.4
	28	30.8	36.9
5.0	1	6.9	7.3
	7	9.7	12.0
	14	18.6	18.5
	21	19.3	19.1
	28	21.8	20.4

When the blended mortars were heated continuously for longer than 2.5 minutes, steam evolution occurred. This probably caused fine cracks in the mortar and can be the reason why the mortars microwave cured continuously for 5 minutes displayed lower compressive strengths after subsequent water curing than the corresponding ones subjected to 2.5 minutes microwave curing. The trend that the highest compressive strength development occurred with a w/c ratio of 0.6 when the microwave heating period was 2.5 minutes and at 5 minutes heating time when the w/c ratio was 0.5, is the same as was observed when the microwave heating was applied intermittently. The fly ash - OPC blends generally show a slower strength gain than the straight OPC mortars, which is in agreement with behaviour normally observed under regular curing conditions [12].

Figure 2. Comparison of achieved compressive strengths for OPC-Flyash mortars after heating continuously and intermittently.

Figure 2 is a schematic presentation of the effect of intermittent and continuous microwave heating of OPC-fly ash mortars, before subsequent normal curing, on the compressive strength after various time intervals. A similar pattern is observed as in the case of the OPC mortars. Similar strengths at the different curing ages were seen, with a trend to marginally higher values in the case of the intermittent heating.

4. CONCLUSIONS

This preliminary investigation yielded most interesting results and opened up some exciting possibilities for future investigations. However, it is of too introductory a nature to result in many definite conclusions.

It can definitely be concluded that:

1. Intermittent heating seems to produce better results than continuous heating, especially if the latter is associated with prolonged heating periods.
2. Excessive heating seems to lead to steam evolution from the mortars, which impairs hydration and compressive strength development.
3. Significant steam evolution led to crack formation in the mortars that were affected and this resulted in lower compressive strengths.

It is recommended that more work be done to differentiate more clearly what the effect of longer similar intermittent and continuous heating times are, that more w/c ratios be evaluated and that some method of measuring the temperature inside and on the top outside part of the mortar be developed, so that it can be correlated with the ultimate strength development behaviour of the material.

ACKNOWLEDGEMENTS

PPC Co. Ltd is gratefully acknowledged for supplying the materials used in the investigation. The NRF, Technikon Pretoria and the University of Pretoria supplied financial funding for this project.

ABSTRACT

The quantitative resolution of cement blends into the various proportions of their components is often of interest for plant control purposes and in forensic investigations. This goal can be accomplished in a number of different ways. An often used method involves the use of a noxious, hazardous reagent for heavy medium separation of cement components. This investigation will describe the use of alternative methods to achieve the same purpose. It involves an extraction procedure to selectively dissolve one of the components from a binary mixture, chemical analyses by XRF of individual cementitious material components and their combinations in binary mixtures and density measurements. Various binary mixtures of fly ash, slag and OPC have been investigated and will be reported on. It is foreseen that the approach taken could easily be implemented on plant level for production control purposes.

1. INTRODUCTION

The adoption of the new cement specifications [1] in South Africa in 1996, governing the composition of cements being sold in the country, has drastically changed the local market. Not only did the three major cement producing companies, namely Pretoria Portland Cement Co. Ltd. (PPC), Alpha and Lafarge South Africa, start to produce a larger variety of blended cements, but new players in the form of so-called third party blenders also entered the market. This led to a lot of confusion for especially the un-informed consumer buying the cheapest possible product in the retail market for his/her "do-it yourself" projects.

After much campaigning on behalf of all the role players in the market, legislation was adopted at the turn of the century, that made it illegal for anyone to sell cement not bearing the S.A. Bureau of Standard's mark of performance. This reduced the number of competitors in the market. However, it did not eliminate third part blenders, who bought all their ingredients separately and blended it themselves, from the building and construction market. Due to these circumstances, a need arose for the qualitative and even quantitative identification of the ingredients in blended cements.

One of the methods recommended in the EN cement standards, and which have been applied for many years prior to its introduction in the S.A cement industry, to separate components like fly ash and slag from cement blends, is based on heavy medium density separation. In this procedure bromoform is used to separate Ordinary Portland cement (OPC) from either fly ash or slag, based on their differences in density. However, it is a tedious method, not very accurate and the medium used, bromoform, is carcinogenic. An optical microscope can also be employed, but has the drawback that it is at best qualitative in the identification of the components of a blended cement. Other crude qualitative

chemical tests included the addition of dilute acid to a blended cement in order to detect the liberation of CO_2 gas if a limestone filler has been used in the blend, or H_2S gas when slag (especially from a steel works) has been blended with OPC. However, none of these are accurate or infallible, so it was clearly necessary to find another means or way to detect the presence of mineral admixtures in cement qualitatively and quantitatively.

Our laboratory recently published a paper [2] to illustrate the fast and simple quantitative determination of limestone in blended cements by employing FT - IR spectroscopy. This paper will describe a variety of other approaches applied to quantify the amount of fly ash or slag in binary blended cements.

2. EXPERIMENTAL PROCEDURE

2.1 Selective dissolution

Previously published work [3] indicated that maleic or salicylic acid selectively dissolves the two silicate phases, alite (tricalciumsilicate) and belite (dicalciumsilicate), as well as CaO , in cement. The C_3A , C_4AF and gypsum are insoluble in any one of these media. It was therefore assumed that both fly ash and slag would also be fairly insoluble if treated with any of the two acids mentioned.

One gram of sample was treated with 25 ml of a 20% (m/m) solution of maleic acid in methanol and stirred at room temperature for 10 minutes. The resultant solution was filtered through a fine paper or a pre-weighed sintered glass crucible. The collected residue was washed with 4 portions of 25 ml each of methanol. Then the crucible was dried at 150°C and the residue weighed after cooling. The percentage residue was calculated and a calibration curve of the % insoluble residue vs % pozzolan / mineral admixture (fly ash, slag) was constructed for a variety of blends investigated.

2.2 Colorimetry

It was noticed that a distinct yellow colour was present each time in the collected alcohol filtrate. It was therefore endeavoured to establish whether a correlation existed between the intensity of the colour of the filtrate and the mineral admixture addition in the binary blends investigated. The absorption of light at a wavelength of 320 nm by the coloured filtrates was measured on a Spectronic 601 UV - VIS spectrometer.

2.3 XRF

Suitable masses of the composed binary blends and virgin materials were milled for 3 minutes in a ring mill using hexane as a grinding aid. The resultant powders were dried on hotplates at either 45°C (OPC) or 150°C (fly ash) and pressed pellets for XRF analyses were prepared on a Herzog press set to a pressure of 20 tonnes. The pressed pellets were analysed on a Siemens 400 MP spectrometer, employing $\text{Rh K}\alpha$ radiation at 50 kV and 30 mA. The concentration of calcium, expressed as CaO , was used to construct a calibration curve of count rate vs the % mineral admixture (usually fly ash) in the blend. From count rates for CaO on commercial samples their mineral admixture content could be established from the calibration curve and correlated with some of the other methods investigated.

2.4 Density measurements

Four grams of sample of various binary blends were compacted under a pressure of 30 tonnes on a Herzog press and their densities measured on a Grabner Mini densitometer. This was used to construct a calibration curve of the measured density versus the mineral admixture content. Production samples were analysed with this instrument and the results compared with those obtained by XRF measurements, as described in the previous method. In selected cases 3g of sample powder was put into an aluminium cup and measured on the densitometer without any prior compaction in order to establish whether compaction is essential for the success of the measurement.

2.5 Raw materials

All materials used in the investigation were analysed by preparing fused beads according to standard procedures [4] and measuring it on a Siemens 400 MP XRF spectrometer.

3. RESULTS AND DISCUSSION

The chemical compositions of the materials used in this investigation are given in Table 1.

Table 1. Chemical compositions of various cement-related materials.

Component	Cement 1 (OPC)	Cement 2 (OPC)	Cement 3 (OPC)	Fly ash	Slag (Vanderbijlpark)
SiO ₂	21.30	21.60	21.99	42.00	30.40
Al ₂ O ₃	3.38	3.59	3.63	28.10	10.40
Fe ₂ O ₃	2.08	2.39	3.03	5.60	1.60
Mn ₂ O ₃	1.00	0.92	0.43	0.07	0.70
TiO ₂	0.29	0.33	0.36	1.61	0.40
CaO	63.72	63.63	63.52	13.18	47.10
MgO	4.42	4.12	2.73	3.64	6.50
P ₂ O ₅	0.013	0.022	0.096	1.640	0.060
K ₂ O	0.68	0.73	0.56	0.95	0.86
Na ₂ O	0.08	0.09	-	0.50	-

The results obtained with the selective dissolution approach are graphically illustrated in Figure 1. There is an excellent linear correlation between the percentage insoluble residue remaining on the filter after the dissolution procedure and the amount of fly ash added to the blend.

Figure 1. Fly ash contents in a binary cement blend determined by selective dissolution.

When all three cements (no. 1-3) were used to produce binary blends with fly ash, the resultant calibration graph in Figure 2 indicates that the curves obtained when applying the selective dissolution approach depend on the origin of the cement. Cements 1 and 2 were produced by PPC, while no. 3 was an Alpha cement. The observed shift in the calibration curve of % insoluble residue versus the amount

of fly ash in the blend is to be expected, because different cements contain different amounts of alite and belite phases.

Figure 2. Fly ash contents in binary blends composed from different OPC's

A comparison in Figure 3 between the application of this procedure with either fly ash or slag added to the binary blends, shows that there again is a small difference in the calibration curves obtained. When selective dissolution is selected as the procedure of choice, care will have to be exercised when the source of cement or mineral admixture changes. However, it should work well when the cement and mineral admixture used in the blend have a reasonably constant composition. Furthermore, it is cheap and easy to use at plant level for quality control purposes. The procedure does not require complicated equipment and can easily be prepared by trained unskilled personnel.

Figure 3. A comparison of results obtained for the selective dissolution method with two different binary mixtures.

A preliminary estimation of the degree of variability in a cement (OPC) and fly ash used regularly to

produce binary blends has yielded the results summarized in Table 2. The selective dissolution procedure was applied in turn to each material collected over a period of six weeks.

Table 2. Estimation of the variability of raw materials used for the production of binary cement blends.

Sample no.	Insoluble residue (%) in	
	Fly ash	OPC no. 3
1	94.2	18.0
2	94.6	18.8
3	95.0	18.4
4	93.8	17.4
5	93.7	18.2
6	95.5	18.8
Average	94.5 ± 0.7	18.3 ± 0.5

From the preliminary investigation conducted over a period of six weeks, it seems that the materials' compositions remain constant enough to allow the selective dissolution method to be employed for plant and quality control. The method will, however, require regular calibration curves to be constructed to ensure that unknown blends that are investigated will be analysed accurately.

An attempt to correlate the amount of fly ash in the binary blend with the light absorbance of the filtrate solution after application of the selective dissolution procedure, proved to be unsuccessful, as can be seen from Figure 4. No linear correlation could be established between the absorbance of the filtrate and the amount of fly ash added to the blend.

Figure 4. Absorbance results for a binary mixture of OPC and fly ash.

A number of binary blended plant samples were analysed on the XRF spectrometer. Each time a calibration curve was constructed from the OPC and fly ash used to prepare the blended cement. For this purpose laboratory mixes containing 0, 25, 50 and 100% fly ash were composed and the fly ash content graphically represented against the number of counts obtained for the CaO in each specimen.

This procedure implies that five samples had to be prepared as pressed pellets for measurement on the XRF spectrometer every time a plant sample of the blended cement were to be analysed. A comparison of a set of results obtained when using selective dissolution with maleic acid and XRF measurements

is given in Table 3.

Table 3. A comparison of the resolution of binary OPC-fly-ash blends.

Sample no.	Cement used in blend (no.)	Linearity of calibration	Fly ash by XRF (%)	Fly ash by selective dissolution	Δ (% - %)
1	3	1.000	13.7	13.3	+0.4
2	3	1.000	29.6	29.2	+0.4
3	3	0.999	29.1	28.9	+0.2
4	3	1.000	29.3	29.3	0
5	3	0.999	29.3	29.6	-0.3
6	3	1.000	30.1	29.9	+0.2
7	2	1.000	29.8	30.1	-0.3
8	1	0.999	30.3	29.1	+1.2

The fly ash content obtained by XRF measurements and an application of the selective dissolution method compares very well with each other. In all but one of the samples the inter-method difference was less than 0.5 percentage points, which is quite acceptable for plant purposes.

The results summarized in Table 4 were obtained from density measurements on OPC no. 3 and fly ash. XRF measurements were also done on the samples from the plant in a similar way as described above.

Table 4. Summarized Results

Sample no.	Fly ash density (g mL ⁻¹)	OPC no.3 density (g mL ⁻¹)	Fly ash content estimated from compressed density (%)	Fly ash content estimated from Powder density (%)	Fly ash content by XRF (%)	Δ (% - %)
1	2.551	3.297	14.0	12.3	13.5	+0.5
2	2.559	3.301	13.5		13.3	+0.2
3	2.500	3.245	12.8	11.8	12.9	-0.1
4	2.489	3.254	12.6	11.4	13.2	-0.6
5	2.513	3.314	22.4		23.1	-0.7
6	2.466	3.265	22.2		22.5	-0.3
7	2.533	3.308	15.7	14.1	15.0	+0.7
8	2.530	3.304	15.3		15.4	-0.1
9	2.504	3.304	15.4	13.7	15.7	-0.3
10	2.506	3.290	23.1		23.6	-0.5
11	2.500	3.285	15.8		16.1	-0.3
12	2.505	3.305	21.9	21.0	22.5	-0.6
13	2.529	3.273	15.8		16.3	-0.5
14	2.515	3.305	22.9		23.8	-0.9
15	2.515	3.305	24.0	22.1	24.4	-0.4
16	2.522	3.308	16.9		16.3	+0.6
17	2.472	3.290	17.0		16.6	+0.4
18	2.526	3.263	25.2		24.4	+0.8
19	2.484	3.303	15.7		15.4	+0.3
20	2.493	3.293	16.4		16.6	-0.2
21	2.503	3.266	23.8	22.5	24.7	-0.9
22	2.439	3.235	25.1		25.2	-0.1

A reasonable degree of similarity is observed between values obtained with the XRF in Table 4 and the measurements done with the densitometer. The differences are small enough to be satisfactory for plant control purposes. The use of powder samples in the uncompressed form is not recommended, as the measured density values differ quite a bit from those of similar compressed samples. This approach is faster than XRF measurements, because for the latter method samples first needed to be milled and dried before any measurements can be done. The densitometer is also much cheaper than a XRF spectrometer and does not require the same extensive maintenance required by XRF instruments. With proper training operator bias could be eliminated from determinations done with a densitometer to yield a fast and inexpensive plant control procedure for binary cement blends.

4. CONCLUSIONS

Three methods of measuring mineral admixture content in binary cement blends have been investigated. Reasonable degrees of similarity between the results obtained with all three procedures were found that are considered satisfactory for plant and quality control purposes. Two of the methods, namely selective dissolution and densitometer measurements, are very suitable for use by unskilled labour and do not require highly skilled operators. Furthermore, both are quite inexpensive and easy to implement without a large capital layout. These methods are recommended for use by third party blenders who do not have the extensive infrastructure of well-equipped laboratories for plant and quality control purposes. The applicability of some of the above-mentioned methods should be investigated to determine their stability to resolve ternary cement blends.

ACKNOWLEDGEMENTS

PPC Co. Ltd., Alpha, Slagment and Ash Resources are thanked for the supply of samples used in the investigation. PPC is also gratefully acknowledged for the use of their XRF equipment. The NRF and Technikon Pretoria financially supported Herman and Sanja Potgieter, as well as Dawie Delport, while conducting this research.

PRODUCT-BASED ASSESSMENT TO BURNING WASTE DERIVED FUEL IN CEMENT KILNS – CASE STUDY IN BRAZIL

V. Maringolo¹, Y. Kihara^{1,2} and A. J. Suto¹

¹ Brazilian Portland Cement Association, São Paulo, Brazil. E-mail: vagner.maringolo@abcp.org.br

² Geosciences Institute, University of Sao Paulo, Brazil. E-mail: yushiro@usp.br

ABSTRACT

An increasing number of cement plants in Brazil are getting the permits to burn hazardous wastes as substitutes for fossil fuels. In the present case study, a waste derived fuel (WDF) from different waste streams is supplied. The trace elements introduced in the system with WDF are – depending on their volatility and compatibility to solid solutions – either emitted and retained in electrostatic precipitators or incorporated into the clinker crystal lattices. A product-based assessment of clinker integrity and mechanical performance of cements resulting from burning WDF was carried out. Analytical techniques comprised reflected-light microscopy, atomic absorption and X-ray spectrometry, leaching and mechanical strength tests. Results evidenced similarity between products from burning either conventional fuel or WDF. Clinker microstructures were alike. Mechanical strengths of cements kept above standard values. Trace elements – even Cd and Hg – showed compatibility with clinker, although Co and especially Pb were rather incompatible. No elements were significantly soluble from cements, thus attesting retention of environmentally relevant elements in the crystal lattice of clinker mineral phases.

1. INTRODUCTION

The environmental implications of burning hazardous wastes in cement kilns are mostly related to atmospheric emissions, which are subject to highly restrictive regulatory limits. Antimony (Sb), arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, molybdenum, nickel, selenium, silver, thallium, vanadium, and zinc are toxic elements that, once introduced in high amounts in the kiln, bring up for the cement industry not only environmental implications but also technological and economical concerns by virtue of the influences that may be favorable or adverse to the process itself and ultimately to the rheological performance of the final product.

The present work derives from the author's unpublished PhD thesis [1] whose research followed a product-centered approach of a case-study – the Tupi Cement Group's Companhia de Cimento Ribeirao Grande plant – burning a waste derived fuel (WDF) in one of its two kilns, substituting for up to 30% the conventional fuel. The plant is located in the State of Sao Paulo, Brazil. It is made up of two suspension preheater kilns and satellite cooler, with daily production capacity of 3000 tons of clinker and a thermal throughput of 910kcal/kg of clinker.

The bulk of the samples comprised 50 clinkers taken from the production line, corresponding to a systematic gathering over three years, from December 1997 to December 2000, 8 of them burned with 100% fuel oil. The clinkers were analysed at the laboratory of the Brazilian Portland Cement Association for their microtexture by reflected light microscopy, total chemical composition by X-ray spectrometry, and trace element components by atomic absorption spectrometry. Leaching tests

were carried out on 14 laboratory composite cements prepared exclusively with WDF-burned clinkers. Mechanical strength tests of 685 industrial cements at 1, 3, 7 and 28 days were carried out, covering the production span from 1996, prior to the beginning of waste combustion, to 1998, when cements were made up from a mix of both conventional and waste-burned clinkers.

2. SAMPLING AND SAMPLE PREPARATION

The clinker samples were in a few cases grabbed during test burns with WDF substituting for 15% or 30% of the oil fuel, but mostly were compound samples, representing monthly production at roughly 10% substitution. Approximately 30kg of clinker were collected. Each sample was homogenized and then parted until 1,5kg to 2,0kg. This quantity was sifted in 19mm, 9.5mm, 4.8mm and 2.4mm mesh apertures. Each grain fraction ($F1 > 19\text{mm}$, $9.5\text{mm} < F2 < 19\text{mm}$, $4.8\text{mm} < F3 < 9.5\text{mm}$, $2.4\text{mm} < F4 < 4.8\text{mm}$ and $F5 < 2.4\text{mm}$) was weighed separately and its percentage calculated. A mean fraction of each clinker was prepared by mixing proportional quotas of all grain fractions. The grains were hammer-ground for the making of polished sections for microscopy, and ground in a swinging mill for five minutes for atomic absorption spectrometry, and for the preparation of fusion beads for X-ray fluorescence spectrometry.

Fourteen cement samples for the leaching test were prepared in the laboratory using 14 different clinkers burned with WDF in the following proportions: 71.3% clinker; 7% carbonate matter; 18% blast-furnace slag and 3.7% calcium sulfate.

3. WASTE DERIVED FUEL (WDF)

The rate of WDF substitution for fuel at the Companhia de Cimento Ribeirao Grande was based on the consumption of 6100kg/h fuel oil at 100% load. The burner was designed for simultaneous injection of oil and WDF allowing burning from 870kg/h to 4,640kg/h WDF – representing substitution for oil ranging from 15% to 40% [2].

The WDF is regularly supplied by a facility that operates the waste handling, pre-treatment, blending and transportation to the cement plant, and is accountable for unloading, storing and injecting WDF into the kiln.

Different waste streams are characterized and pre-selected. The blend is processed from paints, thinners, resins, greases, wash-up solvents and waste oils. The manufacturer keeps analytical control of all WDF shipments in order to check for their compliance with the permit specifications. The analysis included gross and net heat value, humidity, viscosity, flash point, ash content, volatile compounds, heavy metal and sulfur contents, and the amount of solids in suspension. Variations in fuel properties require kiln operation adjustment; therefore WDF must be as uniform as possible. General characteristics are included in Table 1 [3].

Table 1. Specifications for waste derived fuel

Parameters	Characteristics
Water content	Approximately 35%
Content of solids in suspension	<25%
Maximum dimension of solid particles	Non deformable: 3mm Deformable: 8mm
Net heat value	Minimum: 5.000kcal/kg Mean: 8.500kcal/kg
Maximum kinematics viscosity	300cSt
Flash point	<80°C

Table 2 shows average characteristics of WDF used in test burns and of WDF burned regularly from December 1997 to August 1998 [4].

Table 2. Average characteristics of WDF used in test burns and regularly supplied

Characteristics	Unit	test burns WDF	regular supply WDF
Number of samples		3	339
Rate of substitution	%	30	9.2
Net heat value	kcal/kg	5,860	6,434
Cl	%	1.85	0.76
S	%	0.60	0.45
Water	%	26.19	23.23
pH		6.91	7.21
Inorganic class I	g/h	Not detected *	Not detected *
Inorganic class II	g/h	451.00	102.61
Inorganic class III	g/h	12,917.90	2,877.36

* Detection limit of the analytical method not specified

The permit specifications of element maximum concentration in WDF and feed rate (g/h) into the kiln were set based on the test burns and are given in Table 3.

Table 3. Permit limits for element input in WDF and feed rate

Element	Quantity (ppm)	Feed rate (g/h)
Cadmium	0.35	<1.0
Mercury	0.35	<1.0
Thallium	0.35	<1.0
Arsenic	200	560
Cobalt	0.6	<1.7

4. RESULTS

4.1 Chemistry

Trace elements enter the kiln with the raw meal and fuels. They will move to the stack with the exhaust gases and concentrate in the electrostatic precipitator dust or incorporate into the clinker.

Table 4 shows comparative chemical compositions of the raw meals, electrostatic precipitator dusts and clinkers collected during conventional kiln operation with oil and test burns with WDF substituting for 30% oil. Also shown are the trace element ranges in the bulk 50 industrial samples separated into 42 clinkers burned with WDF and 8 clinkers burned without WDF.

Table 4. Chemistry of materials from test burns and average trace element contents of samples

Elements		Materials							
		Test burns					Bulk of samples

Hg = 0.10ppb

CN = 0.1ppm

Se = 0.10ppb

Volatile chlorine concentrated in the electrostatic precipitator dust. As alkali sulfates were not observed in the clinkers, available sulfur must have entered solid solutions in silicates and aluminates. The hazardous wastes account for the higher content of chlorine in the dust when operating with WDF. As a matter of fact, chlorine contents in WDF used in test burns (Table 2) were not possible to record due to clogging of the kiln.

Figure 1 shows comparatively the correlation of element mass concentrations in clinker and in electrostatic precipitator dust, to that in the raw meal for both situations with and without WDF, as seen in Table 4.

Figure 1. Element concentration in clinker and electrostatic precipitator dust from test burns with and without WDF

Tellurium, Pd and Be were not detected. Cadmium, Hg, Pb, Sb, Ta, Se, Pt and Ag concentrated preferentially in the electrostatic precipitator dusts. Higher degrees of incorporation in to the Portland clinker structure are seen with the transition elements Co, V, Mn, Ni, Cr, Cu, Zn, Ba and Sn.

The graphs demonstrate the varying input accounted for by the raw materials themselves. Nonetheless, the wide ranges for Cd, Th, Sb, Pt and V contents are likely due to the hot air from the cooler used in the preheater. Variation in Zn, Cu, Ni, Co, and V are attributed to the fuel oil and WDF input.

Volatile elements show intense and increasing recirculation within the kiln system. This should be the reason why there are high variations in Cd, Hg and Th in the electrostatic precipitator dust. Lead and Ag apparently also behave as volatile elements in the kiln.

The amounts of trace elements in the industrial clinkers are discontinuous. The scattered values proved easier to interpret on a spider diagram, commonly used in igneous petrology [4]. Elements are placed on the X-axis. All samples are normalized to a reference composition, so that on the Y-axis the logarithmic scale does not express contents but actually the ratio between the contents (either percentage, parts per million or parts per billion) of a particular element in the sample and in the reference composition. The points located above or below the baseline “1” on the Y-axis mean the sample is either enriched or depleted in a particular element in comparison to the reference.

For the bulk of clinkers, a sample with the lowest content of trace elements was chosen as reference; values are given on the X-axis under each element. The element sequence on the X-axis was arranged in such a way as to provide a clear visual interpretation of the results. Tellurium, Be, Ta and Se were not, or only occasionally, detected in the samples, and were not included.

Figure 2 shows the distribution of trace elements in the two sets of clinker samples, those burned with and those without WDF, and the overlapping areas of both the graphs.

Figure 2. Distribution of trace elements in the industrial clinker samples: (a) burned without WDF, (b) burned with WDF, (c) overlapping areas of (a) and (b)

Despite the limited number of clinkers burned without WDF, Figure 2a clearly demonstrates the element variation in the raw materials and conventional fuel, which are the only input in the kiln system. There is little variability for Mn, As, Ba and Hg. Lead, Co and Ni are distributed both above and below the baseline. Silver and Sb tend to depletion while V, Cr, Cd and Cu display enrichment. Tin shows no definite trends.

Similarly, Mn, As and Ba showed small variation in the clinkers burned with WDF (Figure 2b). Nickel remained similar (with the exception of a much enriched sample), but Pb and Co highlighted their strong depletion. All of the remaining elements – even Sn – are found to be enriched. The behavior of Hg, Ag and Sb inverted their trend, and Cu intensified the enrichment.

The intersection of graphs (Figure 2c) shows the element trends in both situations – only Ni presents a biased behavior because of one much enriched sample. The diagram emphasizes the trace element enrichment in clinkers when burning WDF, which is expected as WDF manufacture involves various hazardous wastes from different streams whose input will add to that of the raw materials and fuels.

4.2 Clinker Microstructure

Microscopic analysis was carried out on 37 clinkers burned with WDF and 6 without WDF, in order to check for the influence of the introduction of WDF on their texture and mineral composition.

The trace element contents involved in the case-study did not reach levels high enough to influence the kinetics of reactions. The clinkers did not show any distinct feature. On average, the clinkers contained 73% alite, a high proportion of silicates (81%), and a high alite/belite ratio (11) and low free lime content (1.25%). The optimal combination of components resulted from adequate LSF, SR and AR, good grinding and homogenization of raw materials, and optimized burning conditions.

While alite crystals displayed either straight or sub-straight borders, with generally incipient generation of a fringe of secondary belite, belite crystals in zones were invariably internally disorganized. Belite is also present in clinkers as amoeboid crystals in the matrix, surrounding alite crystals and following their contour, but these crystals are clearly not products of alite decomposition.

Characteristic of all clinkers studied is the slightly high potassium content ($\geq 0.75\%$) giving rise to crystallization of prismatic alkali aluminates. Also typical is the occurrence of periclase as a consequence of the high (over 4%) content of magnesium in the raw meal.

The clinker textural features are illustrated in Figures 3a – 3f.

(a) Random occurrence of round-shaped belite zones resulting from the presence of coarse grains (>45 μm) of quartz in the raw meal. Etching MgSO_4 (5%).

(b) Idiomorphic to sub-idiomorphic equant alite crystals, average size 35 μm, with inclusions of belite and pinkish periclase crystals. Etching HNO_3 (1%).

(c) Fingered belite crystals contrasting with straight-sided alite crystals. Etching: HNO_3 (1%)

(d) Amoeboid belite crystals (arrows) in the matrix, along the alite crystals sides. Etching: HNO_3 (1%)

(e) Crystalline matrix. Etching: KOH + saccharose

(f) Prismatic alkali-rich C_3A . Etching: KOH + saccharose

Figure 3. Textural and mineralogical features of clinker burned with WDF

4.3 Leaching

The leaching tests followed the U.S. EPA method [5]. The concentrations of Sb, As, Ba, Be, Cd, Cr, Pb, Hg, Ni, Ag, Se and Ta were determined in the leached extract for each of the 14 laboratory cements (Table 5).

Table 5. Concentration data (ppb) of metals obtained in the leaching tests

Element	Leached metal content (ppb)													
	1	2	3	4	5	6	7	8	9	10	11	12	13	14
Sb	0.20	0.20	0.30	0.20	n.d.	0.60	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.

Pb	n.d.	n.d.	1.7	2.4	5	1.7	0.9	5.0	0.8	6.4	0.7	1.4	2.6	600
Cr	32	102	600	68.3	300	600	400	800	180	86.5	400	96	200	150
Hg	n.d.	n.d.	0.6	0.7	n.d.	1.2	1.4	1.2	0.6	n.d.	2.2	1.4	1.8	n.d.
Ni	1.5	n.d.	13	18	4.2	13	13	11	4.3	4.5	4	0.9	n.d.	5.8
Ag	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.
Se	n.d.	n.d.	n.d.	n.d.	0.8	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.
Ta	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.	n.d.

Detection limits: Se = 0.10ppb, Sb = 0.10ppb, Hg = 0.10ppb, Be = 0.02ppb, Tl = 0.5ppb, Ag = 0.05ppb, As = 0.10ppb

In over half of the analyses, the element contents in the leached extract were below detection limits. Arsenic, Be, Ag and Ta were not detected in any of the samples, while Se was detected in only one. All other values fall far below the U.S. EPA standards. Table 6 lists the highest values found.

Table 6. Highest leaching values opposed to the standards

Metal	Standard limits (ppb)	Highest value (ppb)
Antimony	1,000	0.60
Arsenic	5,000	Not detected
Barium	100,000	9,300
Beryllium	7	Not detected
Cadmium	1,000	0.23
Lead	5,000	600
Chromium	5,000	800
Mercury	2,00	2.2
Nickel	70,000	18
Silver	5,000	Not detected
Selenium	1,000	0.8
Thallium	7,000	Not detected

Regarding the admissible limits, Sb, Cd, Hg, Ni and Se highest values are extremely low. Barium and Pb showed figures that represent 9.3% and 12% of respective standards. The most significant value was a single Cr analysis of 800ppb, which makes up 16% of the permissible limit.

The leaching results confirm the retention of environmentally relevant trace elements in the crystal lattices of clinker mineral phases. No significant solubility of any element occurred; the highest values observed in most of the analyses were about 99% lower than the standard limits. Those found for Ba, Pb and Cr were lower - 91%, 88% and 84%.

4.4 Mechanical Performance of Cements

Composite Portland cements account for about 70% of the production in Brazil. Cement type CP II-E 32 consists of 56% to 94% clinker and gypsum, 6% to 34% blast-furnace slag, and up to 10% carbonate material [6]. Mechanical strength tests of industrial cements followed the Brazilian Test Method NBR 7215 [7] with cylindrical test specimens of 50x100mm, in proportion 1:3 (slag : sand), water cured at 23°C, s/alk sol.=0.5.

Compressive strengths at 1, 3, 7 and 28 days of 685 industrial CP II-E 32 cements are shown in diagrams (Figures 4a – 4c) and cover the period 1996 – 1998, from the time that the plant was not

burning WDF until 1998, the time that cements were made of a mix of clinkers burned with and without WDF.

Figure 4. Cement mechanical strength at 1, 3, 7 and 28 days for 1996, 1997 and 1998

The mechanical strengths at all ages are above the standards required [9]. The performance of cements at 1 day is equivalent to the standard set for 3 days. The same tendency is verified for performance at 3 days, which is higher than the normative limit at 7 days. The input of clinkers burned with WDF in the composition of CP II-E 32 is not even noticeable on the diagrams, which clearly implies that wastes introduced in the clinkering process do not affect cement performance.

5. DISCUSSION

Energy efficiency is a key issue for an energy intensive industry such as the cement industry. The use of WDF as partial substitutes for fossil fuels in cement kilns is strategic for the business and plays a significant role in hazardous wastes management.

On the other hand, WDF inputs an additional amount of elements of environmental concern in to the kiln system. The present work has shown however that higher contents of trace elements in the kiln imply higher contents in the clinker structure. Element entrapping in crystal lattices is done through solid solutions with major elements Ca, Si, Al and Fe up to the each mineral's limit of solubility. The results showed that there is a general compatibility of trace elements, even volatile ones, with clinker. The transition metals Cd, Zn, Cu, Mn, Cr and V were especially compatible, while Ni, Co and also Pb were comparatively less so, suggesting that they do not enter the clinker microstructure as readily.

No distinctive textural features were found in clinker either burned with or without WDF. Moduli LSF, SR and AR and control of the burning conditions in the kiln are surely the main factors to account for the clinkers textural and mineralogical characteristics. The optimal compressive strengths of cements were warranted by maintenance of the clinker quality throughout the time span from when only fuel oil was burned until lately when WDF has been used routinely in the kiln.

Composite cements, prepared exclusively with clinkers burned with WDF, did not leach detectable amounts of As, Be, Ag and Tl, while Sb, Cd, Hg, Ni and Se were extremely low. Slightly higher but still 91%, 88% and 84%, lower than the correspondent standard leaching limits, were Ba, Pb and Cr.

The potential release of toxic constituents is the most appropriate control parameter to check for the environmental impact of cement-based products. The response of cements to the extreme conditions of the leaching test corroborated the retention of trace elements in the crystal lattices of Portland clinker minerals. Because of this, cements made up of clinkers burned with WDF can be seen as environmentally sensitive building materials, meeting performance requirements while safely keeping metals within its structure.

ABSTRACT

This laboratory investigation focuses on the influence of the calcium sulfate source used to prepare sulfoaluminate cement. A sulfoaluminate clinker was ground at a Blaine fineness of 545 m²/kg and mixed with four types of calcium sulfate (phosphogypsum, borogypsum, natural gypsum and fluoroanhydrite) to get anhydrite sulfoaluminate cements. Five amounts of calcium sulfate were used: 5, 10, 15, 20, 25, and 30%.

The wettability of these cements was studied by means of the measurement of the instantaneous spread of a paste (W/C = 0.44). Whatever the sulfate content might be, borogypsum and fluoroanhydrite led to the lowest spreads.

The compressive strength was assessed on standard mortars. No strength gain was recorded with fluoroanhydrite after 6 hours of hydration. With other calcium sulfates, the 6-hr maximum strength was obtained using 5% natural gypsum. After 24 hours of hydration, the use of 20 to 25% fluoroanhydrite led to the best strength. With other calcium sulfates, the maximum strength was reached incorporating 20% calcium sulfate. After 28 days of hydration, the cement containing 20 to 30 % fluoroanhydrite presented the best strength. With other calcium sulfates, the strength was 30% lower.

This research points out that the choice of the calcium sulfate source is very important for the strength development of calcium sulfoaluminate cements.

1. INTRODUCTION

Calcium sulfoaluminate cements have essentially been developed in China and production has now expanded to more than one million tonnes per year [1-14]. The main constituent of calcium sulfoaluminate clinker is yeelimite (C₄A₃ \bar{S}). Belite (C₂S) and ferrite (C₄AF) are both present in calcium sulfoaluminate and Portland clinkers, while C₃S and C₃A, characteristic of Portland clinker are absent in calcium sulfoaluminate clinker. Calcium sulfoaluminate clinker is generally interground with 16-25 % gypsum to get calcium sulfoaluminate cement. Such cement is seen as a potentially very attractive high-performance material. Rapid strength gain and durability in a range of aggressive environments make it applicable to civil engineering needs [15-16].

This laboratory investigation focuses on the influence of the calcium sulfate source used to be mixed with calcium sulfoaluminate clinker on the strength development of calcium sulfoaluminate cement.

2. EXPERIMENTAL

2.1 Starting Materials

A calcium sulfoaluminate clinker was manufactured in a rotary kiln by Carrières du Boulonnais. Its phase composition was as follows:

- $C_4A_3\bar{S}$: 53.5 %,
- C_2S : 21.2 %
- C_4AF : 16.3 %
- perovskite 9.0 %

It was ground at a Blaine specific surface area of 545 m²/kg and mixed with four sources of calcium sulfate to prepare calcium sulfoaluminate cement: borogypsum, phosphogypsum, natural gypsum and fluoroanhydrite.

The physical properties of these materials are presented in Table 1. The main impurities found in the calcium sulfates were respectively:

- borogypsum: traces of quartz,
- phosphogypsum: none,
- natural gypsum: traces of anhydrite,
- fluoroanhydrite: traces of calcium hydroxide and calcium carbonate.

Table 1. Physical properties of starting materials.

Material	Density (g/cm ³)	Blaine specific surface area (m ² /kg)	Average diameter of the particle size distribution (D ₅₀ (μm))
Clinker	2.74	545	12.5
Borogypsum	2.30	280	24.4
Phosphogypsum	2.31	264	14.1
Natural gypsum	2.26	240	17.6
Fluoroanhydrite	2.79	346	10.4

The particle size distribution of the calcium sulfates is shown in Figure 1. Fluoroanhydrite presents a particle size distribution quite different from other sulfates: there are large quantities of particles smaller than 10 μm (50 %) and higher than 50 μm (35 %).

Figure 1. Particle size distribution of calcium sulfates.

2.2. Composition of Calcium Sulfoaluminate Cements

Each of the four calcium sulfates was mixed with clinker at the following contents: 5, 10, 15, 20, 25 and 30 %. Therefore, 24 cements were investigated for their physical and mechanical properties.

2.3 Testing Program

Each cement was hydrated at $W/C = 0.44$ and its workability was assessed by the measurement of the instantaneous spread of a truncated cone ($\varnothing_{sup} = 70$ mm, $\varnothing_{inf} = 80$ mm, $h = 40$ mm).

In a second series of tests, the compressive strength of standard mortars was measured at different ages: 6 hours, 24 hours and 28 days. The composition of mortars was: cement/sand = 1/3; water/cement = 1/2.

3. RESULTS AND DISCUSSION

3.1 Workability of Pastes

As shown in Figure 2, the presence of borogypsum and anhydrite reduces the spread of pastes, especially at contents higher than 15 %.

Figure 2. Initial spread of hydrated cements.

3.2 Compressive Strength of Mortars

At 6 hours of age (Figure 3), not any strength was recorded when anhydrite was used.

Figure 3. Compressive strength after 6 hours of hydration.

To explain this result, conductivity tests were carried out on suspensions ($Water/Cement = 4/1$). The results obtained for cements containing 20 % calcium sulfate are presented in Figures 4 to 7.

Figure 4. Conductivity of cement containing 20% borogypsum.

Figure 5. Conductivity of cement containing 20% phosphogypsum.

Figure 6. Conductivity of cement containing 20% natural gypsum.

Figure 7. Conductivity of cement containing 20% anhydrite.

The curves obtained for borogypsum, phosphogypsum and natural gypsum are similar: a slight decrease of conductivity, followed by a sudden drop which corresponds to the precipitation of ettringite, and then a new increase of conductivity. The conductivity drop appears after 340 minutes for borogypsum and phosphogypsum and 450 minutes for natural gypsum. When anhydrite is used, the curve is totally different: conductivity first increases and reaches a peak after 250 minutes, then it decreases and a minimum conductivity is obtained after 480 minutes. This phenomenon is less marked than for other sulfates and proves that ettringite precipitates later and explains why no strength is recorded after 6 hours. In order to enhance the dissolution of anhydrite, a mixture of calcium hydroxide and potassium sulfate (2 % by weight of anhydrite) was added to cement. A 6 hr-compressive strength was therefore recorded: 2.4 MPa for the cement containing 20 % anhydrite.

After 24 hours of hydration (Figure 8), best strengths are obtained when anhydrite is used, and they are higher than 40 MPa when anhydrite content reaches 15 %.

Figure 8. Compressive strength after 24 hours of hydration.

At 28 days of age (Figure 9), compressive strength as high as 75 MPa is obtained when anhydrite content reaches 20 % other calcium sulfates lead to strength in the range of 50 to 60 MPa at a dosage of 20-25 %.

Figure 9. Compressive strength after 28 days of hydration.

The strength development of cements containing 20 % calcium sulfate is shown in Figure 10. This Figure clearly points out the positive influence of anhydrite on strength after one day of hydration.

Figure 10. Evolution of compressive strength versus time.
Cement containing 20% calcium sulfate.

4. CONCLUSIONS

From this limited investigation, the following conclusions can be drawn:

1. The nature of the calcium source has an influence on the workability of calcium sulfoaluminate cement: borogypsum and fluoroanhydrite reduce the workability.
2. No strength is recorded at 6 hours of age when anhydrite is used, due to a delay in ettringite precipitation. Anhydrite has to be activated to get some strength.
3. The use of borogypsum and anhydrite leads to the best strength after one day of hydration.
4. A calcium sulfate content of 20 % is recommended to get the maximum strength. The use of anhydrite leads to strength 30 % higher than other sulfates.

ABSTRACT

As the hydration of calcium sulfoaluminate cement does not yield any calcium hydroxide, it should be interesting to use such cement in the production of glass fibre reinforced composites. Moreover, in such matrices efflorescences due to the carbonation of calcium hydroxide cannot appear.

A white sulfoaluminate cement was prepared and introduced in a matrix having the following weight composition:

- cement: 50 %,
- siliceous fine sand: 50 %,
- chemical admixtures

The AR-glass fibre (l = 11 mm) content was 2.8% of the matrix mass. The water to matrix ratio was 0.187. The composite was prepared by the premix method. Some specimens contained a mesh in addition to fibres.

The samples were subjected to three-point flexural loading at 3 hours, 24 hours, 7 days, and 28 days.

After 3 hours of hydration, the average maximum stress (MOR) reached 8 MPa. The composite developed ductile behaviour. At 24 hours of age, it reached 9.3 MPa. The presence of a mesh increased this value to 20.2 MPa. At later ages, the performances were: 16.5 MPa at 7 days and 20.5 MPa at 28 days.

These results show that high-performance composites can be obtained using calcium sulfoaluminate cement instead of Portland cement. The main finding is that the initial strength (3 hours) is very high and allows both quick demolding and rapid rotation of molds.

1. INTRODUCTION

Glass fibre reinforced cement (GFRC) is an interesting construction material of considerable potential. But its development has been lower than expected due to the high alkalinity of Portland cement matrices. Borosilicate E-glass is chemically destroyed in Portland cement and even alkali-resistant glass fibre is subjected to physical attack by calcium hydroxide crystals. Pozzolanic additions like metakaolin or microsilica are used to decrease the calcium hydroxide content and therefore guarantee the durability of GFRC composites [1-2]. Less alkaline non-Portland cement matrices have been developed for reinforcement by glass fibres: high-alumina cement, supersulfated

cement and calcium sulfoaluminate cement [3-5]. Accelerated ageing tests have shown that AR glass fibres are more durable in calcium sulfoaluminate cement than in Portland cement.

As no calcium hydroxide is produced during calcium sulfoaluminate cement hydration, efflorescences due to the carbonation of calcium hydroxide are avoided. Therefore, decorative GFRC composites can be developed with guaranteed tint. That is the second advantage of calcium sulfoaluminate cement versus Portland cement

This paper presents the preliminary results obtained on white sulfoaluminate cement reinforced AR glass fibres.

2. EXPERIMENTAL

A white calcium sulfoaluminate clinker was prepared by Carrières du Boulonnais in a rotary kiln, from a mixture of residual aluminium hydroxide and phosphogypsum. The phase composition of this clinker was as follows:

- belite (C_2S): 11 %,
- yeelimite ($C_4A_3\bar{S}$): 84 %,
- ferrite (C_4AF): 4 %,
- perovskite (C_3FT_2): 1 %.

Calcium sulfoaluminate cement was obtained by intergrinding 70 % of that clinker and 30 % phosphogypsum.

The hydration of such cement is described by the following equations:

$C_4A_3\bar{S} + 6CH + 8C\bar{S}H_2 + 80H \rightarrow 3C_3A_3C\bar{S}H_{32}$, in presence of calcium hydroxide yielded by C_2S hydration.

In each case, the main product of hydration is ettringite. The mixture proportions of the matrix are shown in Table 1.

Table 1. Mixture proportions of the matrix.

Cement/Sand	1.00
Water/Cement	0.37
Superplasticizer (% cement)	1.00
Accelerator (% cement)	0.05
Retarder (% cement)	0.27
Water-retaining agent (% cement)	0.06

The sand was a very fine siliceous sand (< 500 μm). All chemical admixtures were powdered products:

- superplasticizer: polycarboxylate,
- accelerator: lithium chloride,
- retarder: sodium tetraborate,
- water-retaining agent: polyethylene-glycol.

Short fibres ($l = 11$ mm) and mesh derived from the same AR-glass (Vetrotex - Cem-Fil). The properties of fibres are presented in Table 2.

Table 2. Properties of short fibres.

Filament diameter	14 μm
Strand tensile strength	1700 MPa
Elastic modulus	72 GPa
Density	2.68g/cm ³
Strand	38 tex (102 filaments)

Cem-Fil 120/1 had a nominal weight of 120 g/m² and was produced using 320 tex and 640 tex Cem-Fil direct rovings. The mesh density was 8 x 8 strands per 10 cm.

The short fibre content was 2.83 % of total weight (cement + sand). The mesh was placed at 5 mm from the extreme tensile fiber of the composite.

Thin plates (350 mm x 350 mm x 14 mm) were cast and cured at ambient temperature. They were demolded 90 minutes after casting. Specimens of 70 mm in width were cut from each plate and subjected to 3-point loading on a span of 200 mm at a cross-head speed of 1 mm/min. The load deflection was recorded during the test and allowed the calculation of the following parameters:

- limit of proportionality (LOP): stress corresponding to the first crack of the matrix,
- modulus of rupture (MOR): maximum stress recorded,
- several toughness indices.

These indices were those described by the ASTM C 1018 85 [6]: I_5 , I_{10} , I_{20} and I_{30} . The residual strength factors $R_{20,10} = 10 (I_{20} - I_{10})$ and $R_{10,5} = 20(I_{10} - I_5)$ were also calculated.

Tests were performed at different ages: 3 hours, 24 hours, 7 and 28 days. Specimens tested after 3 hours were sealed in plastic bags at 20°C until the date of tests.

3. RESULTS AND DISCUSSION

3.1 Mechanical Properties

From the load-deflection curves recorded, equivalent elastic bending stress versus deflection curves were derived. Typical stress-deflection curves are shown in Figures 1 to 3. These are average values, each obtained from six samples.

All composites developed ductile behaviour as shown in Figure 4: all indices are higher than required values and remain constant with time.

Figure 1. Flexural behaviour after 3 hours of hydration.

Figure 2. Flexural behaviour after 24 hours of hydration.

Figure 3. Flexural behaviour after 28 days of hydration.

Figure 4. Indices of toughness at different ages for composites reinforced by short fibres.

As shown in Figures 2 and 3, the presence of mesh increases the performances of the composites, and especially at 24 hours. The MOR values obtained at different ages are summarized in Table 3.

Table 3. MOR values recorded at different ages.

Age	MOR (MPa)
3 hours	8.0
24 hours	9.3
24 hours with mesh	20.2
28 days	20.5
28 days with mesh	22.8

The main remarkable result is the performance obtained after 3 hours of hydration: MOR = 8 MPa, ductile behaviour. This is very important for the precast industry: such performance allows quick demolding and rapid rotation of molds.

At 28 days, the performances of the composite are similar to those obtained for a white OPC composite, reinforced 3 % fibres and mesh, containing metakaolin and a polymer. To get such results, the composite had to be cured at 40°C for 3 days, before being stored at 20°C in sealed plastic bags. Its mechanical behaviour is shown in Figure 5.

Figure 5. Performance of OPC composite.

3.2 Microstructure

Figures 6 and 7 show a good bond between fibres and matrix. Ettringite is present in the matrix and there is no calcium hydroxide.

(a)

(b)

Figure 6. Unattacked fibres well embedded in the matrix.

4. CONCLUSIONS

This preliminary investigation points out the following:

- [1] White calcium sulfoaluminate cement can be developed from waste materials: residual aluminium hydroxide and phosphogypsum.
- [2] This cement can be used to prepare high-performance fibre-reinforced composites.
- [3] Without any temperature curing, those composites develop high bending stress and ductile behaviour, after only 3 hours.
- [4] The use of such composites is of interest to the precast industry: it allows quick demolding and rapid rotation of molds.
- [5] Ductile behaviour is maintained with time at ambient conditions. Ageing tests are needed to confirm these results.

ABSTRACT

Probabilistic strength of materials was used to determine the number of compacted neat cement paste samples to be tested to carry out a probabilistic mechanical characterization of a particular cement, when the fracture probability and its particular tolerance are known. Weibull's parameters were determined from compacted neat cement paste samples. Parameter dispersions were determined through a numerical simulation. A functional relation between parameter deviations and the number of samples tested was estimated with Fischer's matrix. Finally an estimate was made of the necessary number of samples to be tested to meet the tolerance admissible to a predetermined fracture probability by linking the parameters dispersions and their deviations. The number of samples required to be tested when the tolerance in the cumulative fracture probability is much less than the probability was found to be excessively large. In order to get an acceptable number of samples to be tested, both from the point of view of the statistical significance of the results and of the feasibility of testing, the tolerance of the cumulative fracture probability must be of the same order as that of the probability.

1. INTRODUCTION

The quality control tests carried out by the cement laboratories of cement plants, universities and research centers all over the world usually emphasize the physical, chemical and mechanical characterization of the cement. Quality control is carried out by cement plants to monitor their manufacturing processes. It is also performed whenever certification of the cement is sought, either through the control of external-to-the-plant laboratories or through the control of third party laboratories. The dynamics imposed by globalization, in a wide range of markets, has also reached the cement sector. Nowadays, globalization has shortened distances and manufactured products are required from distant points in the planet.

In Chile, in particular, clinker, as well as cement have been imported from remote places. Hence, the necessity of complying with different control standards on intermediate and final products arises, both in the origin places and the destination places. It is within this setting that control standards must work as facilitating agents for commercial exchange, and not as barriers to it. In accordance to this, there exists today a worldwide trend toward the homogenization of control standards in cements.

Nowadays, a great number of countries are adopting modern accreditation systems for laboratories that control a wide range of products. Accreditation has constituted itself into a tool of an economic

nature that increases competitiveness in various industries thus facilitating commercial exchange. As an articulating agent in this process the ISO standards stand out. In particular in [1] the basic guidelines through which a laboratory can perform as an accredited laboratory and, then, offer its services as such are established. One of the advantages of the accreditation system is its practical universal validity. Therefore, laboratory accreditation provides advantages both to laboratories and to users or potential users of laboratory services.

Laboratories benefit by receiving national and international recognition of their competence and qualifications by using the evaluation process as a quality assurance feature and by saving both time and money through the possible elimination of multiple audits from many potential clients. Users of laboratory services benefit by having an independent and objective means of selecting a laboratory for the required services, an easy way to provide specifications for laboratory services, and also by saving both time and money by not having to perform extensive evaluations on their own [2].

For the particular case of cements, the quality controls are aimed at determining certain physical, chemical and mechanical properties. Standardized procedures are followed for the aforesaid; these, through the testing of a particular number of samples, representative of a certain production volume, allow for the characterization of a particular cement. Certain characteristic parameters of cement are estimated from these samples.

One of these estimates relates to the mechanical characterization of the cement, which is one of the most significant variables at the moment of designing structures to be built with a given type of cement. This mechanical characterization is made starting with the preparation, curing and testing of mortars subjected to flexure and compression, and the determination of the fracture strengths. This is also done by using standardized procedures as a function of the curing age of the mortar samples made. Most countries have local standards to carry out these testing procedures; most of them are based on North American, ASTM, or European standards.

The question of the statistical validity of the results obtained from small samples that should be representative for thousands of tons of production appears when considering the present cement production volumes in different factories. Probabilistic strength of materials provides an answer for the aforesaid. The probabilistic treatment of materials or probabilistic strength of materials [3,4] foundations are laid on the impossibility of unequivocally characterizing a material considering the values of characteristic properties with no dispersion.

Fracture strength [5] and the critical stress intensity factor in mode I [6] have been treated as typical properties in compacted cement pastes and in cement mortars. Even when measurement methods have become greatly sophisticated and refined, precision and accuracy of experimental measurements improved, the resultant dispersion phenomenon continues to be present. Taking this into account Weibull [3] proposed the statistical analysis of the experimental results of brittle materials fracture. In this way the experimental results are described through probability distribution functions. These probability distribution functions are defined by means of a certain number of parameters, and it is from the experimental evidence that indicates how many correspond for each particular case. The application diversity and the parameter determination methods can be found in Kittl and Díaz [4].

For some material subjected to any given stress field, the speed of the application of external loads also influences the probability distribution functions. In [7] the applicability of models that use Weibull's distribution functions when the external loads are applied gradually is discussed. Both analytical methods and graphic methods have been used in the estimation of the parameters that describe the probability distribution functions. Graphic methods present the advantage of their simplicity of application according to what was shown by León and Kittl [8].

Estimating the parameters of probability distribution function is not enough; their respective dispersions also have to be estimated. Through Fischer's information matrix it is possible to estimate such dispersions [9]. Then, not only is there variability in the material characteristic properties or stress, which we can represent through their mean values and their corresponding dispersions, but also the parameters of the probability distribution functions present dispersion. For the results obtained from the testing of a certain number of samples to have statistical validity it is necessary to count on a minimum number of these. The aforesaid calls, sometimes, for severe restrictions on the execution of testing. That is why simulation methods which allow for the estimation of the parameters of the probability distribution functions along with their respective dispersions have been developed [9].

The purpose of the present work is estimating, through numerical simulation, the parameter dispersion of Weibull's cumulative probability of fracture function in compacted neat cement paste. And then, with Fischer's matrix, estimating the necessary number of samples to be tested to meet the tolerance admissible to a pre-established fracture probability.

2. EXPERIMENTAL PROCEDURE

In the manufacture of the compacted neat cement paste samples a commercial portland cement devoid of admixtures was used. Its composition was as follows: 20.42% SiO₂, 7.16% Al₂O₃, 2.76% Fe₂O₃, 61.4% CaO and 1.72% MgO having a specific surface of 305 m²/kg and a retention of 13.6% in a moist 45µm sieve.

The cement was mixed with 5% in weight of water and was introduced in a rectangular steel mould 55x20mm in dimension. Then a compacting pressure of 25.6 MPa was applied to it in order to obtain samples 5mm high. The samples were stored in a moist room, with 99% humidity and at 23°C for 24 hours. Once the 24 hours were over the samples were submerged in water until saturation, for their process of hydration to advance as fast as possible. Afterwards, the samples were again entered into the moist room until completing 14 days of hydration. The hydration process was stopped by putting the samples into an oven at 110°C for 24 hours. Later they were stored in a dessicator until the moment of testing. In this way, 32 samples were made. All samples were subjected to the three-point bending test, with a testing span of 40mm.

3. PROBABILISTIC CHARACTERIZATION

According to the probabilistic strength of materials, Weibull's fracture cumulative probability distribution function F is given by:

$$F(\sigma, V) = 1 - \exp \left\{ -\frac{V}{V_0} \phi(\sigma) \right\} \quad (1)$$

where V is the volume of the material subjected to the stress field σ , V_0 is the volume unit, and ϕ is the Weibull's specific risk of fracture function. Experimental data usually adjusts quite well to two- or-three parameter specific risk functions:

$$\phi(\sigma) = \left(\frac{\sigma}{\sigma_0} \right)^m \quad \sigma \geq 0 \quad (2)$$

$$\begin{cases} \phi(\sigma) = \left(\frac{\sigma - \sigma_L}{\sigma_0}\right)^m & \sigma_L < \sigma \leq \infty \\ \phi(\sigma) = 0 & 0 \leq \sigma \leq \sigma_L \end{cases} \quad (3)$$

where m , σ_0 and σ_L are the Weibull's parameters determined from the experimental data, and are representative of the genesis process or the material manufacturing process. σ_L is the stress under which there is no fracture, σ_0 is a normalization parameter and m is Weibull's modulus.

Considering a three-parameter specific risk of fracture function the equation (1) can be rewritten as follows:

$$\xi(\sigma) = \ln \frac{1}{1 - F(\sigma)} = \frac{V}{V_0} \left(\frac{\sigma - \sigma_L}{\sigma_0} \right)^m \quad (4)$$

Weibull's diagram is obtained by making a graph of $\ln \xi(\sigma)$ versus $\ln \sigma$ for a group of experimental data from samples of material similarly made in size and geometry. Then, Weibull's parameters m , σ_0 and σ_L can be estimated.

Once Weibull's specific risk function parameters are estimated, the estimation of the dispersions associated to each one of them can be carried out, in such a way that each parameter is expressed in terms of its estimated mean value plus its dispersion. When big samples or statistically valid samples to estimate the parameters exist, the maximum likelihood estimators are approximately distributed through a multivariate normal distribution with mean values m , σ_0 and σ_L . This last function has a symmetrical R Fischer's information matrix, which is a quadratic form, its elements are given by:

$$\begin{aligned} r_{ij} &= -NE \left[\frac{\partial^2 \ln f(\sigma_i; m, \sigma_0, \sigma_L)}{\partial \theta_i \partial \theta_j} \right] \\ \{\theta\} &= \{m, \sigma_0, \sigma_L\} \\ E(g) &= \int_{\sigma_L}^{\infty} g(\sigma) \frac{dF}{d\sigma} d\sigma \end{aligned} \quad (5)$$

In this matrix, after its inversion, the variances in the diagonal and the co-variances of the estimators are expressed as $(1/N) R^{-1}$, where N is the number of tests carried out.

4. NUMERICAL SIMULATION

With the purpose of illustrating the method, a pair of simplifying hypothesis were used. The first of them is the direct use of Weibull's cumulative probability distribution function, as expressed in equation (1). The second one, since the volume of all the samples remained constant, is $V = V_0$ in the aforementioned equation.

Weibull's parameters were estimated from the fracture strength of the compacted neat cement paste samples through the use of a nomogram [8]. This is a graphic method that allows for the estimation of the parameters in a simple way and with great accuracy. The parameter values are shown in Table 1.

Table 1. Weibull's parameters for compacted cement paste

Weibull's parameters	
m	3.00
σ_0 MPa	0.06
σ_L MPa	6.96

After that a group of 30 random numbers were generated, λ_i . The corresponding value of σ_i was calculated with each one of them according to the following equation:

$$\lambda_i = 1 - \exp \left\{ -\frac{V}{V_0} \left(\frac{\sigma_i - \sigma_L}{\sigma_0} \right)^m \right\} \quad (6)$$

using those of Weibull's parameters included in Table 1 for the equation (6). Afterwards the respective σ_i were set in an ascending way and Weibull's diagram was made, using the following expression as an estimator for the fracture cumulative probability:

$$F = \frac{n - 0.5}{N} \quad (7)$$

in which n is the sequence number in the ascending ranking, and N is the total number of σ_i values, 30 in this case. In Figure 1 the respective Weibull diagram is shown, fracture strength data generated at random.

Figure 1. Weibull's diagram obtained from generating random numbers for the compacted neat cement paste samples.

In Weibull's diagrams of this nature it is possible to make an estimate of the value of $\ln \sigma_L$ the first approximation directly from the graph, corresponding to the asymptote of the inferior branch of the curve. For this case an asymptote near 1.941. Then, several numbers around that asymptote value were taken and a diagram was made for each one of them, using $\ln(\sigma - \sigma_L)$ as an independent variable, for the expression:

$$\ln\left(\ln\left(\frac{1}{1-F}\right)\right) = m \ln(\sigma - \sigma_L) - m \ln(\sigma_0) \quad (8)$$

In each case, the linear correlation coefficient, R^2 , was determined using minimum square method and the respective values for parameters m and σ_0 in function of the different σ_L values used. Figures 2, 3 and 4 illustrate such functional variations respectively.

Figure 2. Linear correlation coefficient as a function of σ_L for the randomly generated data of compacted neat cement paste samples.

Figure 3. Weibull's parameter m as a function of σ_L for the randomly generated data of compacted neat cement paste samples.

Figure 4. Weibull's parameter σ_0 as a function of σ_L for the randomly generated data of compacted neat cement paste samples.

Using the maximum correlation coefficient in the square minimums adjustments of randomly generated data from the parameters estimation of compacted neat cement paste samples subjected to the three point bending test, according to Figure 2, parameter $\sigma_L = 6.948$ MPa. Therefore, from Figures 3 and 4 respectively, the remaining Weibull's parameters $m = 4.1$ and $\sigma_0 = 0.077$ MPa are obtained.

The simulation process, described here with an example, was repeated one thousand times, starting by generating random numbers λ_i again and determining the respective Weibull's parameters m , σ_0 and σ_L in every stage. For each Weibull's parameters the mean values and their corresponding dispersions were calculated from this set of one thousand repetitions (m , σ_0 , σ_L) using the following expressions, respectively:

$$\bar{x} = \frac{1}{N} \sum_{i=1}^N x_i \quad (9)$$

$$\Delta x = \sqrt{\frac{1}{N} \sum_{i=1}^N (x_i - \bar{x})^2} \quad (10)$$

Equations (9) and (10) allows one to obtain the mean value of m , σ_0 and σ_L and their dispersions Δm , $\Delta \sigma_0$ and $\Delta \sigma_L$, respectively. Here $N = 1000$. Table 2 shows the mean value of the parameters thus obtained with their respective dispersions.

Table 2. Weibull's parameters m , σ_0 and σ_L , their mean values and their dispersions for compacted neat cement paste samples randomly generated in numerical simulation process with 1000 iterations.

Weibull's parameter	Mean value	Dispersion
m	3.371	$\Delta m = 0.510$
σ_0	0.065 MPa	$\Delta \sigma_0 = 0.0071$ MPa
σ_L	6.955 MPa	$\Delta \sigma_L = 0.0057$ MPa

According to Fischer' information matrix defined in the equation (5) the following expressions for Weibull's parameters dispersions can be determined:

$$\begin{aligned}\Delta m &= \frac{1}{\sqrt{N}} f(m, \sigma_L, \sigma_0) \\ \Delta \sigma_L &= \frac{1}{\sqrt{N}} g(m, \sigma_L, \sigma_0) \\ \Delta \sigma_0 &= \frac{1}{\sqrt{N}} h(m, \sigma_L, \sigma_0)\end{aligned}\quad (11)$$

where f , g and h are functions which depend on the parameters and N is the number of testing. Therefore, using the parameter dispersions indicated in Table 2 in the equation (11), the values for f , g and h are 2.79, 0.0031MPa and 0.0039 MPa, respectively.

For a determined fixed value of the cumulative fracture probability F the respective fracture strength value, or calculated strength, σ_c , can be determined from the following equation:

$$F = 1 - \exp \left\{ - \left(\frac{\sigma_c - \sigma_L}{\sigma_0} \right)^m \right\} \quad (12)$$

If an ΔF tolerance in cumulative fracture probability F for a calculated fracture strength value, σ_c , is admitted then the Weibull's parameters will also be modified. Parameters m , σ_0 , and σ_L suffer deviations δm , $\delta \sigma_0$ and $\delta \sigma_L$ respectively. That is to say, they become $m + \delta m$, $\sigma_0 + \delta \sigma_0$ and $\sigma_L + \delta \sigma_L$. The cumulative fracture probability changes to $F + \Delta F$. The equation (12) can be written for each of these deviations which allows one to determine the following expressions for the variations of each parameter:

$$\begin{aligned}\delta m &= \left\{ \frac{\ln \left[\ln \left(\frac{1}{1 - (F + \Delta F)} \right) \right]}{\ln \left[\ln \left(\frac{1}{1 - F} \right) \right]} - 1 \right\} m ; \delta \sigma_L = \left\{ \frac{\sigma_c - \sigma_0 \left[\ln \left(\frac{1}{1 - (F + \Delta F)} \right) \right]^{1/m}}{\sigma_c - \sigma_0 \left[\ln \left(\frac{1}{1 - F} \right) \right]^{1/m}} - 1 \right\} \sigma_L \\ \delta \sigma_0 &= \left\{ \frac{\left[\frac{\ln \left(\frac{1}{1 - F} \right)}{\ln \left(\frac{1}{1 - (F + \Delta F)} \right)} \right]^{1/m} - 1}{\left[\frac{\ln \left(\frac{1}{1 - F} \right)}{\ln \left(\frac{1}{1 - (F + \Delta F)} \right)} \right]^{1/m}} \right\} \sigma_0\end{aligned}\quad (13)$$

The number of samples to be tested to perform with tolerance ΔF with a pre- established fracture probability F is determined by equating $\delta m = \lambda \Delta m$, $\delta \sigma_0 = \lambda \Delta \sigma_0$ and $\delta \sigma_L = \lambda \Delta \sigma_L$, where λ is, in general, a number higher than one. When $\lambda=1$, 70% of the fracture strength values falls within the acceptance range. Therefore, considering the equations (13) and the dispersion equality with their respective parameters deviations, the expressions for determining the number of samples to be tested are:

$$N_m = \frac{f^2}{\delta m^2}; N_{\sigma_L} = \frac{g^2}{\delta \sigma_L^2}; N_{\sigma_0} = \frac{h^2}{\delta \sigma_0^2} \quad (14)$$

where N_m , N_{σ_L} and N_{σ_0} are the number of samples to be tested that allow to determine the respective parameters, m , σ_0 and σ_L , with a pre-established probability and an admissible tolerance. For the results to be statistically valid the highest value defined by the equation (14) must be taken as the number of samples to be tested. Table 3 shows the number of samples required to be tested to perform the fracture probability and its tolerance in compacted neat cement paste subjected to three-point bending test.

Table 3. Number of samples to be tested to estimate Weibull's parameters m , σ_0 and σ_L with a fixed cumulative fracture probability F and admissible tolerance ΔF for compacted neat cement paste subjected to the three-point bending test.

Cumulative fracture probability.	Cumulative fracture probability with admissible tolerance.	Number of samples to estimate the corresponding Weibull's parameters.		
F	F+ΔF	N_m	N_{σ_0}	N_{σ_L}
10^{-7}	10^{-6}	43	2	9297
10^{-6}	10^{-5}	31	2	2000
10^{-5}	10^{-4}	22	2	432
10^{-4}	10^{-3}	14	2	93
10^{-3}	10^{-2}	8	2	20

In accordance with Table 3 it was found that when the tolerance in the cumulative fracture probability, ΔF , is much less than that probability, the required number of samples to be tested is excessively large. In order to get an acceptable number of samples to be tested, both from the point of view of the statistical significance of the results and of the feasibility of testing, the tolerance of the cumulative fracture probability must be of the same order as that of the probability.

5. CONCLUSIONS

The assurance of the quality in the manufacture of cement requires strict and rigorous controls. The existence of accredited laboratories that control the properties that characterize cements is fundamental to this. By using probabilistic strength of materials it was possible to determine Weibull's parameters in compacted neat cement paste samples subjected to the three-point bending test, and through numeric simulation the number of samples to be tested for all parameters to be statistically valid with a pre-established probability and with an admissible tolerance was determined.

It was found that when the tolerance in the cumulative fracture probability, is much less than that probability, the required number of samples to be tested is excessively large. In order to get an acceptable number of samples to be tested, both from the point of view of the statistical significance of the results and of the feasibility of testing, the tolerance of the cumulative fracture probability must be of the same order as that of the probability. The choice of probability fracture and its tolerance will depend on the demands, complexities, safety and costs of the structures to be built with a certain cement.

ABSTRACT

Scientific groups have studied a new type of binder obtained by the alkaline activation of granulated blast furnace slag in order to get alternative materials to traditional Portland cements, which are characterized by their high negative environmental impact. Previous studies proved that the nature of the activator is the main process factor to get alkali-activated slag (AAS) cements of appropriate quality, these being waterglass ($\text{Na}_2\text{SiO}_3 \cdot n\text{H}_2\text{O} + \text{NaOH}$) with a concentration of 4 % Na_2O as the best activator. The aim of this research was to study the durability of AAS mortars using the mentioned alkaline activator. A blast furnace slag from Spain was activated using an alkaline solution/slag ratio of 0.51. Mortars with sand/slag ratio 2/1 were prepared to cast different specimen sizes according to the properties to be measured, such as compressive strength, absorption and total porosity, capillary absorption, ability to resist Chloride penetration, Chloride diffusion coefficient, sulphate resistance and electrochemical corrosion tests. The results showed that AAS mortars had half of the absorption of a mortar prepared with an Ordinary Portland Cement (OPC) used as reference. The capillary absorption coefficient was 70 % inferior to that of the reference cement and presented also a lower coefficient than reported for a cement blended with silica fume. AAS mortars reported a Chloride diffusion coefficient 95 % lower than that of the reference hardened mortar. The Kock-Steinegger test showed that the AAS cement is resistant to sulphate environments. The total porosity and pore size decreased with time in all mortars independently of aggressive media. Electrochemical valuation done on steel bars embedded in the alkali-activated slag mortars showed no corrosion after 1 year of exposure to a Chloride medium. These results demonstrate that the AAS mortars when the alkaline activator is $\text{Na}_2\text{SiO}_3 \cdot n\text{H}_2\text{O} + \text{NaOH}$ have high durability when exposed to sulphate and Chloride media.

Keywords: Alkali-activated slag cement mortars, Ground Granulated Blast Furnace Slag, Durability, Chloride diffusion, steel corrosion, aggressive environments.

1. INTRODUCTION

By now, it has been proved that blending cements with high performance pozzolans or with blast furnace slag augments the long-term durability of concrete structures in marine environments. The necessity of using industrial by-products and also of lowering the energy cost of the production of cements and its environmental impact on the atmosphere has switched the attention of the researchers, since 1960, to researching of new types of binders based on the alkaline activation of blast furnace slag^{1,2}. Glukhosky³ in Ukraine first developed these cements from alkali-activated slag (AAS).

Previous studies proved that the nature of an alkaline activator is the most significant factor on the development of mechanical strengths, and showed $\text{Na}_2\text{SiO}_3 \cdot n\text{H}_2\text{O} + \text{NaOH}$ (with a concentration of 4% Na_2O) to be the best activator for good properties^{2,4}. The microstructure of the products of reaction of these materials differs from that of Portland cements. Its high early strength and low permeability are characteristic. Additionally, the resistance of ASS concrete to different aggressive

environments has been studied by different authors⁵⁻⁹. This paper presents the results of research into the durability of mortars with alkali-activated slag (AAS) using $\text{Na}_2\text{SiO}_3 \cdot n\text{H}_2\text{O} + \text{NaOH}$ as the alkaline activator.

2. EXPERIMENTAL METHODS

2.1. Materials

Table 1 shows the chemical composition of a blast furnace slag from Ensidesa, Avilés, Spain was found to be 95%. Its glass content determined by XRD¹⁰ and microscopy techniques¹¹. Its specific surface area was 460 m²/kg. A Portland cement was used as reference material and its chemical composition is also presented in Table 1.

Table 1. Chemical Composition (% wt)

Component	OPC	SLAG
SiO ₂	20.75	35.50
Al ₂ O ₃	6.53	12.15
Fe ₂ O ₃	3.64	1.01
CaO	60.13	41.45
MgO	2.56	8.34
SO ₃	1.97	0.18
Na ₂ O	-	0.58
K ₂ O	-	0.64

Mortars of the alkali-activated slag were prepared by mixing waterglass ($\text{SiO}_2/\text{Na}_2\text{O} = 1.5$) with 4% of Na_2O to the slag. Following other studies^{4,12}, the sand/slag ratio used was 2/1 and the alkaline solution/slag ratio was 0.51. The sand used was a siliceous material with a purity higher than 95% in quartz.

2.2. Testing

The experimental procedure was done according to:

- ASTM C109, Compressive Mechanical Strength¹³
- ASTM C642, Absorption and total porosity¹⁴
- Fagerlund and Swiss Standard Methods, capillary absorption^{15,16}
- ASTM C1202, Ability to Resist Chloride Ion Penetration¹⁷
- Chloride Diffusion Coefficient Method¹⁸
- Kock and Steinegger Techniques¹⁹ and ASTM C1012²⁰, sulphate resistance
- ASTM C876²¹ and ASTM G59²², Corrosion Tests

50.8 mm cubic prisms were used to study the mechanical strength, the total absorption and the sulphate resistance behaviour of mortar specimens. The Koch-Steinegger procedure undertaken using specimens of 100 x 100 x 600 mm. 76.2 x 152 mm cylinders were cast for the rest of the tests. A corrugated steel bar was embedded in each cylinder prepared for corrosion testing. All specimens were cured at ambient temperature in a humid chamber (98%) until the testing day.

3. RESULTS AND DISCUSSION

The evolution of the compressive strengths at ages of 28, 60, 90 and 120 days is shown in Figure 1. Each data point is an average of three specimens. Alkali-activated slag mortars (AAS) yield 75.8% higher strength than the OPC mortar at 28 curing days. The strength increases up to 94.4% at 120 curing days. It is to be noted that OPC blended cements with 70% w/w blast furnace slag or 10%

w/w silica fume reported 50% lower results than for the AAS mortar and that is in agreement with the findings by Deja²³.

Figure 1. Compressive Strength Development

Total absorption results of mortars at different curing days are presented in Table 2. The absorption was evaluated following ASTM C642¹⁴ after drying specimens at 100°C and then by immersing the samples under water for 24 hr. Included in Table 2 is the total percentage of pores and the specific density at 28 curing days. It is noticeable in the AAS mortar a diminishing of the absorption at higher curing days that agreed with greater compactness and strength increases. At 90 curing days there was a reduction of 61% in absorption when compared with OPC mortars. The total porosity was reduced by about 50%, although the density was comparable with that obtained in OPC mortars. These results agree with those reported by Roy et al.²⁴ and Wu et al.²⁵.

Absorption and porosity values lower than 3 and 10% respectively are considered acceptable as parameters of compaction and durability for mortars.

Table 2. Results of Tests according to ASTM C642.

Material	Total Absorption, %			Porosity, % (28 days)	Specific Density, K/m ³ (28 days)
	Curing age, days				
	28	60	90		
AAS	4.96	2.67	2.04	5.78	2183
OPC	5.28	6.26	5.28	11.42	2186

The permeability of mortars was evaluated using the capillary suction technique done in specimens conditioned at 60°C for 48 hours^{15,16}. The results of capillary absorption were calculated as a square root time function, as shown in Figure 2. The capillary Index or the absorption coefficient (k) and the resistance to water penetration (m) are reported in Table 3. Also, the saturation time (t_h) and the capacity of capillary suction at 3 and 24 hours exposure are included. The k values of the AAS mortars is 70 % less than the index showed by the OPC mortar. The observed behaviour is comparable with that found in pozzolans of high reactivity. The index of the mortar blended with 10% of silica fume was 30% higher than that of the AAS mortars. A lower k indicates the refinement of the capillary pores and therefore a reduction of the pore connectivity. The shape of the graph in Figure 2, shows it is more difficult to reach saturation of the AAS specimens when compared to the OPC prisms.

Figure 2. Water Suction Test.

Table 3. Results of Capillary Absorption testing

Material	k kg/m ² s ^{1/2}	m s/m ²	t _n s	Kg/m ² (3 hours)	Kg/m ² (24 hours)
AAS	0.0130	-	-	1.69	2.58
OPC	0.0445	1.56 x 10 ⁷	30.1 x 10 ³	4.90	8.06
OPC+Silica Fume 10%	0.0170	10.3 x 10 ⁷	243 x 10 ³	-	-

Hakkinen²⁶ determined the pore size distribution of AAS mortars by means of mercury porosimetry finding a dense microstructure with fine pores between 5 and 30 nm. Roy et al.²⁴ reported up to 80% in reduction of the median pore size compared with that obtained in OPC mortar. Previous work on AAS mortars, prepared with the same slag used in this research, show that the distribution of the pores is bimodal, a high percentage of the pores had sizes between 0.1 and 10 μm and other presented sizes lower than 0.01 μm ¹².

Permeability to Chloride ions was evaluated following the ASTM C1202 procedure¹⁷, in order to monitor the amount of electric current passing through a 51 mm thick specimen put between two solutions, one of them containing NaCl. The results of this test are presented in Figure 3. The total charge passed is related to the material resistance to chloride ion penetration. AAS mortars gave a charge of 1329 coulombs against 4938 coulombs reported by the reference mortar. This reduction of 73% was obtained at 28 curing days of the specimens. Douglas et al.²⁷, reported similar values working on AAS concrete samples. The ASTM standard defines passing charges in the range of 1000 – 2000 coulombs as materials with low chloride permeability.

The diffusion coefficient of chloride ions was evaluated in a diffusion cell by using plates thinner than 10 mm. 12 V was applied in order to accelerate the process of diffusion. The diffusion coefficient was calculated by using the first law of Ficks, the concept of stationary state flux and the equation of Nernst and Planck^{28,29}. In Figure 4 it is seen that AAS mortars present a diffusion coefficient 95% lower than that of the reference mortar. This is also lower than reports on mortars with additions such as metakaolinite (MK), silica fume (SF) and blast furnace slag (S)^{23,30,31}. Roy et al.²⁴ and Byfors et al.⁸ reported similar values. Byfors working on paste specimens showed coefficients 30 to 40 times lower than those determined in OPC pastes. The same author evaluated the binding capacity of these materials in order to assign the observed behaviour to the formation of Friedel salt; however, the results are not conclusive.

Figure 3. Ability to Resist Chloride Ion Penetration

AAS mortar specimens exposed to sulphates showed reduced values of total porosity when compared to the mortar specimens immersed in the reference solution. Additionally, their pore size decreased about ten times, while the proportion of small size increased significantly. This fact is associated with the kinetics of the activation process and also to the variation of composition and structure of the main product of reaction, hydrated calcium silicate³³. When prisms of hardened AAS mortars were submerged in a Na_2SO_4 solution, the analysis of the microstructure of the reaction products, by means of SEM/EDX and DRX showed neither sulphur nor gypsum. Also, free $\text{Ca}(\text{OH})_2$ as Portlandite was not found³³.

Figure 4. Comparative Analysis of Chloride Diffusion Coefficient

Flexural and compressive strength results of AAS mortar prisms submerged in aggressive solutions containing sulphates did not show negative effects when compared with those conserved in the reference medium, which was deionised water, as is observed in Figure 5. On the contrary the compressive strength increased, which agrees with the observation reported by Xuequan et al³³.

AAS mortars presented expansion values of 0.016% after 200 days of exposure to a Na_2SO_4 solution. The visual aspect of the mortar specimens after the testing is presented in Figure 6. These findings are in accordance with those reported by other researchers^{34,35}.

Figure 5. Flexural (R_F) and Compressive (R_C) Strength (MPa)

Steel bars embedded in OPC and AAS mortars, exposed to partial immersion in 3.5% NaCl, were evaluated, in order to determine their corrosion behaviour by of half cell potential and linear polarisation resistance techniques. The results of these tests and the visual observation of these specimens, after one year of exposure, indicate that the AAS material gives protection against steel corrosion. This could be attributed to its reduced permeability. Deja³⁴ concluded that AAS mortars are highly resistant to corrosion based on electrochemical techniques and weight losses of the steel bar reinforcement after 365 days of exposition to chlorides environment.

Figure 6. OPC and AAS mortars after 180 days of exposition to Sulphates

4. CONCLUSIONS

The results of the experimental work carried out until now confirm the excellent durability of AAS mortars prepared with waterglass as an alkaline activator when exposed to sulphate and chloride environments. It is noted that the protection of the steel bars embedded in the AAS mortar after 1 year of exposition to chlorides environment is satisfactory. This is mainly attributed to the reduced capillary absorption and low chloride permeability.

EFFECT OF THE ADDITION OF ULTRAFINE CEMENT ON THE PROPERTIES OF FIBER REINFORCED COMPOSITES

Josef Kaufmann, Thomas Matschei and Daniela Hesselbarth

ABSTRACT

Mixing powders of different mean grain size at certain mix proportions may increase the packing density. This packing effect is used in concrete technology by adding fine fly ash or microsilica to the coarser cement, leading to denser materials. In this paper the effect of the addition of ultrafine cement, mostly based on blast furnace slag, to normal grain sized Portland cement is presented. A decrease of the porosity and hence an improvement of the mechanical properties of the hardened paste is observed. Additionally the rheological properties of the fresh paste are influenced positively, leading to much improved workability. Such dense materials generally are very brittle. The use of fiber, increases the ductility significantly and leads to a further improvement of the strength properties. The excellent rheological properties allow the conventional mixing of composites with a high fiber content and low w/c ratio.

1. INTRODUCTION

Most material properties such as mechanical properties, gas and water transport, shrinkage, frost resistance and hence durability are influenced by the porosity [1].

In fiber reinforced composites the porosity of the fiber-matrix interface is of crucial importance. High interfacial porosity leads to a poor bond between matrix and fiber and hence a loss of strength. Additionally, high porosity may create connected pathways along the fibers, increasing permeability and therefore gas, water and ion transport which may cause serious durability problems. The quality of a fiber-matrix interface can be improved either by a surface treatment of the fiber itself or by adjusting the matrix properties like rheology, shrinkage and porosity [2].

Porosity depends on the chemical composition of the raw materials, their hydration processes and the packing properties of the different components (sand, cement, filler). Packing density may be increased by combining two or more components with different particle size distribution [3]. Especially fine particles may improve the density of a fiber-matrix or aggregate-matrix interface, as they can be packed closer to the surface of the fiber or the aggregate [4].

New concrete mix designs like DSP (densified small particle) are based on this concept. They involve a dense granular matrix with high superplasticizer and silica fume content and extremely hard aggregates (granite, calcined bauxite etc.) [5]. Due to the higher water demand and the susceptibility to shrinkage, a new concept of replacing silica fume by ultrafine cement and/or pozzolanic active and non-active fillers was tested.

The influence of microfillers on enhancement of concrete strength and fluidity has been demonstrated [6,7]. Different amounts of ultrafine cement and filler were added to ordinary Portland cement. A conventional mixing process was used. The application of superplasticizers allowed the preparation of cement slurries and mortars with very low water-cement-ratios [6]. Mechanical, rheological and length change properties of these binder systems and the effect of fiber reinforcement was studied.

2. EXPERIMENTAL

Ordinary Portland cement CEM I 42.5 N according to European Standard EN 197-1, ultrafine cement (Portland cement blended with blastfurnace slag), limestone filler and fly ash were used as part of the binder system. The chemical composition of the cementitious binder compounds are given in Table 1. Figure 1 shows the particle size distributions obtained by laser diffraction. As water-reducing agent a polycarboxylate type superplasticizer was used.

Table 1. Chemical composition of the cements used

Ultrafine cement	45.3	8.1	32.6	9.9	0.6	0.3	0.4	2.6	1.5

Figure 1. Grain size distribution of the raw materials

3. RESULTS

3.1 Rheology

In a first test series Portland cement CEM I 42.5 N pastes were prepared with different fillers - ultrafine cement, limestone filler and fly ash. The water/binder ratio was 0.20, and 2.0% superplasticizer in respect of the binder was used. Mixtures with a filler content of 10%, 20%, 30% and 50 weight-% were tested.

For the rheological measurements a rheometer (Paar Physica MCR 300) in controlled shear rate mode was used. It was equipped with a spherical measuring system, developed especially for cement pastes and mortars [8].

The pastes were mixed as described above. Immediately after mixing a flow curve with shear rates from 0.01 s^{-1} to 100 s^{-1} was recorded. Apparent yield stress and plastic viscosity were calculated according to the Bingham model. Ultrafine cement and limestone filler showed the best results concerning workability (see Figure 2) leading to low plastic viscosity and apparent yield stress. Low fly ash content (10% - 20%) led to significantly higher values.

Figure 2. Bingham parameters of the investigated cement pastes with different filler contents

3.2 Mercury intrusion porosimetry

The positive packing effect of the ultrafine cement is demonstrated in the mercury porosimetry measurement (Figure 3) of hardened cement pastes. Ordinary Portland cement CEM I 42.5 N was blended with 25 vol.-% of different fillers. Superplasticizer dosage (2 weight-% of binder) and slump flow (230 cm) was kept constant, while water-binder-ratio was adjusted. The specimens, which were cured under water, were measured at an age of 7 days. Previously to the measurement the specimens were dried at 110°C . The use of ultrafine cement significantly reduces total porosity and shifts the pore size distribution towards smaller pores.

Figure 3. Pore size distribution (mercury intrusion) of hardened cement pastes containing 25 vol-% of filler

3.3 Influence of ultrafine cement on shrinkage and strength properties

Because of its positive effects on rheology and density, the system ordinary Portland cement/ultrafine cement was studied in further detail. In a test series, length change behavior of hardened cement pastes containing different amounts of ultrafine cement was studied. Slump flow (200 mm) and superplasticizer content (2 weight-% of binder) were kept constant and water content was adjusted. Length change was measured on steel plates fixed on the specimens (40 mm x 40 mm x 160 mm) directly after demoulding at an age of one day. After that, a series of three specimens were stored under water.

Table 2. Mix proportions of pastes for length change measurement

No.	CEM I 42.5 N [%]	Ultrafine cement [%]	Superplasticizer [%]	w/b -
1	100	0	2.0	0.19
2	90	10	2.0	0.17
3	80	20	2.0	0.155
4	70	30	2.0	0.145

While for pure Portland cement pastes expansion is observed, hardened cement pastes containing low amounts of ultrafine cement (10% , 20%) show some shrinkage during the first seven days (Figure 4). After that, expansion dominates. This might be owing to the very fine powder and hence accelerated hydration kinetics leading to self desiccation within the sample. At higher ages the water then is replaced by suction from the outside. This may induce stress.

At higher contents of ultrafine cement (30 weight-%) significant swelling, beginning on the first day, is measured. This effect possibly originates from the very low w/b ratio (0.145).

Total length change is influenced positively in each case by the addition of ultrafine cement [9].

Figure 4. Influence of ultrafine cement content on length change (curing under water)

Mechanical properties (compressive strength and flexural strength) were determined on a series of 3 specimens (40 mm x 40 mm x 160 mm). The effect of the addition of ultrafine cement on the

compressive strength at ages 7 and 28 days under water is shown in Figure 5. The addition of ultrafine cement leads to a significant increase of compressive strength. The addition of medium amounts of ultrafine cement (10%, 20%) has a positive effect on the flexural strength (see Figure 5) determined in a three point bending test arrangement, meanwhile a high content (30%) of ultrafine cement has a detrimental effect on this property. The loss of flexural strength with age might be caused by microcrack formation initiated by shrinkage stress.

Figure 5. Compressive strength of hardened cement pastes containing different amounts of ultrafine cement

Figure 6. Flexural strength of fiber reinforced composites containing different amounts of ultrafine cement

The influence of different curing regimes on the strength properties was further analyzed. Ordinary Portland cement was blended with 25 vol-% of ultrafine cement. Water-binder ratio was 0.20. After

demoulding, the specimens were stored at different curing conditions at 20°C. The reference was pure Portland cement paste. The addition of ultrafine cement has a positive effect on the compressive strength of hardened cement paste independent of curing regime. Low standard deviations ranging from 1 to 5 N/mm² were observed. The best results for compressive strength are obtained for specimens that are stored under water during the first 7 days.

The influence of the storage regime on the flexural strength (three point) is shown in Figure 8. For some curing regimes high standard deviations up to 5 N/mm² are observed, originating from some specimens having significantly lower values. This indicates a cracking tendency for these sets of specimens. For illustration besides the mean value, the lowest value of a specimen set is also plotted (asterisk in Figure 8). The flexural strength is negatively influenced by initial curing, under water, during the first 7 days. Microscopic studies revealed crack formation beginning between 1 and 7 days. Gradual water supply from the outside may prevent stress formation between the outer and the inner paste. Hence increased flexural strength is observed for specimens cured at wet (98% RH) conditions at an early age.

Figure 7. Compressive strength of hardened cement pastes containing 25 vol-% of ultrafine cement

Figure 8. Flexural strength of hardened cement pastes containing 25 vol-% of ultrafine cement (asterisk indicating lowest values)

3.4 Effect of fiber reinforcement

Owing to the great sensitivity to microcrack formation and hence loss of tensile strength, reinforcement with low content (1 vol-%) of different short fibers was studied. The properties of the fibers used are given in table 3. The matrix consisted of Portland cement blended with 25 vol-% of ultrafine cement. Water-binder-ratio was 0.20 and superplasticizer content was 2 weight-%. Curing was under water.

Table 3. Fiber properties

	modulus of elasticity [GPa]	tensile strength [GPa]	density [g/cm ³]	diameter [μm]	length [μm]
carbon	238	3.95	1.77	7	6
polypropylene	8.5	0.34-0.15	0.91	35x250-600	6
metal	not tested	>2	7.5	160	13

The influence of fiber reinforcement on the compressive strength was negligible. While the polypropylene fibers even have a negative effect, the use of metallic or carbon fibers increases the flexural strength significantly (see Figure 9) compared to the reference without fiber reinforcement. The strong influence of the fiber properties, e.g. tensile strength, however indicates that the fiber mostly acts as reinforcement and does not necessarily control crack tendency.

Microscopic analysis revealed that crack formation is not prevented by the introduction of short fibers as is shown in Figure 10 (left). The observed cracks are mostly very long and discrete, e.g. the matrix in the vicinity of the cracks is completely intact and very dense. The crack path follows an array of carbon fibers and goes around unhydrated cement grains. This indicates that the fiber is effective, absorbing part of the fracture energy and that the cement grains are tougher than the hydration products. The good fiber-matrix bond also is demonstrated in Figure 10 (right).

Figure. 9. Flexural strength of fiber reinforced composites containing 25 vol-% of ultrafine cement (curing under water)

Figure 10. ESEM micrograph of carbon fiber reinforced hardened cement paste containing 25 vol-% of ultrafine cement at an age of 7 days left: crack right: matrix-fiber interface

3.5 Application

The good rheological properties and the very dense packing of cement blended with ultrafine cement may be used for mixing high performance composites with very good mechanical properties. For example, bending properties of hardened cement pastes containing different amounts of metal fiber are shown in Figure 11. Such materials even fulfil the requirements for steel bar replacement in concrete. Additionally, the very dense matrix may improve durability of such composites compared to other mixing concepts. Extension of service life, replacement of cost and energy intensive parts as well as weight considerations may make such materials, despite the higher material costs, a sustainable alternative to actual technology.

Figure 11. Load-deflection response of metal fiber reinforced composites (40mm x 40mm x 160mm) containing 20 weight-% of ultrafine cement (3 point bending)

4. CONCLUSIONS

The effect of the addition of ultrafine cement on rheology, mechanical properties and length change behavior of hardened cement paste was studied. Rheological properties, viscosity and yield value, can be improved by blending ordinary Portland cement with ultrafine cement. The bimodal grain size distribution also leads to a high packing density. Consequently, in combination with superplasticizers, very dense materials with very low porosity can be produced even with conventional mixing and casting techniques.

The addition of ultrafine cement to normal Portland cement improves the compressive strength, especially early strength, of hardened cement pastes. Flexural strength however strongly depends on curing conditions. This indicates microcrack formation caused by shrinkage at an early age. Flexural strength may be improved by early wet (98% RH.) curing, which is preferable to full immersion in water.

In fiber reinforced composites this dense matrix leads to a good fiber-matrix bond. The fibers however do not necessarily control crack tendency. Strong and stiff fibers may bridge such shrinkage cracks and a good tensile behavior is obtained. High amounts of metallic fibers for instance lead to very high flexural strength and ductile materials.

Super-Pozz®: AN ULTRA-FINE POZZOLANIC CLASS F FLY ASH FOR SUPERIOR CONCRETE

E.Y. Seedat and R.A. Kruger

Sphere-Fill (Pty) Ltd, South Africa.

ABSTRACT

“Super-Pozz®” is a unique, ultra-fine, highly reactive Class F fly ash, which can be beneficially applied to variety of cementitious systems. This paper presents the results of an investigation into the characteristics and quality of concrete when Portland cement is replaced by a reactive ultra-fine pozzolan such as Super-Pozz®. In particular its effect on water demand, and the amount of high range water reducer (superplasticiser) is discussed. Data is presented which illustrates strength development and durability characteristics similar to that achieved when silica fume (microsilica) is used as a pozzolan.

The work also highlights the morphological particle size characteristics of the ultra-fine fly ash (UFFA) and illustrates how these can be utilized to produce superior quality concrete. Results obtained confirm that astutely designed mixes exhibit properties similar to formulations containing silica fume. Of major benefit over silica fume is however the reduction in water and/or admixture dosage required for a given workability. The lower water: binder ratio improves durability.

Finally, three examples where UFFA was used in mining applications are discussed.

1. INTRODUCTION

Fly ash of high quality and consistency is an integral part of the civil engineering and construction industries. Its benefits in concrete are well documented and it is widely utilized where quality and durability are of concern.

The air classification of fly ash to extract the more reactive fine fraction is used to improve its performance, increase consistency and thus ensure compliance to the stringent specifications necessary for high quality concrete. In South Africa, classified fly ash with a maximum retention of 12,5% on a 45-micron sieve has been commercially produced for more than 25 years.

Recently beneficiation technology has been developed to produce an ultra-fine fly ash (UFFA), where in excess of 85% of the particles are below 10 μ m. Such a product is now commercially marketed under the trade name, Super-Pozz®. In this study the technical performance of concrete using this UFFA has been found to be equal to or exceeding that where silica fume is utilized.

2. CHARACTERISTICS AND PROPERTIES

As can be seen in the chemical composition and physical characteristics listed in Tables 1 and 2, Super-Pozz® is extremely fine. The D₉₀ value of 11 micron indicates the particle size below which 90% of the particles are to be found. Figure 1, illustrates the comparative particle size distribution

analysis of silica fume as well as the UFFA and conventional SABS (1491 Part 2) fly ash. As can be seen the Super-Pozz has a particle size distribution intermediate to the other two pozzolans.

3. CONCRETE QUALITY AND MIX DESIGN

The quality and impermeability of high-performance concrete are, inter alia, determined by the amount of water utilized in the mix design i.e. the water/binder ratio. High range water reducers (HRWR) are extensively used to ensure effective consolidation during placement with low water contents. Ultra-fine pozzolanic materials such as silica fume are often utilized in high performance

concrete where the presence of the extremely fine particles decreases the permeability and improves durability.

In order to measure the effect of the UFFA on the workability, water requirement and HRWR dosage, three series of concrete mixes were prepared, based on the following mix design methodology:

- A. Workability: Keeping the w/b ratio (binder=cement + pozzolan) and HRWR content constant and measuring the variation of the slump
- B. Water Demand: Keeping HRWR dosage the same and varying the amount of water required to achieve the same slump
- C. Admixture Requirement: Keeping the w/b ratio the same and varying the amount of HRWR required to maintain similar slump measurements.

In all 3 series, the UFFA was used at replacement levels of 5%, 10%, 15% and 20% of the total binder content. For silica fume mixes, replacement levels of 5% and 10% were used. The total binder content was kept constant at 400kg/m³. Crushed dolerite with a specific gravity of 2.92 served as the coarse aggregate. The sand content was a blend of dolerite crusher sand and filler sand with a specific gravity of 2.82. Prior to their use, the materials were completely dried. The cement used was CEM I 42.5. The HRWR was a naphthalene-based admixture.

On all mixes, compressive strengths were measured at 1, 3, 7, 28, 56 and 90 days. Water permeability and absorption as well as chloride permeability were used to evaluate durability. Workability was measured in terms of slump. The target slump was 125mm.

4. EXPERIMENTAL PROGRAMME

With the exception of HRWR and water, the mass of the mix constituents remained the same in all 3 series (Table 3). Using this as a starting point, the design for a specific series A, B, C was then characterized by a particular water and HRWR content. Mix 1, using plain PC (CEM I 42.5) as the binder served as the control mix.

5. SERIES A: EVALUATION OF WORKABILITY

Table 4 and Figure 2 shows that the replacement of a portion of cement with UFFA, improves the workability of the concrete substantially. If all constituents of the mix proportion are kept constant i.e. w/b ratio and admixture content, the introduction of UFFA provides a major increase in workability. For series A, 5.2 ltrs/m³ of HRWR and 152 ltrs/m³ of water (w/b 0.38) were used

throughout. As can be seen from the data in Table 4 the slump increased with the amount of UFFA used. The increase in workability can be ascribed to the morphology of the UFFA. In particular the sphericity of the particles enables them to “roll” in the concrete mix. This ball-bearing or lubricating effect aids flow and increases the slump. Furthermore the specific particle size distribution and efficient dispersion of Super-Pozz allows for effective packing in the interces and thus facilitates consolidation.

Table 4. Workability data for concrete specimens of equal w/b ratio and containing the same amount of HRWR

Figure 2. Evaluation of Workability: Slump recorded for constant water content of 152 l/m³ and 5.2l/m³ of HRNR

The rates of strength development of these concrete mixes (Series A) are given in Table 5. It will be noted that while the specimens containing silica fume initially developed strength more rapidly, at 90 days the compressive strength of the specimens containing the UFFA was the same. This indicates that the UFFA exhibits latent pozzolanicity.

Table 5. The effect of the addition of UFFA on the rate of development of compressive strength for concrete specimens of equal w/b ratio and containing the same amount of HRWR.

6. SERIES B. EVALUATION OF WATER DEMAND

One of the main features expected of the UFFA is, by virtue of its sphericity and ideal particle size distribution, is to reduce the amount of water required to achieve a specific slump value. In this series, the binder content, HRWR content and work ability were kept constant and the effect of water requirement measured. The HRWR was dosed at 5.2ltrs/m³ (1.3% wt of binder).

Table 6. The effect of UFFA on the water required to maintain a constant slump

EVALUATION ON WATER REQUIREMENT

HRWR (liters)	5.2	5.2	5.2	5.2	5.2	5.2	5.2
W/b ratio	0.41	0.42	0.43	0.38	0.35	0.34	0.33
Slump (mm)	130	130	125	140	125	130	140

Figure 3. Evaluation of Water Requirement: Water content/m³ of fluxes with constant slump and HRWR dosage

The results from Table 6 and Figure 3 shows that the formulations containing silica fume required more water than their UFFA counterparts to achieve a slump of about 125mm. The water demand of concrete decreased along with the amount of cement replaced by UFFA.

Table 7. The compressive strength for concrete specimens of equal HRWR and slump

COMPRESSIVE STRENGTH (MPa)							
Reference	B1	B2	B3	B4	B5	B6	B7
Extender	Nil	5% CSF	10% CSF	5% UFFA	10% UFFA	15% UFFA	20% UFFA
1 day	15.5	15.5	13.5	15.0	20.5	17.0	15.0
3 day	35.0	32.5	30.0	35.0	40.0	36.5	35.0
7 day	52.0	48.5	47.0	50.58	58.5	56.5	52.5
28 day	70.5	77.5	78.5	69.5	82.0	85.0	81.0
56 day	80.0	80.5	84.0	84.0	91.5	91.5	97.0
90 day	81.0	81.0	79.0	86.0	93.5	102.5	93.5

At constant binder content, the compressive strength of concrete increased along with a reduction in the w/b ratio. The incorporation of UFFA in concrete facilitates a lower w/b ratio and as a result, improved compressive strength is achieved at all ages. After 56 days the compressive strength achieved by the mixes containing UFFA exceeded that of the mixes containing silica fume.

As a result of the ongoing pozzolanic reaction the concrete specimens containing the UFFA showed a far higher rate of gain in strength between 28 and 90 days than their silica fume counterparts.

7. SERIES C: EVALUATION OF HRWR REQUIREMENT

For concrete where compressive strength is easily achievable, lower admixture content can be used to attain the desired workability. Due to the particle shape and size of the UFFA, workable concrete can be made using less admixture content.

For the C series, both workability and water content (152 liters/m³) were kept constant and the amount of HRWR required for a slump of about 125mm was measured.

Table 8. Evaluation of the amount of HRWR required to maintain similar slumps in concrete containing UFFA and silica fume

EVALUATION OF HRWR REQUIREMENT							
Reference	C1	C2	C3	C4	C5	C6	C7
Extender	Nil	5% CSF	10% CSF	5% UFFA	10% UFFA	15% UFFA	20% UFFA
W/b ratio	0.38	0.38	0.38	0.38	0.38	0.38	0.38
HRWR (liters)	5.3	6.3	6.8	5.1	3.7	2.9	2.5
Slump (mm)	150	140	130	135	130	125	125

From the results in Table 8 and Figure 4, it can be seen that in order to maintain the same workability, concrete containing 10% UFFA reduces the HRWR requirement whilst silica fume increases it. Generally, when silica fume is used in concrete, its performance is enhanced by the variable HRWR addition used to control water demand. With UFFA, the situation is changed. UFFA provides a lower HRWR dosage or alternatively a normal water-reducing admixture (plasticiser) can be used instead as a minimum to achieve the desired workability.

Figure 4. Evaluation of Admixture Requirement Variation in admixture content for constant slump of W/b ratio

At all ages, mixes containing comparable amounts of UFFA and silica fume exhibited similar rates of strength development (Table 9). At higher replacement levels the pozzolanic behavior of the UFFA is responsible for significant rates of gain in strength at later ages.

Table 9. The compressive strengths for concrete specimens of equal slump and w/b ratio

COMPRESSIVE STRENGTH (MPa)

90 day	93.0	89.0	105.0	103.5	100.0	106.0	103.0

8. DISCUSSION OF MIX DESIGN CRITERIA AND THEIR TEST RESULTS

The foregoing vividly illustrates the importance of understanding the factors that influence the rate of strength development in concrete mixes containing UFFA. In order to maximise the benefits of fineness, sphericity and pozzolanic activity of UFFA, particular attention must be given to mix design criteria.

In the first instance, using the same amount of water and superplasticiser in concrete mixes containing the UFFA, as used in comparable concrete with silica fume, results in large increase in slump. This is mainly due to the sphericity of the UFFA, which facilitates flow. As can be expected, the concrete with higher slumps exhibited a slower initial rate of strength development. At later ages (90 days) the compressive strength of concretes with UFFA was similar to those containing silica fume.

If, however the amount of water or superplasticiser used in the mix is adjusted and the concretes are designed to have similar slumps, the picture changes entirely. Not only are the rates of strength development comparable but also due to its latent pozzolanic activity, the compressive strength of the mixes containing UFFA exceeds those with silica fume.

The long-term pozzolanic activity of the UFFA can be seen as a function of its particle size distribution. Silica fume is much finer than the UFFA. As a result of the higher surface area the pozzolanic reaction proceeds rapidly and strength is quickly developed. The downside of this is that as the surface of the silica fume becomes covered with the reaction products the $\text{Ca}(\text{OH})_2$ can no longer reach and the pozzolanic reaction slows down. UFFA on the other hand has a wider range of particles sizes. As the finer particles are covered and thus prevented from participation in further reaction, the larger particles still remain available. The pozzolanic reaction can thus still proceed at later ages.

The above is certainly not the definitive explanation since the glass content of the pozzolan as well as the composition and concentration of both alkaline and alkali hydroxides influence the rate and extent of the pozzolanic reaction. Nevertheless the higher rate of strength development exhibited at later ages by the UFFA must necessarily take the difference of particle size distribution into account.

9. DURABILITY

While strength development is an important criterion for concrete performance, it fails to give an insight into durability. Durability was assessed by means of a series of tests designed to measure the density and impermeability of the binder paste microstructure. Water permeability and absorption as well as chloride permeability were measured. Probably the most important consideration when using UFFA, is its ability to improve the durability of concrete by decreasing the water demand without adversely affecting the workability. Thus, samples for the durability tests were prepared using series “A” specimen’s i.e. constant slump and HRWR, taking into effect the water reducing properties of the UFFA.

9.1 Water permeability

The DIN 1048 test method was used to measure the impermeability of concrete. In this test, slabs initially water-cured for 28 days, are then exposed to a water pressure of 5 bars for 72 hours after which the slab is split and the depth of water penetration measured. Penetration of less than 25mm is generally considered to be impermeable concrete

Table 10. Water permeability (DIN 1048)

WATER PERMEABILITY (mm)					
CEM I 42.5	5% CSF	10% CSF	5% UFFA	10% UFFA	15% UFFA
19	8	14	12	6	18

As can be seen, the results achieved generally fell within the range of 5 to 20mm with the 10% UFFA mix showing the best resistance to water penetration.

9.2 Water Absorption

In this test the cubes are initially water cured for 28 days, following which cores are drilled out and oven dried for 72 hours before once again being immersed in water. The increase in mass resulting from the immersion is expressed as a percentage of the dry specimen. Higher water absorption figures are indicative of permeable concrete.

As can be seen from the results obtained in Table 11, concrete specimens containing the UFFA have the lowest absorption values. This is indicative of a denser microstructure. The decrease in values from 28 to 56 days reflects an increase in density as the result of the refinement of the pore structure.

Table 11. Water Absorption (BS 1881: Part 118)

WATER ABSORPTION (%)						
	CEM I 42.5	5% CSF	10% CSF	5% UFFA	10% UFFA	15% UFFA
28 day	1.70	1.61	1.56	1.53	1.41	1.38
56 day	1.67	1.58	1.45	1.47	1.32	1.25

9.3 Chloride Permeability

The Rapid Chloride Permeability Test (ASTM 1202) measures the total charge (coulombs) flowing through a 2 inch thick concrete specimen during 6 hours of applied potential of 60V. The test is conducted on cores, cured in water for 28 days or longer. The one end of the specimen is immersed in NaCl solution, the other in NaOH. The total charge passing through is regarded as a measure of the resistance of concrete to the diffusion of chloride ions. The higher the charge the easier the ions migrate and the poorer the concrete.

Table 12. Chloride permeability (ASTM C1202)

CHLORIDE PERMEABILITY (Coulombs)						
	CEM I 42.5	5% CSF	10% CSF	5% UFFA	10% UFFA	15% UFFA
28 day	2206	1329	598	2008	1769	1681
56 day	1798	772	279	1699	972	816

The results obtained (Table 12), substantiates the fact that cement extenders decreases the permeability of concrete. This is mainly attributed to the conversion of Ca(OH)_2 to calcium silicate hydrates. Although it would appear that silica fume mixes are more resistant to chloride diffusion, the mixes containing UFFA continue to develop strength at later ages. This on-going refinement of the pore structure will be accompanied by a concomitant reduction in chloride diffusion.

10. CURRENT APPLICATIONS

During the last year extensive trials have been conducted both locally and internationally to demonstrate the benefits of UFFA in high performance concrete. The following are some typical examples.

10.1 Ore-Pass Lining

Ore passes are key elements in underground mining. They are subject to harsh environmental conditions and are designed to the highest standards to limit the effect of impact and abrasion, blasting shock, geological stress and aggressive waters. With high durability and low maintenance being crucial much attention is paid in optimizing the concrete mix design. It is widely accepted that calcium aluminate cement based concrete will outperform other equivalent cementitious base concretes in terms of abrasion resistance. However, the use of Portland cement based mixes provided a viable alternative in terms of material cost and performance. In a study carried out at a south african gold mine it was shown that the use of Portland cement with UFFA and silica fume has a great potential in achieving very high strengths, particularly over longer periods. The total addition of these pozzolans was 15% of the total binder content with the ratio of UFFA/silica fume at 1:1. The primary benefits found, with the use of UFFA was a mix of lower water demand and improved workability. Additionally, the UFFA preserved the integrity of the paste matrix both with regard to prevention of cracking and the resistance to aggressive attack.

10.2 HPC for Underground Roads

High performance concrete is essential for underground roads in order to withstand the abrasion and impact loading caused by the grinding action of the LHD (front end loader) wheels and buckets. In two very large underground operations, UFFA was used to compliment the mix to meet the design requirements. Based on the success with the ore-pass lining referred to above, a concrete using 15% Super-Pozz as the only cement extender was designed. Compressive strength in excess of 80 MPa was achieved with a concrete that had high initial flow and maintained its placeability for an extended period. Abrasion resistance and impact criteria were achieved.

10.3 Use in HPC as Steel fibre reinforced shotcrete (SFRS)

The application of SFRS is a well-known concept and method of support within the tunneling industry. With the growing use of sprayed concrete as a permanent construction material, demands on its durability characteristics have increased proportionately. In a very deep shaft, located in dynamic rock conditions, SFRS was specified as a permanent rock support system. The design parameters assessed included early and long-term compressive strength, in-situ strength, energy absorption capabilities and yield. Additionally the placed shotcrete was required to be sufficiently impermeable to ensure long-term durability. The design compressive strength target was a minimum 60 MPa. Using the EFNARC (European Federation for Sprayed Concrete) specifications, the energy absorption criteria, was set at 1000 J (Joules) for a 28-day plate test. Sporadic incidences of strain bursting of the shaft sidewalls required an early age strength of 5 MPa after 48 hours and the ability to absorb 400 J of energy after 4 – 8 hours.

Following the trial mix process, the mix finally adopted was a complex blend of very high quality materials. UFFA was added to the mix to reduce water demand, assist pumpability, increase resistance to chemical attack and provide long-term strength gain. By incorporating UFFA, the cohesion and adhesion properties were also enhanced. The SFRS was successfully applied for this project; a total of 7500m³ being placed within the shaft barrels.

11. SUMMARY AND CONCLUSIONS

Results obtained show that UFFA such as Super-Pozz can be used as a viable substitute for silica fume. If the advantages of the UFFA are exploited in the concrete mix design, the initial rate of strength development was found to be the same or similar to those of silica fume mixes. At later ages, however, the pozzolanic activity of the UFFA leads to higher compressive strength values.

Durability test measuring the water permeability and absorption as well as chloride permeability showed comparable values for both silica fume and the UFFA mixes.

The use of UFFA, as an alternative to silica fume can be effective in enhancing the properties of concrete, both in its fresh and hardened state. Due to the lower water demand required, UFFA can be ideally used to:

- Lower the water/binder ratio
- Lower the amount of HRWR required; or
- A combination of the above

Super-Pozz is not only a new-generation cement extender offering exciting opportunities to the design high performance concrete. With its unique properties, there are other additional applications that will certainly benefit the use of Super-Pozz. Some that spring to mind are:

- Specialist Grouts
- Ready mix concrete
- Precast Concrete
- Self-leveling flooring

- Self Compacting Concrete (SCC)
- Cement modified Pre-mix bagged materials

Future developments could possibly see the co-utilization of UFFA and silica fume, as this will provide civil engineers with the opportunity to simultaneously exploit the best properties of both products.

BLAST FURNACE SLAG WEATHERING STUDY

Battagin, Arnaldo Forti¹ and Pecchio, Marcelo²

Brazilian Portland Cement Association, São Paulo, Brazil.

¹E-mail: arnaldo.battagin@abcp.org.br and ²marcelo.pecchio@abcp.org.br

ABSTRACT

Blast-furnace slag as an addition to Portland cement is extensively used in Brazil. In spite of the high addition content (up to 70 mass %), the cement industry cannot absorb the total slag production, leading to storage of millions of tons in open air. Slag is thus exposed to weathering for years.

This paper presents the study carried out on three long-stored slag samples compared to two new ones, aimed at checking their degree of aging and its influence on their reactivity, and consequently on the mechanical performance of the corresponding blended cement.

Old slag samples showed lower hydration heat liberation and significant - in some cases reaching 30% to 40% - loss in performance, followed by changes in setting times.

1. INTRODUCTION

About 7.3 million tons of blast furnace slag was produced in Brazil in 2000 [1] and around 6 million tons was converted into granulated blast furnace slag (GBFS).

Granulation is obtained by quenching the molten slag into glass using high pressure water jets. The rapid cooling prevents crystallization producing a granular glassy material that, after grinding, has good hydraulic properties making it a Portland clinker substitute or extender.

GBFS in slag cement or blended Portland slag cement has been extensively used in Brazil for more than 50 years [2] but the cement industry cannot absorb the whole slag production. Although consumption in 2000 was about 4.9 million tons there was an excess 1.1 million tons that was not used. Due to this, around 12 million tons of GBFS are stockpiled mainly in cement plants.

Many publications have dealt with the use of fresh-made GBFS as a cementitious material but less work has been done about the use of weathered slag. In fact, there is only one known contribution of Hiroshima and Igarashi [3] that studied the effect of weathering of GBFS and concluded that there was a loss of 28-day compressive strength and an increase in setting times of cements containing “old” slag. On the other hand, Brazilian cement manufacturers have reported an improvement in slag grindability.

It is generally agreed that slag reactivity is due to both inherent characteristics and external factors. Inherent characteristics are related to operational conditions of blast furnace, temperature and viscosity of molten slag, granulation process and installation, etc.

External factors are characteristics that are imposed to slag by means of handling, storage and grinding. For practical purposes and quality control, we can summarize as inherent slag characteristics their chemical composition and their glass content. External factors determining slag reactivity are mainly slag fineness, alkali concentrations of the reacting system, temperature during early phases of the hydration process, and degree of weathering.

This paper reports results from a laboratory study on the weathering effects on slag reactivity using chemical analysis, microscopy examination, conduction calorimeter, accelerated compressive strength tests by NaOH activation and cement compressive strength tests with partial slag replacement.

2. EXPERIMENTAL DETAILS AND RESULTS

2.1 Chemical Composition and Glass Content

Five slag samples were selected: UV1, UV2 and UN produced by USIMINAS, a Brazilian steel plant located in Minas Gerais State, VRV and VRN produced by Companhia Siderurgica Nacional (CSN) located in Volta Redonda, Rio de Janeiro. UV1, UV2 and VRV were stockpiled in un-ground form for more than 10 years and UN and VRN have just been produced. Chemical compositions are given in Table 1.

Table 1. Chemical composition

Oxide	% in mass				
	UV1	UV2	UN	VRV	VRN
CaO	42.54	42.28	41.91	42.50	42.47
SiO ₂	34.68	35.10	35.10	35.65	34.31
Al ₂ O ₃	12.23	12.08	12.54	11.32	11.42
Fe ₂ O ₃	0.96	0.84	0.53	1.14	3.26
SO ₃	2.40	2.44	2.65	2.45	2.58
MgO	6.18	6.38	6.39	6.09	5.08
K ₂ O	0.37	0.40	0.39	0.52	0.28
Na ₂ O	0.11	0.10	0.11	0.113	0.12
TiO ₂	0.52	0.40	0.37	0.19	0.46
Total	99.99	100.02	99.99	99.973	99.98
IB1(*)	1.76	1.73	1.73	1.68	1.72
IB2(**)	1.23	1.20	1.19	1.19	1.24

$$(*)IB1 - I = \frac{CaO + MgO + Al_2O_3}{SiO_2} > 1$$

$$(**)IB2 - i = CaO/SiO_2$$

Results show that slags are basic and comply with the requirements of Brazilian Standards. There are no significant differences among slag chemical compositions. Although expressed as SO₃, sulphur is mostly present as sulphide, especially for UN and VRN slag samples. Sulphide oxidation is supposedly more expressive in old slags (UV1, UV2 and VRV).

The glass content was determined by means of optical polarizing microscope according to the method proposed by McMaster [4]. Results are given in Table 2.

Table 2. Slag glass content

Slag	%
UV1	95.2
UV2	93.6
UN	97.9
VRV	92.9
VRN	86.9

The slag melt has a high content of thermal energy. If this energy is fully dissipated by slow cooling a stable crystalline and non-hydraulic slag is formed. On the other hand, if quick cooling is used, a glassy slag with latent hydraulic properties is obtained. It is generally agreed that slag should have a high glass content to develop cementitious properties. As shown in Table 2, samples present a high glass content, most of them higher than 90%. Only VRN exhibited a glass content below 90% but it seems that small amounts of crystalline material in vitreous slag will not have very detrimental effects. Demoulian and collaborators [5] have even reported that crystal nuclei have an advantageous effect.

2.2 Loss on Ignition (LOI), Insoluble Residue (IR) and Scanning Electron Microscopy

In order to evaluate the effect of storage conditions on slag LOI and IR were determined in all samples. LOI value could detect a certain stage of hydration/carbonation because it is known that slags are formed after solidification of high temperature molten material and do not present any LOI. However, vitreous slags are soluble in HCl solution and any IR value detected could be related to contaminations of slag during storage. Table 3 presents the results of LOI and IR.

Table 3. LOI and IR values

Sample	Insoluble Residue (%)	Loss of Ignition (%)
UV1	0.70	2.30
UV2	0.25	0.90
UN	0.25	-0.50
VRV	0.49	2.50
VRN	0.25	-1.70

(Obs.) Negative sign indicates a gain of mass due to an oxidation process

Table 3 shows that “old” slags presented higher values of LOI and IR compared to new ones. Figures 1 and 2, obtained by sample observation under scanning electron microscope show that weathered slag exhibits grains with a coating surface of hydration/carbonation and probably sulphate products. It is believed that the hydrated layer is thin but tends to increase the longer the time of storage in an open-air environment.

Figure 1. Slag grains with coating surface of hydration/carbonation and probably sulphate products

Figure 2. Slag grains with coating surface of hydration/carbonation and probably sulphate products

2.3 Hydraulic Activity of Slag by Reaction with Alkali: Compressive Strength Tests and Heat of Hydration

Accelerated strength tests using sodium hydroxide solution as mixing water were employed. Slags were ground to a fineness of $(4000 \pm 150)\text{cm}^2/\text{g}$. Cylindrical test specimens of 50x100mm, in proportion 1:3 (slag: sand), water cured at 23°C, $s/\text{alk sol.}=0.5$, according to an adaptation of Brazilian Standard NBR 7215 [6] were carried out. Alkali solution (20%) was prepared by dissolving 200g of sodium hydroxide in 1 liter of distilled water and cooled to room temperature. Average strength results at 48h are given in Table 4.

Table 4. Slag hydraulic activity with NaOH

Samples	Density (g.cm^{-3})	Blaine surface area ($\text{cm}^2.\text{g}^{-1}$)	Hydraulic activity with NaOH (MPa)
UV1	2.79	3950	7.4
UV2	2.84	4120	12.2
UN	2.91	3980	15.0
VRV	2.80	4040	8.6
VRN	2.94	4030	12.8

A conduction calorimeter was used to measure the evolution of heat of hydration. Slag pastes with slag/alkaline solution equal to 0.4 and curing temperature 23°C were adopted. Results of total heat liberation up to 72 hours are shown in Figure 3.

Figure 3. Total heat of hydration liberation

From Figure 3 we conclude that the total heat liberated by “new” slag from a single source is higher than that of the corresponding weathered slag. Accordingly, the same conclusion can be deduced from results of hydraulic activity with NaOH shown in Table 4. Weathered slags both from USIMINAS (UV1 and UV2) and Companhia Siderurgica Nacional (VRV) presented lower values of hydraulic activity with NaOH compared to the new slags from the same origin.

Brazilian former studies [7] have shown that typical compressive strengths for good quality slags are expected in range of 9 to 11MPa. We can deduce that “new” slags comply with these values while weathered slags presented values below of these limits. It should be noted, however, that slag UV2 presented a good behavior perhaps due to its higher fineness.

2.4 Cement Compressive Strength Test and Setting Time

In order to evaluate the mechanical performance behavior, each slag sample after being ground to a fineness $(4000 \pm 150) \text{ cm}^2/\text{g}$ was mixed with an industrial ordinary Portland cement with Blaine fineness $4400 \text{ cm}^2/\text{g}$.

The proportions of mixes were 0, 20%, 30%, 40%, 50% and 60% of slag replacement. Test specimens were prepared and tested for 7 and 28 day compressive strength in accordance with NBR 7215. Results obtained are given in Table 5 and Figures 4 and 5.

Table 5. Compressive Strength (MPa)

Slag content (%)	UV1		UV2		UN		VRV		VRN		Reference	
	7 days	28 days	7 days	28 days	7 days	28 days	7 days	28 days	7 days	28 days	7 days	28 days
0	-	-	-	-	-	-	-	-	-	-	40.3	47.1
20	34.9	44.6	38.2	46.2	40.8	51.0	37.4	44.6	41.1	50.7	-	-
30	33.4	43.1	35.8	46.4	40.5	53.4	36.0	44.9	38.3	50.1	-	-
40	29.6	40.8	33.9	44.9	41.3	54.3	37.0	42.3	37.2	52.3	-	-
50	25.3	37.2	29.9	42.1	35.8	51.9	29.4	40.7	34.4	51.4	-	--
60	21.4	34.0	25.2	39.9	33.6	50.6	25.1	36.6	29.3	49.2	-	-

Figure 4 shows the 7-day compressive strength of cement mortars *versus* slag replacement from 20% to 60%. It is showed that the higher the slag replacement, the higher the strength loss for both weathered and new slags. However, it seems that strength loss is higher for weathered slags compared to “new” slags.

Figure 4. Slag contents *versus* 7-day compressive strength

A different behavior was found for 28-day compressive strength, Figure 5. Accordingly, a strength gain was obtained for mixes containing new slags. For 40% slag replacement strength gains are 15% and 10%, compared to reference for UN and VRN, respectively.

Figure 5. Slag contents *versus* 28-day compressive strength

By comparing mortar strength of mixes with same slag replacement and from a single source, results showed that strength losses are higher for weathered slags. For instance, for 60% slag replacement, UV1 presented a loss of 36% compared to UN at 7 days.

Table 6 clearly shows that raising the slag replacement there is an increase in setting time for both weathered and new slags. By comparing weathered and new slags from the same source, there is a slight decrease of initial setting time and a shortening of final setting time for mixtures containing weathered slag that reached up to 85 minutes.

Table 6 shows the results of initial and final setting times

Table 6. Setting Time (min)

Slag content (%)	UV1		UV2		UN		VRV		VRN	
	Initial	Final	Initial	Final	Initial	Final	Initial	Final	Initial	Final
20	155	235	165	235	175	245	175	235	155	235
30	185	245	165	235	200	240	145	205	215	245
40	170	260	175	245	170	240	175	225	185	275
50	185	275	195	265	205	265	155	215	235	295
60	195	275	145	245	205	275	170	220	225	305

3. CONCLUSIONS

From the results of tests carried out in this investigation the following conclusions may be drawn.

- Slag weathering is linked to a hydration/carbonation/oxidation process that causes a loss of slag reactivity;
- By comparing weathered and new slags from a single source tests showed a decrease of heat of hydration liberation as well as a decrease of alkali accelerated strength in weathered slag;
- LOI and IR tests, for its simplicity, could be used for quality control of slag weathered degree;
- For 7-day compressive strength, test of mixes with slag replacement from 20% to 60% showed that the higher the slag replacement, the higher the strength loss for both weathered and news slags compared to the reference. However, it seems that strength loss is higher for weathered slags;
- A different behavior was found for 28-day compressive strength tests. In spite of mixes containing weathered slags having exhibited a strength loss for all slag replacement, mixes containing new slags presented a strength gain of 10% to 15% with replacement from 30% to 50%;
- For some slag replacement, mixes presented strength loss of up to 40% by comparing new and weathered slags from a single source.
- Finally, by raising the slag replacement, there is an increase of setting time for both weathered and news slags. By comparing weathered and new slags from a single source there was a slight decrease of initial setting time and a shortening of final setting time for mixes containing weathered slag that reached up to 85 minutes.

ABSTRACT

The effect of high temperature on the residual properties of granulated blastfurnace slag modified cement paste was investigated. Portland cement paste with a slag content of 60 % and water binder ratio of 0.32, was exposed to temperatures of 20, 50, 75, 100, 120, 150, 200, 300, 400, 440, 520, 600, 700, 800, and 1000°C. The unsealed specimens were heated at a rate of 4°C/min to test temperature, were kept there for 60 minutes, were cooled at a rate of 4°C/min to 20°C, and were tested. Residual compressive and flexural strengths were measured and pore structure of the pastes was determined by mercury porosimetry. Tests were performed at the age of 90 days. The total porosity of the pastes more than doubled when exposure temperature was increased from 20°C to 1000°C. The gradual heating coarsened the pore structure. The most notable coarsening of pore structure - together with strength loss and decomposition of hydration products - took place at exposure temperatures higher than 440°C. After 600°C the residual compressive capacity ($f_{c600^\circ\text{C}}/f_{c20^\circ\text{C}}$) was still over 57 %. Strength loss due to the increase of temperature was not linear. According to the tests it seems that exposure temperatures from 50°C to 120°C can be as dangerous as exposure temperature of 440°C to the residual compressive strength when granulated blastfurnace slag modified cement paste with low water binder ratio is in question.

1. INTRODUCTION

Properties of clinker minerals, hydrated clinker minerals, hydration products, hardened cement paste, mortar and concrete at high temperatures as well as their residual properties have been extensively investigated. The basic phenomena governing changes of cement based materials at high temperature are known: desiccation of pore system, diversified and opposite thermal deformations, chemical phase transformations, decomposition of hydration products, and destruction of microstructure [1-8]. In general, phases present in hardened cement paste expand in the temperature range 20-200°C, but above 200°C shrinkage with different intensity prevails [1,2]. All changes seem to coarsen pore structure [3], which is one basic factor controlling the strength of any material.

Finely ground granulated blast furnace slag is utilized to control fresh and hardened properties of cement based materials. A partial replacement of cement decreases water requirement, slows down evolution of heat of hydration and strength gain. It has to be activated by e.g. Ca(OH)_2 produced during hydration of Portland cement. This produces different mineralogical and structural composition of paste, which has been reported to have advantageous high temperature behaviour [2].

2. MATERIALS AND TEST SPECIMEN MANUFACTURING

2.1 Materials

The binders used in the research project were a normal Portland cement CEM I 42.5 R and a granulated blast furnace slag (GBFS), both of local origin. The chemical compositions of the binders are given in Table 1. Blaine specific surface area of the cement was 497 m²/kg. Initial and final setting times of the cement were 90 and 180 minutes, respectively. At the age of 1, 7 and 28 days the compressive strength of standard cement mortar prisms were 27, 45 and 54 MPa, respectively. City tap water was used. Particle size distribution of the binders was analysed using a laser diffraction granulometer (LDG). The LDG specific surface areas of the cement and GBFS were 372 m²/kg and 525 m²/kg, respectively.

Table 1. The chemical composition of the binders.

Binder		Portland cement CEM 42.5 R	Granulated blast Furnace slag
Chemical analysis			
SiO ₂	(%)	19.72	36.59
Al ₂ O ₃	(%)	5.15	8.77
Fe ₂ O ₃	(%)	2.39	0.81
MgO	(%)	3.05	9.75
CaO	(%)	61.7	36.71
Na ₂ O	(%)	0.73	1.19
K ₂ O	(%)	0.82	0.58
TiO ₂	(%)	-	3.58
MnO	(%)	-	0.70
S	(%)	-	1.56
SO ₃	(%)	3.02	-
Insoluble	(%)	1.11	1.1
Ignition loss 950° C	(%)	3.02	0.01

2.2 Paste manufacturing

Mixing was performed by a Hobart 200 mixer. In the mixing procedure the dry ingredients were mixed for 30 seconds before water was added into the rotating mixer and thereafter mixing was continued at speed 1 for two minutes. Then the mixer was stopped and mixing was continued at speed 2 for two additional minutes. The total mixing time was four and half minutes. The water binder ratio of the paste specimens was 0.32.

2.3 Test specimens and curing

Paste prisms having dimensions of 40 mm x 40 mm x 160 mm were produced for flexural strength and compressive strength tests. The prisms were cast in steel moulds containing three parallel prisms. The prisms were compacted on a vibrating table in two layers. After trowelling, the specimens were covered by two plastic sheets. The specimens were in the steel moulds for the first 22 ± 2 hours after which they were cured in water at 20° C for six days. After water curing, the prisms were moved into the climate room to a temperature of 20° C and relative humidity of 45%. There they were stored until testing. Tests were performed at the age of 90 days.

3. HEATING PROCESS AND HARDENED PASTE TESTS

3.1 Heating device

Heating oven used is Ceramotherm® N 300 by Nabertherm GmbH. The inside dimensions of the oven are 550 mm x 700 mm x 780 mm. The maximum operating temperature is 1280° C. The heating of the device was performed from all walls, door, and bottom of the kiln, which produced a uniform temperature distribution. The bottom heating elements were covered by a silicon-carbide-plate having a thickness of 20 mm. The temperature of the kiln was measured by a platinum-rhodium-thermocouple mounted on the back wall of the kiln (height of 10 cm from the bottom). The temperature and heating of the kiln were controlled by Program Controller S19 by Nabertherm.

3.2 Heating procedure and strength tests

The prisms were moved from the curing environment half an hour before heating started. The unsealed specimens, prisms and mercury intrusion porosimeter (MIP) samples were heated at the same time. They were subjected to continuous heating at a rate of 4° C/min to the test temperature in question. The maximum test temperature was kept constant for a period of 60 minutes. Figure 1 presents a photograph of test specimens in the kiln at 1000° C. The specimens were cooled in the kiln at the rate of 4° C/min to the ambient temperature (20° C) after which they were immediately tested. From each prism both flexural and compressive strengths were measured. After the four-point flexural strength test, the compressive strength was measured from the end parts of the prism.

Figure 1. Test specimens in kiln at 1000° C.

3.3 MIP test

MIP samples with dimensions of 15 mm x 15 mm x 15 mm were sawed using diamond saw (water as a lubricant agent) from the centre of the 40 mm x 40 mm x 160 mm test prisms. The intact, non-cracked and non-carbonated material was required and therefore the surface layer of about 12 mm of the prisms was not used. After sawing, the surfaces of the MIP samples were dried with compressed air. Then the samples were weighed and transferred into the kiln. The temperature exposure program (temperatures from 50 to 1000° C) was started not later than half an hour from the sawing. After cooling, the specimens were weighed and stored in vacuum until testing. The control samples (stored at 20° C) and the samples, which were heated to the temperatures below 200° C, were stored in vacuum for at least 36 days before their pore structure was determined.

3.4 XRD test

The mineralogical composition of the binders, their chemical phase transformations and decompositions were analysed by X-ray diffraction. A Philips PW1710 diffractometer with $\text{CuK}\alpha$ radiation was used (40 kV and 40 mA). The measurements were carried out from 2θ angles from 5° to 60° with a step of 0.02° . Each step took 0.5 s. Tests were carried out three times. The investigated material was collected from the temperature exposed test prisms. After the strength tests, the fragments of three crushed prisms were collected into two Pyrex® 26 x 100 SVL 25 culture tubes, which were equipped with teflon gaskets. The fragments were stored in the tubes before they were powdered by a Herzog laboratory mill. The powdered sample and an internal standard of CaF_2 (5% of the sample weight) were ground manually using mortar and pestle. After grinding, the sample was dispersed in ethanol, the suspension was dropped onto a sample holder PW 1817/32 and the ethanol was allowed to evaporate. The analysed sample weight was about 10 mg. Residual paste diffractograms were determined after the temperature exposures of 20, 120, 150, 200, 440, 520, 600, 700, 800, and 1000°C .

4. TEST RESULTS AND DISCUSSION

4.1 Residual crystal structure

Residual crystal structure of the paste was surprisingly stable. The residual diffractogram was quite changeless when the paste was exposed to the temperatures of 120, 200, and even up to 440°C . Minor phase transformations took place at these temperatures, but were overlapped by the background hump of GBFS (due to the amorphous and vitreous nature of GBFS). After the exposure temperature of 520°C , decomposition of $\text{Ca}(\text{OH})_2$ and development of CaO were registered. The residual diffractogram peaks of these two phases are shown in detail in Figure 2. The higher exposure temperature of 600°C did not change the composition of paste, but 700°C caused some changes in crystalline phases. After 800°C , the whole amorphous nature of GBFS disappeared. New peaks in the residual diffractogram indicated crystallizations and transformations in phases of the paste matrix. After temperature exposure of 1000°C , the residual diffractogram intensities (due to more complete crystal transformations) increased and crystallization of new phases also took place.

Figure 2. Residual XRD diffractogram peaks of the paste. Destruction of $\text{Ca}(\text{OH})_2$ is shown on the left and formation of CaO is apparent on the right. Each curve is an average of three measurements. The sample exposure temperatures are shown in the pictures.

4.2 Residual compressive strength

Strength loss due to the increase of temperature was non-linear. In the temperature range from 50 to 120° C strength losses could be noticed, Figure 3. Significant loss of residual compressive strength at about 100° C confirms literature findings [4,5]. Residual compressive strength of the paste also fluctuated as a function of exposure temperature. After temperature exposures of 150° C, 400° C and 440° C, the residual compressive strengths equalled the reference strength at 20° C. After higher exposure temperatures (from 520° C to 1000° C), the residual compressive strengths of the paste decreased. After the temperature exposure of 600° C the residual compressive capacity ($f_{c600^{\circ}\text{C}}/f_{c20^{\circ}\text{C}}$) of paste was still 57 %.

4.3 Residual flexural strength

The effect of high temperature on the residual flexural strength was very non-linear. When the temperature was increased from 50 up to 120° C, the residual flexural capacity decreased to a local minimum value of 42 %. However, the exposure temperatures of 20, 50, 150 and even 400° C gave identical residual flexural strengths. Flexural strength seems to be more sensitive to cracks and other defects of the material. The flexural test appears to describe this strength loss more clearly, (the maximum loss was noticed at 120° C), which can be attributed to the swelling of water layers in the paste causing weakening of the bonds [6], or it can be caused by water evaporating from the pore structure of the specimens [7]. Temperature range from 150° C to 440° C increased residual flexural strengths. The higher exposure temperatures from 520 to 700° C decreased residual flexural strengths. Comparing residual flexural strengths in Figure 3, it can be noticed that temperatures around 120° C are as dangerous as temperatures from 520° C to 700° C to residual flexural strength, when GBFS modified Portland cement paste with low water binder ratio is in question. The highest exposure temperatures 800° C and 1000° C had equal residual compressive and residual flexural strengths.

Figure 3. Residual strengths of the test prisms. Residual compressive strength is an average of six test results and residual flexural strength is an average of three test results. Standard deviations are also shown.

4.4 Residual porosity

The residual porosity of the paste increased with the increase of exposure temperature. Total porosity increase from 14,7 % to 42,3 % when the exposure temperature was raised from 20° C to 1000° C. The increase of pore volume of paste specimens heated up to 300° C was significantly

smaller than could be expected from the weight losses. This confirms the findings with mortar specimen [3]. At exposure temperatures above 300° C the residual pore volume clearly increased. The effect can be caused by the significant increase of microcracks [1]. This is also detectable as an increase of porosity at about 10 nm range in Figure 5 (particularly above 400° C). Gel porosity (radii 2 nm) is also quite stable in this temperature range (from 150° C to 350° C) [2] but increases after higher exposure temperatures. In general, it seems that sample weight losses in the exposure temperature range from 100° C to 500° C does not explain changes of pore structure (detectable with MIP) when GBFS modified cement paste with water binder ratio of 0.32 is studied.

4.5 Residual pore size distribution

The gradual heating coarsened the pore size distribution of the paste. Already with a thermal load of 50° C the mean pore radius was shifted a bit towards larger pore radii due to the water evaporation, Figure 4. Increased microcracking is already observed after exposure temperature of 40° C [7]. With increasing temperature from 50° C to 75° C and to 100° C caused a temperature gradient large enough to clearly coarsen the pore structure. This coarsening effect might originate also from decrystallization of ettringite [9]. With a temperature increase up to 120 and 150 a small increase in the zone from 40 nm to 100 nm was observed. After dewatering, the porosity changes originate mainly from decomposition of the paste components.

Figure 4. Residual pore size distributions of the test pastes. Sample exposure temperature is given in the legend. Each curve is an average of two measurements.

The pore structure of paste was quite stable in the temperature range from 200° C to 300° C, Figure 5. The increase in sample exposure temperature from 300° C to 400° C or to 440° C had only a minor effect on the pore size distribution of paste. Only a little increase of porosity around 10 nm was observed. The residual pore size distribution of the paste was characterised by one distinct peak at temperatures up to 440° C. Beyond 440° C, at temperature 520° C, a new growth in the pore volume from 5 nm to 15 nm was observed. It might originate from the porosity of CaO formed during dehydration of Ca(OH₂) [1,7,8], which is also verified in Figure 2. In addition, the porosity in the pore radius zone from 70 nm to 120 nm increased. After 600° C, a new capillary pore structure with two peaks (one at about 20 nm and the other at 80 nm) was formed. At higher temperatures the residual pore size distribution consisted of two peaks.

Figure 5. Residual pore size distributions of the test pastes. Sample exposure temperature is given in the legend. Each curve is an average of two measurements.

At exposure temperatures beyond 600° C the total pore volume and the mean pore radius were continuously increased, Figure 6. Especially the macropore volume, pore radii > 100 nm, showed a more distinct increase at sample exposure temperatures of 700, 800, and 1000° C.

Figure 6. Residual pore size distributions of the test pastes. Sample exposure temperature is given in the legend. Each curve is an average of two measurements.

4.6 Porosity and strength

Exposure temperatures above 600°C caused strength losses together with a significant coarsening of the pore size distribution. More notable loss of residual compressive strength can be connected to the increase of total porosity of the cement paste from 21 % to 32 % after the exposure temperatures of 400°C and 520°C, respectively.

5. CONCLUSIONS

The pore volume and the mean pore radii of the GBFS modified Portland cement paste increased continuously with the increase of exposure temperature. These changes were not linear with respect to the temperature increase. The changes of pore size distributions were mainly caused by the capillar porosity (radii below 100 nm) changes below the exposure temperature of 520°C. Higher exposure temperatures increased the volume of macropores (pore radii > 100 nm). Beyond 1000°C the residual pore structure consisted of macropores.

Total porosity almost trebled when exposure temperature was increased from 20°C to 1000°C. The gradual heating coarsened the pore structure. The most notable coarsening of pore size distribution together with a strength loss took place at exposure temperatures higher than 440° C. XRD diffractograms verified decomposition of $\text{Ca}(\text{OH})_2$ at these temperatures.

Strength loss due to the increase of temperature was also non-linear. It appears that exposure temperatures from 100°C to 120°C can be as dangerous as exposure temperature of 440° C to residual compressive strength. After 600° C the residual compressive capacity ($f_{c600^\circ\text{C}}/f_{c20^\circ\text{C}}$) of the paste was still over 57 %. Residual flexural strength fluctuated considerably. Temperature exposure of 120°C decreased residual flexural capacity ($f_{f120^\circ\text{C}}/f_{f20^\circ\text{C}}$) to local minimum value of 42 %. This temperature (120° C) caused residual flexural strength equal to residual strength after temperature exposure of 700° C.

Cement based materials are much weaker under tension than under compression. When properties of cementitious materials are investigated after temperature exposure the flexural or tensile strength should be studied, because in this respect all the material defects seems to be noticed more sensitively.

ABSTRACT

As part of a concrete durability research programme undertaken by two universities, three durability index tests were developed. When practitioners tried to use these methods problems were experienced with achieving the specified index values when in-situ concrete was tested. An inter-laboratory precision evaluation was undertaken for these tests. The results were analysed and recommendations were made about the test methods and the recommended limits for results. The rewritten test methods were used in a second round of testing, the results of which will be reported later.

1. INTRODUCTION

The Cement and Concrete Institute (C&CI) has administered and managed the investment by cement producers in research projects on concrete durability at the Universities of Cape Town and The Witwatersrand for more than a decade. Amongst the projects tackled by the researchers have been those in which some method of determining concrete permeability and its resistance to ingress of harmful gasses and fluids has been required. This work led to the publication of a series of monographs on the issue of durability index testing^{1,2,3}. When this information became incorporated into contract specifications certain practical implementation problems occurred, such as measurement differences between laboratories for the same test, and difficulty in achieving the required index values under site conditions.

These implementation problems were discussed at a workshop of interested parties. It was agreed that further work was required to determine the reproducibility and repeatability of the test methods, which, until then, had been methods in development at the research facilities. It was agreed that the C&CI laboratory would manufacture and distribute to participating laboratories a number of sets of test specimens, and that C&CI would collate and analyse the test results from all participants. This paper covers this test programme.

It was also agreed that to exploit the full potential of the test methods, it would be desirable to try to provide guidance on the desirable limits for test results for tests carried out on site concrete. The latter would be investigated as another project, as it was anticipated that there would be a need to

evaluate conditions in three or four different curing zones across South Africa, namely Eastern Coastal, Western Coastal and Moist and Dry Interior.

2. TEST METHODS

The researchers developed three test methods, namely an oxygen permeability test, a water sorptivity test and a rapid chloride conductivity test. In each case a set of test specimens consisting of 25-mm thick slices from a 68-mm core are used.

The details of these tests are as follows:

2.1 Oxygen Permeability Test

This test is a falling head permeameter test. Oven dried specimens are subject to a head of 100 kPa of oxygen pressure and the pressure decay with time is recorded. The coefficient of permeability is determined from the slope of the line produced when the natural log of the ratio of initial pressure to pressure at any time is plotted against time. The oxygen permeability index (OPI) is defined as the negative log of the coefficient of permeability.

2.2 Water Sorptivity Test

This is a unidirectional absorption test and involves placing the test specimens (the edges of which have been sealed) in a shallow layer of water. The test uses the mass of water absorbed from the bottom face of the sample (in mm/ \sqrt{h}) as a measure of sorptivity.

2.3 Rapid Chloride Conductivity Test

This test involves determining the DC conductivity of test specimens, which have been saturated with a sodium chloride solution. The test provides a rapid indication of the resistance of concrete to the penetration of chloride ions. The values are stated in milliSiemens per centimetre (mS/cm).

The full details of the test methods are given in reference 3.

3. THE TEST PROGRAMME

The working group participants agreed that C&CI would manufacture the concrete cubes and prepare the test specimens for all the laboratories from these cubes after the required curing period.

The following mix proportions were used in making the concrete in the laboratory:

Table 1. Mix proportions used for test program

Material	Mass of dry material (kg/m ³)	
Water	205	220
CEM I 42,5N	315	489
19-mm andesite coarse aggregate	1174	1174
Granite crusher sand	769	584
Water:cement ratio	0,65	0.45

Cubes were made from the laboratory mixes and these were all subjected to either 1 or 14 days of curing submerged in water at 22 to 25 °C. After completing the water curing process, the cubes were exposed to the laboratory air at 22 to 25 °C at a relative humidity of 65%. At 28 days, core drilling was done horizontally into each of two opposite vertical faces (as cast) of each cube and then the outer 5 mm was trimmed off each side before the two 25-mm thick test specimens were cut

off the two opposite cores. The sides of the test specimens were coated with epoxy resin to seal them.

The test specimens were then placed in an oven at $50 \pm 2^\circ\text{C}$ for a minimum of 7 days and relative humidity below 20% and then sets of these specimens were sealed in plastic bags before being distributed to all participating laboratories. Each laboratory received the following specimens:

Table 2. Numbers of test specimens made for each test laboratory

Test method	Number of test specimens
OPI	4
Sorptivity	4
Chloride conductivity	3

On receipt, each laboratory was expected to recondition the test specimens in an oven for a further 7 days at $50 \pm 2^\circ\text{C}$ and relative humidity below 20% before initiating the tests.

In each case the laboratory was required to report their results to C&CI. In the case of the OPI and Sorptivity tests the laboratories were also asked to submit the correlation coefficients for the regression analysis on the data from each test.

4. PARTICIPATING LABORATORIES

All South African laboratories that had the equipment to do these tests, at the end of 2001, participated in this inter-laboratory evaluation. It should be noted that not all laboratories were equipped to undertake all of the tests under consideration. These details are included in the table overleaf.

Table 3. Test undertaken by the participating laboratories

Laboratory	Tests undertaken		
	OPI	Sorptivity	Chloride conductivity
Lab 1	Y	Y	Y
Lab 2	Y	Y	Y
Lab 3	Y	Y	Y
Lab 4	N	N	Y
Lab 5	Y	Y	Y
Lab 6	Y	Y	Y
Lab 7	Y	Y	N

5. TEST RESULTS

Table 4 gives the suggested ranges for durability classification using these index values for the three tests from reference 1. (It should be noted that one of the reasons for undertaking this testing programme was to generate information which could help with a review of these suggested ranges.) These ranges have been used to categorise the values reported by each laboratory. Colour has been used to emphasise these categories

Table 4. Suggested ranges for durability classification

Durability class	OPI (log scale)	Sorptivity (mm/√h)	Chloride Conductivity (mS/cm)
Excellent	>10	<6	<0,75
Good	9,5-10	6-10	0,75-1,50
Poor	9,0-9,5	10-15	1,50-2,50
Very poor	<9,0	>15	>2,50

Tables 5a to 5d give the summarised average test results and coefficients of variation for the four different test conditions from each laboratory.

Table 5a. Test results for specimens made to w/c=0,45: curing 1d

Laboratory	OPI (log scale)		Sorptivity (mm/√h)		Chloride Conductivity (mS/cm)	
	Average	CoV	Average	CoV	Average	CoV
Lab 1	9.50	1.63	12.66	13.84	0.72	7.19

CoV (%)	0.97		22.60		11.52	

6. DISCUSSION OF TEST RESULTS

6.1 Internal Precision of Test Method (Within Laboratory Precision)

The internal precision of the test results from each laboratory was assessed from the coefficient of variation CoV (%) of each set of results from each laboratory presented in tables 5a to 5d above.

6.1.1 OPI

In general, the coefficients of variation for the results of the OPI tests are very low indicating that within each laboratory the results of the tests of the four different specimens are very similar. This suggests that the OPI test has a good internal precision. There does not appear to be any trend in this precision for the different mix types or curing regimes.

6.1.2 Sorptivity

The coefficients of variation recorded for this test are much higher indicating that the internal precision of the method is rather poor. Although the differences are small, it does seem that the repeatability of this test improves as the curing period is increased.

6.1.3 Chloride Conductivity

For this test the coefficients of variation are higher than might be considered acceptable (although a limit for this acceptability has yet to be established) and the internal precision is considered to be unsatisfactory. It should be noted that in all cases laboratories 3 and 4 have significantly higher CoV values than the other laboratories. Omitting these two sets of values still leaves the mean CoV higher than 5% and therefore unsatisfactory. However, it was suggested that laboratories 3 and 4 should investigate their laboratory procedures to determine if there might be ascribable causes for the poor repeatability.

6.2 External Precision of Test Method (Between Laboratory Precision)

The between laboratory precision of the test results from each laboratory was assessed from the coefficient of variation CoV (%) of the results for each test method for all laboratories is presented in the bottom row in tables 5a to 5d above.

6.2.1 OPI

The between laboratory precision of this test is very good with a CoV of substantially less than 5%. There is however a concern that the classification resulting from the results from different laboratories differs in two cases in tables 5b and 5d.

6.2.2 Sorptivity

The between laboratory precision for this method is poor. In addition, there seems to be a deterioration of the precision as the curing period is increased. The same problem occurs with this test where different laboratories arrived at different classifications in some cases.

6.2.3 Chloride Conductivity

Again, the between laboratory precision for this method is poor. The precision does however appear to be better for the mixes with the higher w/c ratio. While the internal precision of this test for laboratories 3 and 4 was shown to be very low, it does not appear to have affected the mean values reported. The same problem occurs with this test where different laboratories arrived at different classifications in some cases.

7. RECOMMENDATIONS

It is recommended that the test methods be rewritten giving more detail and restricting the possibility of different interpretation or practice.

In addition, it is recommended that the user of this information be provided with guidance to the interpretation of the results in a different format. For example, instead of applying terms such as “excellent”, “good” or “poor”, estimates should be provided of the life expectancy of concrete given certain index values. While a specifier might be unwilling to specify concrete that had poor durability for his client he might be more comfortable to recommend that it was not necessary to opt for a higher durability than the design life required.

8. CONCLUSION

The test methods have been rewritten as recommended above and are included as appendices 1 to 4.

These rewritten procedures have been used in a second round of inter-laboratory precision evaluation tests. It is hoped the results of the second round will be presented in the final submission of this paper or a later paper.

Appendix 1

PROPOSED TEST METHOD FOR SAMPLE CUTTING AND PREPARATION PRIOR TO DETERMINING DURABILITY INDEX VALUES

1. SCOPE

This test method describes how to cut and prepare test specimens in order to carry out tests for determining the durability indices of concrete as described by Alexander, Ballim and Mackechnie ⁽¹⁾.

Each test specimen shall consist of a 68mm diameter concrete disc cut in a direction perpendicular to the direction of casting from a shuttered surface of a concrete member or laboratory specimen.

The thickness of the specimen should be 5mm greater than the maximum nominal aggregate size and ± 2 mm tolerance is allowed. Thus for concrete with a nominal aggregate size of 19mm a 25 ± 2 mm thick by 68mm diameter sample will be required. As far as possible try to keep specimen thickness standardised at 25 mm.

2. APPARATUS

- a) A water-cooled diamond tipped core barrel with an inner diameter of 68mm, attached to a suitable coring drill.
- b) In the case of preparing test specimens from cubes: A holding device in which cubes can be clamped to ensure they remain in position while coring takes place.
- c) A water-cooled moveable bed diamond saw using an un-notched, thin (circa 2mm) blade
- e) A facing machine (if possible) or other machine capable of removing the outer 5mm of surface of the specimens but without changing the orientation or flatness of the face.
- f) A sample holding device in which samples can be held in position on the movable bed of the diamond saw but which can allow rotation of the sample while facing and cutting.
- g) An oven capable of maintaining a temperature of $50 \pm 2^\circ\text{C}$ and relative humidity below 20%. The relative humidity can be maintained by the inclusion of trays of saturated calcium chloride solution. The trays should provide a total exposed area of at least 1m^2 per 1m^3 of volume of the drying facility and should contain sufficient calcium chloride to show above the surface of the solution throughout the test.

3. TEST SPECIMEN PREPARATION FROM CUBES

- a) If samples are prepared from cubes they need to be cut from the surfaces perpendicular to the trowelled face of the cube.
- b) Clamp the specimen firmly into the holding device and place the core barrel perpendicular to the concrete face.
- c) If only one specimen per cube is required, core approximately 40mm into the sample.
Two specimens may be cored from one cube:
 - i) One behind the other to assess the effects of curing, core approximately 80mm into the cube.
 - ii) Another specimen may be cored from the other side of the cube, core approximately 40mm on both sides perpendicular to the trowelled face.
- d) Secure the sample tightly on the movable bed of the diamond saw. Cut or grind the first 5mm from the cored face of the cube. Cut the required thickness of the test specimen from the cube.

- e) Mark the test specimens with the correct reference number on the non test face. The test face is the outside or exposed face of the concrete cube.
- f) The results of this process is a 68mm diameter by aggregate size +5mm thick specimen marked with the correct reference number. The test face is that face of the specimen that has no marking on.

4. TEST SPECIMEN PREPARATION FROM CORES FROM SITE CONCRETE

- a) Place the core barrel perpendicular to the surface of the concrete, and secure so that it can not move.
- b) Core to a depth of 60-80mm.
- c) Carefully remove the core from the concrete face by breaking it off with a hammer and chisel.
- d) Mark each core and remove to the laboratory.
- e) Follow steps 3 d) to 3 f) above.

5. CURING AND AIR DRYING OF LABORATORY SPECIMENS

The duration of moist curing of laboratory specimens should be either 7 days or 28 days. In the case of site concrete, the age at which the specimens are taken for testing is generally specified by the consultant or project specification.

After the above period of “moist” curing the specimens should be air-dried until 28-days old before sample conditioning can commence.

Cutting of the specimens can take place after 21 days.

6. SEALING OF SAMPLE EDGES

The edges of the sample discs for sorptivity testing still have to be sealed. This is done using ABE Epidermix 365 epoxy, or similar, which is carefully applied to the curved surfaces with a sponge to completely coat and seal them. Care must be taken not to get the epoxy on the flat test surfaces.

Put the samples back in the oven after the epoxy have touch dried.

While this process can be used to seal the edges of all specimens it may be omitted in the case of OPI and Chloride Conductivity testing.

Appendix 2

STANDARD PROCEDURE FOR OXYGEN PERMEABILITY TEST

1. SCOPE

This test method sets out the procedure for determining the oxygen permeability index as described by Alexander, Ballim and Mackechnie ⁽¹⁾.

The test is suitable for the evaluation of materials and mix proportions for design purposes as well as research and development. Care should be taken in interpreting the results of this test when it is used on surface treated concrete's, or on concrete that has been exposed to environmental influences such as carbonation or marine salts.

2. APPARATUS

- a) A water-cooled diamond tipped core barrel with an inner diameter of 68mm, attached to a suitable coring drill.
- b) In the case of preparing test specimens from cubes: A holding device in which cubes can be clamped to ensure they remain in position while coring takes place.
- c) A water-cooled moveable bed diamond saw
- d) A facing machine.
- e) A sample holding device in which samples can be held in position on the movable bed of the diamond saw but which can allow rotation of the sample while facing and cutting.
- f) An oven capable of maintaining a temperature of $50 \pm 2^{\circ}\text{C}$ and relative humidity below 20%. The relative humidity can be maintained by the inclusion of trays of saturated calcium chloride solution. The trays should provide a total exposed area of at least 1m^2 per 1m^3 of volume of the drying facility and should contain sufficient calcium chloride to show above the surface of the solution throughout the test.
- g) Permeability test arrangement as described in ⁽¹⁾ page 8-10, housed in a room where the temperature is controlled at $23 \pm 2^{\circ}\text{C}$ and relative humidity at $60 \pm 5\%$. The air-tightness of the equipment needs to be tested on a regular basis using impermeable test specimens. If there is zero drop in pressure of 100kPa over an eight-hour period the equipment is considered to be in good working order.
- h) Silicone rubber collars for each cell made of silicon with Shore hardness 39A. The collars need to be replaced when cracks and tears occur.
- i) Standard grade 99.8% oxygen supply and regulator capable to regulate flow to 100kPa.
- j) Vernier calliper

3. TEST SPECIMENS

The test specimen shall consist of a 68mm diameter concrete disc cut in a direction perpendicular to the direction of casting from a shuttered surface of a concrete member or laboratory specimen using test method AAA

Four test specimens are required per test.

4. CONDITIONING OF THE SAMPLES

After cutting and coring store the specimens in the oven at $50 \pm 2^{\circ}\text{C}$ and less than 20% relative humidity for seven days, or until dried to a constant mass.

5. TESTING OF SAMPLES

- a) After drying, take the samples out of the oven and cool on a steel tray for 45 minutes.
- b) After 45 minutes mark the samples of the same mix 1, 2, 3 and 4 on the inner face.
- d) Measure the thickness of each sample with the vernier at 4 points equally spaced around the perimeter of the sample and record on the data sheet to the nearest 0.1 mm.
- e) Place the sample in the rubber collar with the test face (outer face) at the bottom.
- f) Place the rubber collar in the PVC sheath with the wooden ring on top of the collar.
- g) Place on top of the permeability cell.
- h) Place the coverplate in position and fasten. Repeat for samples 2, 3 and 4
- f) Start the test exactly 1 hour after removing the specimens from the oven, turn the gas on the regulator to 120 kPa.
- g) Open the gas inlet and outlet valves of the permeability cells and allow oxygen to flow through the permeameters for 5 seconds.
- h) Close the gas outlet valve of all four permeability cells.
- i) Wait till pressure rises above 100 kPa on the gauge of the permeability cell and close the inlet valve.
- j) Tap the gauge and release air by opening the outlet valve slightly until the pressure on the permeability cell gauge is 100 kPa. Record the time and pressure.
- k) Repeat for all cells.
- l) After 5 minutes tap the gauge and record the time and reading; Continue to check the pressure.
- m) Subsequent readings should be taken before a pressure drop of 5 kPa occurs. Record the pressure and time on a standard form.
- n) The test may be terminated when the pressure has dropped to 50 kPa.
- o) In the case of automated systems, pressure readings should be recorded on the computer at 15 minute intervals for two to eight hours.

6. CALCULATION OF THE OXYGEN PERMEABILITY INDEX

The calculation involves conducting a linear regression analysis on the best fit line obtained by plotting values of $\ln(P_o/P_t)$ against t where:

P_o	=	initial pressure at start of test (at time t_o) kPa
P_t	=	subsequent readings in pressure kPa at time t , measured from t_o ,
t	=	in seconds

The simplest way to calculate the slope of the regression line is by entering the data in a Microsoft Excell range and use the function $\text{SLOPE} \{(\text{data range of } \ln(P_o/P_t)) ; (\text{data range of time})\}$. The correlation coefficient can be obtained by using the $\text{CORREL} \{(\text{data range of } \ln(P_o/P_t)) ; (\text{data range of time})\}$ function.

The coefficient of correlation should be greater than 0.99. Where the correlation is less than 0.99 a retest should be done on the same sample.

The D'arcy coefficient of permeability is given by:

$$k = \frac{\omega \cdot V \cdot g \cdot d \cdot z}{R \cdot A \cdot \sigma}$$

k	=	coefficient of permeability of test sample (m/s)
ω	=	molecular mass of oxygen = 32 g/mol
V	=	volume of oxygen under pressure in permeameter (m^3)

g	=	acceleration due to gravity (m/s^2)
R	=	universal gas constant = 8313 (Nm/K mol)
d	=	sample thickness (m)
θ	=	absolute temperature (K)
z	=	slope of the line determined in the regression analysis

The coefficient of permeability is calculated for each of the test samples. The permeability index is given as the negative log of the average of the coefficient of permeability of the samples, which for four samples is:

$$\text{Permeability index} = -\log_{10} \left[\frac{1}{4} (k_1 + k_2 + k_3 + k_4) \right]$$

7. REPORTING

Report the following, if known:

- source of the specimen.
- Identification number of specimen .
- Location of specimen within core or cylinder.
- Type of concrete, including binder type , water/cement ratio and other relevant data supplied with the sample.
- Description of specimen.
- Curing history.
- Unusual specimen preparation eg removal of surface treatment.
- Test results.

Appendix 3

STANDARD PROCEDURE FOR WATER SORPTIVITY TEST

1. SCOPE

This test method sets out the procedure for determining the water sorptivity index as described by Alexander, Ballim and Mackechnie ⁽¹⁾.

The test is suitable for the evaluation of materials and mix proportions for design purposes as well as research and development. Sample age may have a significant effect on the test results, depending on the type of concrete and the curing procedure. Care should be taken in interpreting the results of this test when it is used on surface treated concrete's, or on concrete that has been exposed to environmental influences such as carbonation or marine salts.

2. APPARATUS

- a) Vacuum saturation facility as described in ⁽¹⁾ page 18.
- b) Plastic or stainless steel tray 20mm deep and large enough to hold six test specimens.
- c) Absorbent paper towel.
- d) Vernier calliper
- e) Weighing scale with accuracy to 0.01g
- f) Tap water saturated with calcium hydroxide. (180grams of $\text{Ca}(\text{OH})_2$ per 1 liter of water).
- g) A stopwatch for each sample being tested
- h) Epoxy paint and paintbrush. (Suitable products are ABE Epidermix 365 or Sikaguard Wetseal A+B)
- i) The water sorptivity test must be conducted in a room in which the temperature is controlled at $23 \pm 2^\circ\text{C}$ and relative humidity at $60 \pm 5\%$.

3. TEST SPECIMENS

The test specimen shall consist of a 68mm diameter concrete disc cut in a direction perpendicular to the direction of casting from a shuttered surface of a concrete member or laboratory specimen using test method AAA

Four test specimens are required per test.

4. CONDITIONING OF THE SAMPLES

- a) After cutting and coring store the specimens in the oven at $50 \pm 2^\circ\text{C}$ and less than 20% relative humidity for seven days, or until dried to a constant mass.
- b) During the seven day drying period take the specimen out of the oven and let it cool for an hour.

5. TESTING OF SAMPLES

- a) After drying, take the samples out of the oven and cool on a steel tray for 45 minutes.
- b) After 45 minutes mark the samples of the same mix 1, 2, 3 and 4 on the inner face.
- c) Measure the thickness of each sample with the vernier at 4 points equally spaced around the perimeter of the sample and record the measurements to the nearest 0.1mm on the data sheet.

- d) Place 10 layers of tissue paper on the tray leaving a gap between the sides of the tray and the edge of the paper.
- e) Pour calcium hydroxide solution into the tray until the tissue paper is properly wet and a 1mm layer of water is visible on top. Remove all the air bubbles by smoothing the paper pad towards the edges.
- f) After exactly one hour of cooling weigh the samples to an accuracy of 0.01g and record the weight as the dry mass at time 0.
- g) Place the samples with the test face (outer face) on the wet paper start the stopwatch.
- h) 30 seconds later place the 2nd sample test face at the bottom on wet paper and start the second stop watch.
- i) Weigh the samples at 1, 2, 4, 8, 16, 32 and 64 minutes, after patting it once on a damp piece of absorbent paper.
- j) Record weights to the nearest 0.01g on a standard form replacing the samples each time with the test face on the wet paper.
- k) After weighing of the samples is complete, place the samples in the vacuum saturation tank. Seal the lid with petroleum jelly and close it.
- l) Evacuate the tank to -75 ± 3 kPa and leave the samples under vacuum of -75 ± 3 kPa for 2 hours.
- m) After 2 hours, isolate the tank and allow calcium hydroxide saturated water to flow into the chamber until the water level is approximately 40mm above the top of the samples .
- n) Reconnect the vacuum pump to the tank and maintain the vacuum for 24 hours at -75 ± 3 kPa.
- o) After 24 hours remove the samples from the water, dry the surface with a paper towel and immediately weigh to a accuracy of 0.01g. Record this as the saturated weight of the sample on a standard form.

6. CALCULATION OF THE WATER SORPTIVITY INDEX

The mass of the water absorbed at each weighing period (M_{wt}) is given by:

$$M_{wt} = M_{st} - M_{so}$$

$$M_{st} = \text{mass of the sample at time } t$$

$$M_{so} = \text{mass of the sample at time } t=0$$

By conducting a linear regression analysis determine the value of F given by:

$$M_{wt} = F \times \sqrt{t}$$

$$F = \text{the slope of the best fit line obtained by plotting } M_{wt} \text{ against } \sqrt{t}$$

$$t = \text{time in hours after a sample is first exposed to water on its lower face}$$

The simplest way to calculate the slope of the regression line is by entering the data in a Microsoft Excell range and use the function SLOPE {data range of M_{wt} ; data range \sqrt{t} }. The correlation coefficient can be obtained by using the CORREL {data range M_{wt} ; data range of \sqrt{t} } function.

The coefficient of correlation should be greater than 0.99. Where the correlation is less than 0.99 it is recommended to plot the curve M_{wt} against \sqrt{t} and examine the curve for non-linear sections. Carry out further regression analysis selecting the linear portion of the plot. At least 5 points are required to obtain a reliable regression analysis.

The water sorptivity (S) is given by:

$$S = \frac{F \cdot d}{M_{sv} - M_{so}}$$

- F = the slope of the regression line (g/√h)
d = average sample thickness (mm)
M_{sv} = the vacuum saturation mass of the sample (g)
M_{so} = Mass of sample at t=0 (g)

The water sorptivity is calculated for each of the test samples. The sorptivity index is given as the average of the water sorptivity of the four samples.

7. REPORTING

Report the following, if known:

- a) Source of the specimen.
- b) Identification number of specimen .
- c) Location of specimen within core or cylinder.
- d) Type of concrete, including binder type , water/cement ratio and other relevant data supplied with the sample.
- e) Description of specimen.
- f) Curing history.
- i) Unusual specimen preparation eg removal of surface treatment.
- j) Test results.

Appendix 4

STANDARD PROCEDURE FOR CHLORIDE CONDUCTIVITY TEST – RESEARCH MONOGRAPH NO 4

1. SCOPE

This test method sets out the procedure for determining the chloride conductivity index as described by Alexander, Ballim and Mackechnie ⁽¹⁾.

The test is suitable for the evaluation of materials and mix proportions for design purposes as well as research and development. Sample age may have a significant effect on the test results, depending on the type of concrete and the curing procedure. Care should be taken in interpreting the results of this test when it is used on surface treated concrete's, or on concrete that has been exposed to environmental influences such as carbonation or marine salts.

Since the test results is a function of the electrical resistance of the specimen, the presence of reinforcing steel or other embedded electrical conductive material may have a significant effect.

2. APPARATUS

- a) Vacuum saturation facility as described in ⁽¹⁾ page 28.
- b) Conduction cell as shown in Figure 3.2 page 29⁽¹⁾. The anode and cathode part of the cell should be permanently marked on the outside of the cell.
- c) DC power supply 0-12 Volt, 0-1 Ampere stabilised.
- d) Digital Voltmeter and ammeter (2 multi-meters), 4 digits, 0-20 V range, 0-300 mA, rated accuracy 0.1%
- e) Electrical cables and plugs.
- f) Weighing scale 0.01g.
- g) Due to the highly corrosive solutions used during the test all equipment has to be cleaned thoroughly with warm soapy water after each use. The copper electrodes and banana plugs need to be cleaned with sandpaper or an acidic solution. Replacement electrical connections might be necessary from time to time.
- h) 10 liter container with a lid.
- i) CP grade NaCl (99% purity).

3. SOLUTIONS

- a) Sodium chloride solution: Add 2.93 kg of NaCl (salt) to the 10-liter container. Add tap water up to the 10-liter mark. Stir occasionally for 1 day or until all the salt has dissolved. Seal the lid of the container.
- b) Saturated calcium hydroxide solution: Add 180 grams of Ca(OH)₂ to 1 liter of water.
- c) Saturated copper sulfate solution.

4. TEST SPECIMENS

The test specimen shall consist of a 68mm diameter concrete disc cut in a direction perpendicular to the direction of casting from a shuttered surface of a concrete member or laboratory specimen using test method AAA

Four test specimens are required per test.

The samples should be discarded after testing and cannot be retested.

5. CONDITIONING OF THE SAMPLES

- After cutting and coring store the specimens in the oven at $50 \pm 2^\circ\text{C}$ and less than 20% relative humidity for seven days, or until dried to a constant mass.
- After drying, take the samples out of the oven and cool on a steel tray for 45 minutes.
- After 45 minutes mark the samples of the same mix 1, 2, and 3 on the inner face.
- Measure the thickness of each sample with the vernier caliper at 4 points equally spaced around the perimeter of the sample and record the measurements to the nearest 0.1mm on the data sheet.
- Place the samples in the vacuum tank, seal the tank and evacuate to 75 ± 3 kPa. Maintain the vacuum for 3 hours.
- After exactly 3 hours allow the salt solution to enter the vacuum tank and cover all the samples. Maintain the vacuum of 75 ± 3 kPa for another 5 hours.
- After 5 hours allow the samples to soak for another 18 ± 1 hours
- The above implies that the samples are ready to be tested 27 hours after being taken from the oven.

6. TESTING OF SAMPLES

- First fill the capillaries of the chloride cell and then both parts of the cell with the salt solution.
- Take a sample and place it in the rubber ring
- Place the rubber ring into the central section of the cell and screw it onto the cathode part of the cell. Turn around and screw on the anode part of the cell. Tighten both parts
- Place the chloride cell horizontally.
- Pour copper sulphate solution into the connecting points.
- Connect the ammeter and voltmeter as shown in figure 3.2⁽¹⁾
- Adjust the DC power supply until the voltmeter reads 5 or 10 Volts.
- Record the ammeter and voltmeter reading on a standard form.
- Samples can be discarded after testing.

7. CALCULATION OF THE CHLORIDE CONDUCTIVITY INDEX

The chloride conductivity is given by:

$$\sigma = \frac{i \cdot t}{V \cdot A}$$

σ = conductivity of the sample (mS/cm)

i = electric current (mA)

V = potential difference (V)

t = thickness of sample (cm)

A = cross-sectional area of the sample (cm²)

The chloride conductivity is calculated for each of the test samples. The chloride conductivity index is given as the average of the chloride conductivity of the four samples.

8. REPORTING

Report the following, if known:

- a) source of the specimen
- b) Identification number of specimen
- c) Location of specimen within core or cylinder
- d) Type of concrete, including binder type, water/cement ratio and other relevant data supplied with the sample.
- e) Description of specimen.
- f) Curing history.
- i) Unusual specimen preparation eg removal of surface treatment.
- j) Test results.

ABSTRACT

The present market trend for early setting of Portland Slag Cement (PSC) has necessitated the need to look for certain controlling parameters keeping the cost factor intact. For this purpose, three different qualities of industrial clinker with $C_3S=45, 50$ and 59.3% having a grain density of $2.66, 2.70$ and 2.54 g/cc with its degree of sulphatization (SD) = $47.3, 29.0$ and 35.7% respectively, along with a batch of granulated slag with its glass content as 97% collected from a nearby source, are taken to produce PSC prepared by both intergrinding (IG) and separately grinding, followed by intermixing (SGIM) the different combinations of clinker and slag.

It is found that by separately grinding a suitable combination of clinker and slag % (by volume) and intermixing, the resultant cement shows set acceleration, which is in contrast to interground cement wherein selection of suitable clinker/slag combination is not possible, and hence cannot give rise to the required Particle Size Distribution (PSD) of cement and thereby exhibits maximum set retardation. It is observed that irrespective of the process by which cement is ground, it needs to have wide PSD and suitable clinker chemistry with respect to C_3A and SD % in order to get set acceleration. It is also found that with the difference in clinker grain density by 0.04 g/cc there is subsequent increase or decrease by 5.5% (by vol.) in the clinker/slag composition.

1. INTRODUCTION

In consideration of the increasing demands of the cement customers with regard to quality and efficiency of the products, the technology of the cement grinding process in most of the cement industries have switched over to separate grinding and subsequent mixing process [1]. With respect to set control parameters since it depends on the PSD of cement and clinker chemistry, it is obvious that the proportion of clinker/slag should be such that it can provide the required PSD during grinding that favours the process of coagulation and rigidification [2,3 & 5] in the presence of required level of SD % [4].

This relates to fundamental aspects of grain density of the components as it reflects its volume and thereby brings changes in the clinker/slag proportion which after grinding to a respective fineness shows either narrow or wide PSD, accordingly with the availability of C_3A and SD % setting commences as the hydration of cement progresses.

2. RAW MATERIALS AND TEST PROCEDURES

Three different qualities of clinker- A, B and C, a batch of granulated slag and by-product gypsum are characterized with respect to oxide constituents, clinker phases, degree of sulphatization, grain

density of slag and clinker and SO_3 content in gypsum, Table 1. Each quality of clinker along with the granulated slag and by-product gypsum in the weight proportion of 48.5 %, 50 % and 1.5 % respectively, is interground and separately ground and intermixed to a specific surface area of $350 \text{ m}^2/\text{kg}$ in the laboratory ball mill, and each fraction of ground components and finished cements are subjected to particle size analysis through FRITSCH analysette 22 and the setting time of each finished cement is determined. Two compositions each with clinker- A and C representing low and high grain density as 2.54 and 2.70 g/cc respectively, are prepared using different combination of clinker and slag and put on trial after separate grinding to $350 \text{ m}^2/\text{kg}$ and subsequent intermixing and based on its results, the volume % of clinker and slag that is required to reduce the setting time is determined with respect to clinker-B representing grain density 2.66 g/cc and is ground to a fineness of $350 \text{ m}^2/\text{kg}$. The results of its particle size distribution with respect to gradient n and setting time are then compared with the relationship drawn between the difference in clinker grain density and subsequent changes in the volume proportion of clinker and slag while using clinker-A and C. In the case of interground cement, all the components are taken together and ground to fineness identical to cements produced through separate grinding and subsequent intermixing. Irrespective of the process of grinding the composition of the finished cements are kept same all through the trials.

Table 1. Raw materials characterization

Constituents %	Clinker A	Clinker B	Clinker C	Granulated slag	By- product gypsum
SiO_2	19.11	20.40	19.28	34.80	ND
Al_2O_3	6.01	6.20	5.93	21.10	ND

Grain density, g/cc	2.54	2.66	2.70	1.97	-
Glass content in slag, %	-	-	-	97.00	-

3. RESULTS AND DISCUSSIONS

Clinker-A: The intermixed cement no.07 records 45 % reduction in the initial setting time with respect to interground cement no.90 as because one of its separately ground fraction no.31 shows n and x^1 value as 0.202 and $17.10 \mu\text{m}$ respectively representing wide particle size distribution (PSD) whereas cement no.26 attributes to set retardation due to comparatively narrow PSD and is almost the same as interground cement, Table 2.

It is certain that this difference in setting time is due to the change in the volume % of clinker and slag incorporated into the composition nos.76 and 77 as a result the trend represented by the line FG in Figure 1 takes the position towards the composition made with clinker-B and C.

Table 2. Properties of interground and separately ground PSC prepared by using clinker-A

Composition No.	Composition (Clinker+slag+gypsum)		Grinding Process	Blains (m ² /kg)	PSD		Setting time (minutes)	
	Weight %	Vol. %			Gradient n	Position x ¹ μm	Initial	Final
90	48.5+50+1.5	43+57	IG*	352	0.215	16.27	275	305
30	20+20	43.5+56.5	SG*	350	0.215	16.38

76	15+30	28+72	SG	351	0.215	15.35		
77	33.5+20+1.5	56.5+43.5	SG	350	0.226	16.27		
26(76+77)	48.5+50+1.5	43+57	IM	351	0.220	16.00	260	285

*IG, SG & IM represents intergrinding, separate grinding & intermixing

Clinker-B: The volume % of clinker and slag required to reduce the setting time is calculated for the nos.72 and 73 based on the results obtained using clinker-A and C and the finished cement no.106 on being tested for setting time records set acceleration by 31 % with respect to interground cement no.176, Table 3. This is represented by the trend line HI in Figure 1.

Table 3. Properties of interground and separately ground PSC prepared by using clinker-B

Composition No.	Composition (Clinker+slag+gypsum)		Grinding Process	Blains (m ² /kg)	PSD		Setting time (minutes)	
	Weight %	Vol. %			Gradient n	Position x ¹ μm	Initial	Final
176	48.5+50+1.5	41.7+58.3	IG*	350	0.227	15.90	225	265
72	15+30	27+73	SG*	352	0.205	17.50		
73	33.5+20+1.5	55.4+44.6	SG	351	0.227	15.88		
106(72+73)	48.5+50	41.7+58.3	IM	351	0.217	16.10	155	190

*IG, SG & IM represents intergrinding, separate grinding & intermixing

Clinker-C: Two compositions (48, 51 & 197) and (65, 66 & 145) representing two different combinations of clinker and slag by volume prepared by using clinker-C, out of which the compositions nos. 65, 66 & 145 have a tendency towards reduction in setting time because one of its fraction composition no.65 indicates wide PSD, comparatively the nos. 48, 51 & 197 records narrow PSD and thereby maximum retardation in setting time results with respect to interground cement no.177, Table 4.

Table 4. Properties of Interground and Separately ground PSC prepared by using clinker-C

Composition No.	Composition (Clinker+slag+gypsum)		Grinding Process	Blains (m ² /kg)	PSD		Setting time (minutes)	
	Weight %	Vol. %			Gradient n	Position x ¹ μm	Initial	Final
177	48.5+50+1.5	41.5+58.5	IG*	352	0.226	15.85	205	
48	20+20	42.2+57.8	SG*	350	0.214	16.53		
51	28.5+30+1.5	41+59	SG	352	0.231	15.59		
197 (48+51)	48.5+50+1.5	41.5+58.5	IM*	351	0.226	15.76	285	310
65	12.3+32.7	21.5+78.5	SG	351	0.201	17.25		
66	36.2+17.3+1.5	60.2+39.8	SG	352	0.236	15.12		
145(65+66)	48.5+50+1.5	41.5+58.5	IM	351	0.219	15.83	190	220

* IG, SG & IM represents intergrinding, separate grinding & intermixing

However, compared to clinker-A and B, the composition made with clinker-C does not give rise to an appreciable amount of set reduction because C₃A content is only 8.5 % compared to 10.4 and 10.1 % in clinker-A and B respectively. As a result more C₃A could not react despite having high K₂O and low sulphatization % [4]. This accordingly has reflected in the orientation of the trend lines JK and LM representing the composition nos.48, 51, 197 and 65, 66, 145 respectively, Figure 1. The reasons for having same trend of HI and LM joining the compositions 72,73,106 and 65, 66, 145 respectively is because of having less difference in the volume % of clinker and slag.

Figure 1. Gradient n as a function of clinker / slag volume %.

It is clear from the compositions contributing to set reduction, Table 2, 3 & 4, that with the difference in clinker grain density by 0.04 g/cc there is simultaneous increase or decrease by 5.5 % (by vol.) in the clinker/slag composition. This linear relationship is shown in Figure 2 where I and II represents two fractions of separate grinding.

Figure 2. Difference in clinker grain density as a function of difference in clinker / slag volume %.

4. CONCLUSION

It is possible to accelerate the setting time of PSC by separately grinding a suitable combination of clinker and slag % by volume and subsequent mixing which provides the required particle size distribution in cement and the clinker chemistry with respect to C_3A and sulphatization of alkalis. By suitable combination of clinker and slag does not mean to have an approach in acquiring equal grindabilities; rather it is to be referred as an attempt towards achieving favourable PSD in cement. Such combinations, however, are found to vary with the grain density of clinker, which decides the intake of volume of each component that are to be ground. This suggests a linear relationship wherein it is found that with a difference in clinker grain density by 0.04 g/cc there is subsequent increase or decrease in the volume % of clinker/slag by 5.5 %. Further a definite trend is found to exist between the compositions that indicate set acceleration; its gradient n and grain density of clinker, which highlights identical trend for the compositions prepared with the clinkers having less difference in their grain density. Selection of a suitable combination of clinker/slag is however not possible in an interground cement, and hence cannot be aimed for a required PSD which leads to having no control over its setting characteristics.

Dr. J.D. Panda

Dr.Panda after completion of his post graduation in Applied Chemistry from Calcutta University and Dr.Ing.Degree in Ceramics-Technical from University of Clausthal, West Germany, served as Research Chemist with Dr.C.Otto and Company, W.Germany, as Manager Refractory Division with OCL India Limited and since 1975 onwards leading a group of Scientists engaged in the field of Cement and Ceramics as Director, DISIR,Rajgangpur, India. He has visited number of countries and have published 100 research papers in National and International Journal, have attended 80 seminars and conferences and also chaired conferences in number of occasions. He has been awarded Refractory Technologist of the year-1993 by Indian Ceramic Society, Import substitution Award in 1987, 1992 and 1999 and awarded with a Silver Shield by The Invention Promotion Board for import substitution work in 1975. He is a member of Indian ceramic Society, Indian Institute of Ceramic, German Ceramic Society and a Corporate member of American Ceramic Society.

Dr. D.K. Mitra

Dr.Mitra after completion of his post graduation and Ph.D degree in the field of applied geology from IIT., Kharagpur, India, served in different capacity in the field of cement and refractory for the last more than 16 years. Presently as a Sr.Scientist with DISIR, he is actively associated with the fundamental research and developmental work in cement. He has published 6 scientific papers in National and International journal and have attended many seminars/conferences/workshop.

WHAT TRIGGERS CONCRETE DETERIORATION IN AQUEOUS UNDERGROUND ENVIRONMENTS?

ABSTRACT

Interactions of concrete with percolating water produce complicated deterioration-textures and chemical zonations. Although concrete corrosion has many different faces, there are some general phenomena, which are observed in most field studies of deteriorated concrete. As can be estimated from field evidence, many of these parameters (pH-value, chemistry of percolating water and of pore solution) vary with time and place. At a fixed point of consideration different corrosive processes follow each other because the reactive front is moving with time. These processes include dissolution of cementitious phases, transportation of dissolved chemical species and (re-)precipitation of secondary minerals. Further complicated reactions include various kinds of carbonation and sulfate attack. In detail these processes are difficult to predict, because there are a large number of chemical parameters which are difficult to quantify.

The observed textural relationships indicate that chemical attack is triggered by permeable inhomogeneities which serve as pathways for the percolating water. Leaching and dissolution of the cement paste seem to be restricted to the neighborhood of these pathways. Depending on the size of the pathway and the flow rate large amounts of aggressive substances may be brought far into the system and lead to serious degradation. The performance of a defined concrete based on laboratory tests may therefore lead to over optimistic prognoses.

1. INTRODUCTION

Cement based materials are generally characterized by durability qualities. Durability criteria are defined for laboratory tests and bulk properties of material samples. In contrast to these circumstances, situations in reality look quite different and are complicated by a number of factors.

First, the severity of concrete deterioration is related to the risk of failure on one hand and to the costs of repair on the other, but service life of buildings is not related to the average quality of its building materials.

Second, the action of the environment is composed of many different physical and chemical components which generally vary in their intensities over time and within short distances.

Third, the factor of time is of crucial importance. Laboratory tests as a matter of fact have to accelerate the deterioration processes, physical and chemical test conditions are intensified accordingly. The resulting mechanism may therefore be different from the mechanisms during long time interaction.

In order to initiate protective countermeasures against all the different forms of chemical interaction it is important to understand the underlying deterioration processes. Because modeling of chemical interaction is complicated by a vast number of variables and many assumptions have to be made, we try to derive some evidence about the interaction mechanisms on the basis of microscopical investigation of field samples.

2. CHEMICAL INTERACTION OVER SPACE AND TIME

Building materials based on Portland cement always interact with aqueous environments. The porous space inside these materials contains partly or completely an aqueous solution. The chemical composition of this solution is derived from cement and its hydration products and is in equilibrium with the solid components of the system [1]. In contact with an environment of different composition, chemical gradients develop in the building material as well as in the environment leading to diffusion and mass transfer interactions between the ground water and the saturated cement paste [2,3].

The chemical composition of the environment (chemical gradients, diffusion) and the kind of water flow (advective flux) are the promoters of the chemical interaction. The latter is very much dependent on the permeation properties of the building material, capillary suction being the most important driving factor in cases of Portland cement based systems. On the other hand, the transportation of chemical ingredients through the porous system is only possible for those not reacting with the pore solution to form stable solids [4]. The composition of the pore solution as well as the density of the porous structure will both be affected and changed with ongoing chemical interaction.

Water of the environment may principally penetrate porous materials continuously throughout the connected pore space or along local inhomogeneities with larger permeability. The latter pathways have the potential of bringing chemically reactive components far into the material system and of maintaining the diffusion steep gradients. In reality, one can often find locations with advanced degrees of concrete deterioration being related to cracks, joints or interfaces whereas efflorescence on the overall concrete surface gives evidence of a water movement through the porous structure of the building material towards its surface. Most of the concrete damages in underground constructions which require repair or maintenance are related to chemical degradation along local inhomogeneities.

3. SURFACE PHENOMENA

Elevated water saturation of concrete is often associated with pathways (joints, cracks) through the concrete component. The formation of layers of secondary minerals on the surface of concrete could only be observed with relatively thin shotcrete and sodium sulfate hydrates (Figure 1) [5]. Surface scaling of concrete due to the crystallization of salt near the surface is rare in tunnels (maybe due to high levels of humidity). In most cases water is moving along local and permeable inhomogeneities through the concrete. Low flows of water are accompanied by formation of calcite and/or water soluble salts on the surface of the concrete close to the intersection (Figure 2) [6]. Larger flows of water are frequently conducted by biofilms (Figure 3) on the concrete surface and water soluble salts may form in the lateral drying region of the wet concrete. Under biofilms the concrete surface may show phenomena of cement paste dissolution and erosion due to acid attack (Figure 4).

In contrast to these surface phenomena the back of underground constructions is much less accessible for investigation but more pronounced for interactions.

Figure 1. Shotcrete lining in the service tunnel "St. Gotthard" (upper part of the wall) showing a more or less uniform cover with bright efflorescence. Dark (wet) regions within the shotcrete mark localities with water transport and evaporation through the shotcrete.

Figure 2. Shotcrete lining in the "Bauen" Tunnel showing formation of a calcite crust directly on the intersection of small deformation induced cracks through the concrete. There are no signs of water running over the concrete surface.

Figure 3. "Gotschna" tunnel: ground water locally penetrating the shotcrete lining. Depending on the amount of running water large amounts of biomass may form. The white mass in the center of the picture represents a colony of sulfur bacteria.

Figure 4. Shotcrete surface from underneath the biomass of Figure 3 (thin section perpendicular to the surface): portlandite in the hardened cement paste is leached off, the top layer of the paste is extensively carbonated whereas part of the original paste is eroded and aggregates are exposed on the surface.

4. CONCRETE DETERIORATION IN CONTACT WITH GROUND WATER

On the surface of concrete exposed to ground water we find the evidence of aggressive components of this water. In a simplified view two processes may be distinguished: 1st - components of the hardened cement paste are dissolved and leached off by the ground water. 2nd - components of the ground water may form stable compounds with constituents of the pore solution or the cement paste. Components of the environment like magnesium or sulfate will react fast with original concrete due to the possibility of the formation of stable reaction products. Therefore only dilute concentrations of water-soluble reactive components may be transported together with pore solution through the concrete, as a consequence this process is followed by substantial leaching. Potassium,

sodium and chloride may be transported in higher concentrations due to their more or less inert behavior.

Phenomena on the inner (accessible) surface of tunnel linings may or may not give indications of severe deterioration processes regarding interactions with ground water. Detailed examination of localities in the concrete with high permeabilities (pathways for ground water) may deliver indirect evidence of corrosive interactions on the outer surface of the concrete exposed to ground water.

Samples of shotcrete and massive concrete of tunnel structures representing different situations in Switzerland have been investigated. The samples were cored carefully in locations showing representative deterioration phenomena as well as at positions without any evidence of deterioration serving as reference samples. After cutting and drying, fractions of the material were chosen for microscopical or analytical investigation.

4.1 Shotcrete

Shotcrete is mostly characterized by a diffuse layering due to the spraying procedure (Figure 5). Alteration by interacting with percolating water produces complicated deterioration-textures and chemical zonations along the contact to the shotcrete support and to a lesser extent along the layer contacts within the concrete. On a microscopic profile starting in the unchanged shotcrete towards the above mentioned contacts the alteration increases and 3 distinct zones can be distinguished (Figure 6). In the zone of leached cement paste the lack of portlandite and the general grain size reduction of cementitious phases give evidence for general dissolution processes. The corrosion zone is characterized by complete dissolution of cement paste resulting in a highly porous and mechanically weak material. The transitions between the regions of different state of alteration are quite sharp. A detailed description of the microscopic and chemical aspects of zonations in deteriorated shotcrete (tunnel lining) is given in [7].

Figure 5. Sample of shotcrete lining of “Koblenz” railway tunnel showing several distinct layers parallel to the support (bottom) due to irregular accumulations of sand, aggregate, paste and air voids.

Figure 6. Thin section perpendicular to the crack surface with layering on microscopy scale within one mm (picture size). Leaching zone to the left, corrosion zone to the right with a distinct layer of carbonation in-between (dark). Zonations are propagating to the left with time.

In intensely deteriorated samples the growth of secondary minerals in small veins is superimposed onto the chemical dissolution phenomena. Cracks, veins and pore spaces are filled with very fine and fibrous matter. In relation to the interaction of ground water in tunnel concrete the formation of sulfate containing minerals was dominated by thaumasite. Ettringite on the other hand could be

detected as recrystallized needles in air voids surrounded by unaltered paste that is interpreted as a ordinary consequence of high degrees of water saturation over longer periods of time [8]. Thaumasite in contrast is associated with different kind of chemically altered or deteriorated concrete[9].

4.2 Massive concrete

After more than 30 years of interaction with percolating sulfate-rich groundwater the concrete of a road tunnel locally displays massive corrosive damage up to complete chemical disintegration reaching up to 20 cm thickness. Chemical and mineralogical alteration along the rock-concrete contact leads to cracking and loss of attachment with the underlying rock, giving way to contact-parallel migration of groundwater. Corrosive interactions along primary inhomogeneities within the concrete are taking place in a similar way. The pattern of interaction phenomena may change drastically along a single intersection though the concrete showing evidence of extensive leaching or the formation of new mineral solids like brucite or gypsum (Figure 7). As a result of long time interaction over decades, larger volumes of concrete may be affected starting from these primary inhomogeneities whereas the majority of the concrete structure is more or less unaffected by interactions with ground water (Figure 8).

Figure 7. Layers of brucite(*) and thaumasite (arrow) together with a rosette of aragonite/calcite on the concrete crack surface (bottom left).

Figure 8. Concrete lining of “San Bernardino” tunnel: depending on whether the altered concrete is wet or dry it shows properties of a mush or a crumbly material.

5. DISCUSSION

The observed textural relationships indicate that chemical attack is triggered by permeable inhomogeneities which serve as pathways for the percolating water. Shotcrete linings are rather thin and inhomogeneous regarding the distribution of porosity. Therefore shotcrete is quite often found to be substantially affected by ground water whereas the deterioration in ordinary concrete is mostly restricted to primary inhomogeneities like joints, cracks or regions with poor compaction. Leaching and dissolution of the cement paste seem to be restricted to the neighborhood of these pathways.

The stability of hydration products in hardened cement paste is dependent on the chemical composition of the pore solution which itself is chemically buffered by the latter. As a consequence the interaction with an aqueous environment of different composition is not resulting in a continuous alteration over distance but in the formation of a zonation pattern: regions with different solid compositions show relatively sharp transitions between them. This gives evidence of a moving boundary behavior in the opposite direction of the diffusion flux [4].

At a fixed point of consideration different corrosive processes follow each other because the reactive front is moving with time. These processes include dissolution of cementitious phases, transportation of dissolved chemical species and (re-)precipitation of secondary minerals. The flow of water through a crack always leads to leaching of the crack walls.

Depending on the flow rate and the density of the concrete as well as on its state of leaching the water in the crack is shifting its composition in the direction of the chemical composition of pore solution. At the same time the chemical concentration of the percolating ground water is important for the diffusion of aggressive components like sulfate into the neighboring paste. Depending on the flow rate through the crack, leaching effects and formation of new reaction products are superimposed (Figure 9). For the same original composition of interacting water different phenomena and reaction products may be formed dependent on the pathway and whether the composition of the local cement paste is leached at the same time or not [10].

Figure 9. Schematic presentation of the parameters flow rate and chemical concentration of the percolating water and the interaction patterns resulting in different combinations of these parameters.

Extensive leaching of concrete in underground constructions (pattern ① and ② in Figure 9) is not only important for the degradation of the building material itself, it may also cause the formation of precipitates in the drainage system. This process leads to the failure of the drainage and to a pressure increase which itself will force the water to penetrate new pathways. Pattern ③ represents the situation in laboratory test conditions and pattern ④ could be illustrated with the situation of a dam wall. The latter patterns are related to decelerating processes whereas extended leaching may lead to accelerating interaction mechanisms.

6. CONCLUSIONS

The observed textural relationships of deteriorated concrete in underground constructions indicate that chemical attack is triggered by permeable inhomogeneities which serve as pathways for the percolating water.

It is therefore important to note that physical parameters like permeability or inhomogeneities are at least as important as chemical parameters like the composition of the paste, pH-values and composition of the interacting water. Performance test in general don't take into account the effects of cracks and other pathways of percolating water and may therefore lead to over optimistic prognosis.

The flow rate of percolating water in a defined cavity is defining the route of chemical interaction by having a major impact on the bringing in of reactive constituents, the formation of diffusion gradients and the advective transport of soluble paste components out of the system. Because of different sizes of intersections and resulting flow rates, interaction phenomena may be quite different within short distances.

In all investigated tunnel structures with concrete in contact with ground water, the processes of leaching and the formation of sulfate minerals, predominantly thaumasite, have been detected. As a consequence thaumasite may be a very common finding in a large number of underground constructions. The concentration of sulfate in the ground water as well as the use of cement with low contents of aluminum seem to be less important.

The adhesion of shotcrete linings may be affected by small amounts of interactions on the interface. In this regard not only water described as "aggressive" corresponding to regulations has to be considered but a wide range of chemical compositions, severe conditions may therefore be related to ground water not considered as aggressive corresponding to current standards.

The workmanship in the production of concrete as well as in the placement and after-care are crucial for the bulk properties of the concrete components as well as for tight joints between them. In aggressive environments the contact of ground water with concrete has to be prevented by sealing off the concrete structure.

ACKNOWLEDGMENTS

The projects have been funded by the Swiss Federal Roads Authority (ASTRA) and by the Swiss Federal Laboratories for Materials Testing and Research (EMPA). We would also like to thank Marcel Pfiffner and Andreas Leemann for contributing with field work and microscopical investigations.

INFLUENCE OF CEMENT EXTENDERS ON THE CORROSION RATE OF STEEL IN CRACKED CONCRETE

Scott, A.¹ and Alexander, M. G.¹

¹ Department of Civil Engineering, University of Cape Town, RSA, E-mail: mark@eng.uct.ac.za

ABSTRACT

In-service cracking in reinforced concrete structures allows for the rapid onset of corrosion due to chloride ion ingress. The impact of cracking on the subsequent corrosion rate is, however, less clear, particularly where different cementitious materials are used.

The influence of cement extenders on the corrosion of steel in cracked beam specimens exposed to chloride solutions is being investigated in a research program at the University of Cape Town. As part of a wider program, four concrete mixes comprising OPC, 50% slag, 30% FA and 7% SF were studied. Specimens were loaded to produce a centrally located crack with a nominal width of 0.2mm. The results showed a significant dependence of corrosion rate on the type of extender.

1. INTRODUCTION

The corrosion of reinforcing steel in concrete has been the subject of extensive investigations for many years. There are numerous articles that describe the fundamental principles and mechanisms relating to the corrosion of steel reinforcing [1,2,3]. Cement extenders have been shown to improve the time to initiation of corrosion given adequate curing and cover [4,5]. There is however less understanding and agreement on the influence of cement extenders on the corrosion rate of steel in concrete. The subject of cracking is another area that tends to complicate the corrosion issue and one that has also been the subject of much debate. Relatively little work has been done on the influence of cement extenders on the corrosion of steel in cracked concrete.

Slag concretes in particular have been the focus of concern primarily due to the presence of sulphides in the pore water. Tromans [6] has suggested that sulphides may be incorporated into the oxide layer thus reducing its ability to protect the steel. Valentini et al [7] conducted an investigation into the corrosion rates of steel in blastfurnace slag mortars, at slag replacement levels of 20, 45 and 75%. A water:binder (w/b) ratio of 0.5 was used with covers of 10 mm and water curing for 28 days prior to storage at 50% and 100% relative humidity (RH). Their results showed that immediately after curing the slag-containing samples had a corrosion rate 10 times higher than the Ordinary Portland Cement (OPC) control. This difference decreased with time but the slag-containing samples generally maintained somewhat higher passive corrosion rates at 50% RH. These articles note that tests performed at different ages may give contradictory results, and this may be attributed to the variation in sulphide pore solution concentration which is not constant with time.

Arya and Xu [8] examined a number of cement extenders using steel anodes with cast-in chlorides at 1 and 3% coupled by a Zero Resistance Ammeter to a chloride free cathode. For 3% chlorides it was shown that corrosion rates occurred in decreasing order of Fly Ash > OPC > Slag > Silica Fume, for cement replacement levels of 35, 0, 65 and 10% respectively. The FA and OPC samples

displayed similar corrosion rates with the Slag and SF samples both showing much lower rates. Sirivivatnanon et al [9] investigated the influence of similar cement extenders in mortar samples and found different results. Mild steel samples were cast into blocks of mortar with a w/b ratio of 0.8, 10 mm cover and a number of cement replacement levels. After initial curing, the samples were exposed to a 3% NaCl solution. The macrocell corrosion rates at 6 months were in the order of OPC > FA > Slag > SF as shown in Table 1. There was however a significant difference in corrosion rate between the 5% and 10% SF replacement levels, which would alter the corrosion ranking order.

Table 1. Corrosion rate as a function of binder type [9]

<i>Binder Type</i>	<i>Approx Rate ($\mu A/cm^2$)</i>
OPC	2.25
20-40% FA	0.75
40-60% Slag	0.5
5% SF	1
10% SF	0.2

The results of Sirivivatnanon et al [9] showed a variation in order of corrosion rates, based on cement replacements, which differed from those of Arya and Xu [8]. The presence of chlorides from the onset may inhibit the formation of the passive layer and have further effects on the concrete microstructure which would otherwise not have occurred thus giving different results as noted.

The presence of cracks and their impact on corrosion is equally contentious. Beeby [10] and Arya and Wood [11] suggest that there is no direct relationship between crack width and corrosion rate. They refute other claims of a correlation by stating that the cracks may accelerate corrosion initiation, but not necessarily the propagation rate. Assuming two cracks A and B, which become active at 1 and 2 years, after 3 years there is 100% more corrosion at crack A, this falls to 50% at 4 years and 5% after 20 years. Thus the time at which the measurements are taken will affect the comparison. Arya and Wood [11] state that the more important considerations are: 1) crack properties, for instance whether the crack is active or dormant, 2) concrete – steel properties, whereby low permeability of the concrete will limit ionic transport, high moisture limits oxygen ingress and increased strength leads to better bond and less slip at the steel-concrete interface, 3) service environment. Controlling the environment around the steel concrete interface is seen to be more important than the presence of the crack itself.

The work of Francois and Arliguie [12] and Suzuki et al [13] also supports the argument of limited effect of crack width on corrosion rate. Suzuki et al. [13] however showed that there are some early-age differences in corrosion rate based on crack width but these decrease with time. It was found that the w/c ratio had a more significant impact on corrosion rate. Pettersson and Jorgensen [14] looked at a number of crack width and cover combinations using both OPC and SF concrete. For a w/b of 0.3 it was found that cover had an effect on corrosion rates for crack widths of 0.4 mm. For cracks widths above this value cover had negligible effect on corrosion. The smaller crack widths would be more likely to benefit from autogenous healing and thus limit the effect of the crack. The corrosion rate was shown to vary with addition of micro silica from a value of 10 $\mu m/year$ for OPC, 5 $\mu m/year$ for 5% replacement and approximately 2.3 $\mu m/year$ for 10 and 15% replacements at 300 days. Marcotte and Hansson [15] have also shown reductions in corrosion rates associated with cracked high performance concrete (HPC). They state however that the use of HPC resulted in less than expected performance improvements. The greater degree of microcracking in the HPC may have been responsible.

The focus of the current investigation therefore is directed towards an improved understanding of the influence of cement extenders on the corrosion rate of steel in concrete. Since cracks clearly represent a point of easy access of chlorides to the steel, thus circumventing the normal requirement for diffusion of chlorides or carbonation, it was deemed necessary to examine what further effects they would have coupled with the use of cement extenders. Four binder types consisting of OPC, slag, FA and SF were used in the current investigation. A surface crack width of less than 0.2 mm was chosen which would be considered allowable under most environmental conditions.

2. EXPERIMENTAL METHOD

The corrosion of steel was investigated in concretes, using four different binder types, and subjected to cyclic wetting and drying. Identical samples of OPC, slag (50%), FA (30%) and CSF (7%), at a water: binder ratio of 0.58, were prepared. The oxide analyses of the materials used are presented in Table 2. The mix proportions and 28 day strengths for the concretes are given in Table 3.

Table 2. Oxide analyses of binder materials (%)

<i>Oxide</i>	<i>OPC</i>	<i>SLAG</i>	<i>FA</i>	<i>SF</i>
SiO ₂	21.5	35.4	53.1	91.9
CaO	65.9	33.5	4.2	0.0
Al ₂ O ₃	3.7	15.8	33.7	0.7
Fe ₂ O ₃	3.6	0.9	3.6	0.8
Mn ₂ O ₃	0.06	0.90	0.05	0.09

* Superplasticiser used to ensure particle dispersion

Mild steel bars of diameter 16 mm were cast into the samples at a cover depth of 20 mm. The bars were first brushed to remove the mill scale and thoroughly cleaned. A wire was attached to one end of the bar and both ends were heat shrink-wrapped and epoxy-coated to provide an exposed surface area of 158 cm². Prior to casting, the bars were again cleaned and degreased with acetone. The overall dimensions of the concrete samples were 375 x 120 x 120 mm.

The specimens were demoulded after 24 hours and water-cured for another 14 days at 20°C. A centrally located transverse crack was created in the samples by three-point bending. There was some relaxation of the crack once the load was removed and thus it was necessary to initially overload the sample. The crack widths were measured and those corresponding to a surface crack width of approximately 0.2 mm were chosen. The cracks were maintained through partial slipping of the round bar. The crack widths have been reasonably constant over the initial exposure period.

A reservoir was created on the surface and specimens exposed to a weekly cycle of three days wetting with a 5% NaCl, solution and four days drying, at 30 °C. A number of identical non-cracked specimens were also cast and subjected to the same exposure conditions for comparative purposes.

The samples were monitored bi-weekly for corrosion potential, rate and resistivity. Resistivity measurements were taken using a 4 probe Wenner system. Corrosion rate data was obtained by means of coulostatic technique whereby a small charge was applied to the steel and the relaxation of the potential monitored over a fairly short period of time, see Figure 1. The characteristic profile of the decay curve as given by equation 1 was then used to determine the time constant

$$n_t = n_o \exp\left(\frac{-t}{\tau_c}\right) \quad (1)$$

where n_t is the potential shift at time t , n_o is the initial potential shift and τ_c is the time constant [16]. The polarization resistance (R_p) is then obtained from the time constant and capacitance (C) information, equations 2 and 3, with q_s being the applied charge.

$$\tau_c = CR_p \quad (2)$$

$$C = \frac{q_s}{n_o} \quad (3)$$

The polarization resistance was then converted into a corrosion rate (i_{corr}) by means of the Stern Geary relationship, equation 4 [2], with an assumed constant value B of 26 as suggested by Andrade and Alonso [17].

$$i_{corr} = \frac{B}{R_p} \quad (4)$$

The potential was monitored against a Ag/AgCl reference electrode and recorded using an HP 34970A data acquisition unit. The perturbation was produced by means of a single shot pulse generator capable of supplying a charge of up to 30 mA over a defined period, usually less than 30 milliseconds.

Figure 1. Coulostatic potential transients

3. RESULTS

3.1 Resistivity Data

Resistivity measurements were taken on three occasions: at the start of the drying cycle, at the same time as the corrosion rate measurements (taken during the drying period), and finally at the end of the drying period just before ponding. The results reported are based on a moving average of three periods corresponding to time of corrosion rate measurements. The results of resistivity measurements for the four binder types are shown in Figure 2. It can be seen that mineral extenders have a marked effect on the resistivity of the concrete. The FA samples had the highest resistivity stabilizing at approximately 75 kOhm.cm after steadily increasing for the first 26 weeks. The resistivity of the slag samples increased fairly slowly from their initial value of 20 kOhm.cm to a high of 50 kOhm.cm before reducing somewhat to 40 kOhm.cm. SF showed an initial rapid rise of resistivity similar to that of FA but subsequently leveled off after approximately 14 weeks at about 35 kOhm.cm. There was a very slow and minor increase in the resistivity of OPC concrete and values remained well below those of the other three binder types. The decrease in resistivity measurements after week 40 may be a result of some climate control problems that were experienced; it is not clear at this stage whether the subsequent downward trend may be due to chloride ingress.

Figure 2. Resistivity measurements

The measurements of resistivity over each weekly drying cycle showed significant variability, dependant on binder type. The OPC samples showed the least variability in resistivity, about 19 percent, over a typical weekly cycle, with the SF, slag and FA samples displaying typical variations of 28, 30 and 31 percent respectively.

3.2 Corrosion Rate Data

The results for the cracked samples are shown in Figure 3 as a moving average of three readings. The corrosion rate of steel in cracked concrete appears to be strongly influenced by the use of cement extenders. The OPC samples displayed the highest initial corrosion rate of approximately $0.67 \mu\text{A}/\text{cm}^2$ and continued to increase over the study period to a maximum of about $2.5 \mu\text{A}/\text{cm}^2$. The samples containing cement extenders had initial corrosion rates of 0.15, 0.25 and 0.43 for the SF, slag and FA samples respectively. The rates for the SF samples increased fairly rapidly and settled at a similar value to FA of approximately $0.45 \mu\text{A}/\text{cm}^2$ by week 26. During this same period the OPC samples increased from their initial value of 0.67 to over $1.4 \mu\text{A}/\text{cm}^2$. The slag samples showed a minor increase in corrosion rate from $0.25 \mu\text{A}/\text{cm}^2$ to a reasonably steady value of $0.35 \mu\text{A}/\text{cm}^2$.

Figure 3. Corrosion rates ($\mu\text{A}/\text{cm}^2$) of 0.2 mm cracked samples

The corrosion rates of cracked and uncracked concretes were also compared for OPC samples only. The onset of active corrosion was marked by a substantial increase in both corrosion potential and rate. Corrosion initiation for cracked concrete was almost immediate upon exposure to the chloride solution, whereas the steel in the uncracked concrete only started to corrode when sufficient chlorides had diffused through the concrete and reach the steel (a period of approximately 25 weeks). The comparison of corrosion rates for cracked concrete and uncracked concrete adjusted to similar times for initiation are shown in Figure 4. There is clearly a more gradual increase in corrosion rate for the uncracked specimens.

Figure 4. Corrosion rates ($\mu\text{A}/\text{cm}^2$) for cracked and uncracked OPC concrete

3.3 Pre-Ponding Potential Data

It was observed that prior to cracking, and before ponding, the samples containing slag had a significantly higher negative potential value compared with the other samples, which then fell rapidly after cracking. A limited and ongoing investigation into the effects of cracking on the

potential of slag-containing concretes was then conducted. The potentials of samples after two weeks of wet curing showed that SF had the least negative of -90 mV, followed by FA and OPC at about -190 to -250 mV and finally slag at -600 mV. Two subsequent set of mixes (SL, SH) containing 25 and 75 % slags were then cast and the potentials immediately following cracking are shown in Figure 5.

Figure 5. Post-crack potentials of slag concrete

The potentials values of the slag concretes rose rapidly, from an initial potential of approximately -550 mV before cracking, to -300 mV or more after thirty minutes for SL. Twenty four hours after cracking the potentials of SL and SH had further increased to more than -200 mV. This rapid rise in potential was only observed in the slag bearing concretes.

4. DISCUSSION

The development of cracking, as previously noted, was obtained through limited slipping of the bar which in turn could act as a preferential site for the movement of chlorides and subsequent corrosion. Ingress of chloride ions along slipped versus un-slipped bars was investigated separately using a silver nitrate, ultra-violet test method adapted from Schoppel et al [18]. The preliminary results indicate that while there is preferential movement of chlorides along the bar interface, compared to the bulk concrete, there was no significant difference between the slipped and un-slipped bars. Furthermore as cracking was introduced at 14 days there was still some time for subsequent healing of the bond interface due to continued hydration. The SF and OPC would have the least reserve capacity for continued hydration, followed by slag and FA. An examination of the corrosion rates reveals that OPC had significantly the highest corrosion rate followed by FA and SF and then slag with the lowest. As the continued hydration of the FA should limit the impact of the early bar slip it is clear that factors other than degree of slip and subsequent healing are the more important parameters.

It has long been argued that resistivity of the concrete plays a significant role in the corrosion rate of steel in concrete [19]. While this generally appears to be true, a significant variation can be seen with respect to the FA samples. FA concretes had a resistivity approximately 2 times greater than the SF concrete despite having nominally the same corrosion rate, and 1.5 times greater than slag concrete while having a higher corrosion rate. The resistivity ratios for OPC, FA, and SF are similar to those given by Baweja et al [20].

The results of 28 day chloride conductivity tests, as given by Alexander et al [21] and Magee [22], generally correlate with the corrosion rates obtained for the current study. The approximate values given in Table 4 for chloride conductivity show the highest values for OPC and FA with similar values for Slag and SF.

Table 4. Chloride conductivity measurements
(14d curing, w/b 0.6)

<i>Binder Type</i>	<i>Chloride Conductivity (mS/cm)</i>
OPC	2.0
FA	1.5
Slag	1.1
SF	1.0

The use of chloride conductivity measurements therefore may offer some additional insight into the corrosion rates of steel and is currently being investigated.

A clear relationship has been demonstrated between increasing pH and chloride levels required for the initiation of corrosion [23]. The impact of cement extenders on pH levels has been shown by Arya and Xu [8] with OPC having the highest OH⁻ concentration followed by similar levels for slags and FA and considerably reduced levels for SF. The reduced OH⁻ concentration in SF concretes may offset the improved physical properties of the material thus accounting for the similar corrosion rates to FA concrete which are higher compared to slag. The variations in corrosion rates between any of the cement extenders is however relatively small when compared to the substantial reduction in rate they offer over OPC concrete.

The impact of pore water chemistry on corrosion rates must also be considered. Salvarezza et al [24] demonstrated a relationship between SH⁻/OH⁻ ratio and nature of the passive layer, such that at high SH⁻/OH⁻ ratios a more porous sulphide-containing layer dominates the composition. Cao et al [25] however stated that the passivation of steel is more stable in slag solutions than OPC. The exact role of sulphides present in slag concretes is still not entirely understood and further investigations are necessary. The presence of sulphides in the slag may account for the high negative potentials just prior to cracking. It was observed that once the samples were cracked these values very quickly reduced to more passive conditions. The cracks could allow an easy pathway for the movement of oxygen thus overcoming the more reducing environment associated with the sulphides at the steel. These rapid reductions in potentials were only observed in the slag-bearing concretes. Further research is currently being conducted to more accurately quantify these phenomena.

5. CONCLUSION

The addition of cement extenders has a significant impact upon the corrosion rate of mild steel in cracked concrete, in the order of OPC>FA>SF>slag. The OPC concrete had corrosion rates at least 5 times higher than any of the other extended cement concretes at week 48. All cracked extended concretes therefore displayed superior performance compared even to un-cracked OPC concrete. The magnitude of resistivity measurements did not adequately explain the variations in corrosion rate with FA having by far the highest resistivity and yet the second highest corrosion rate (0.50 $\mu\text{A}/\text{cm}^2$). It appears that chloride conductivity measurements may offer some help in explaining the likely corrosion rates in the light of the cement chemistry of the pore solution. Of particular interest is the rapid decline in corrosion potential of slag concretes following initial cracking which has been attributed to oxidation of sulphides at the steel concrete interface.

MODELLING THE DURABILITY PROPERTIES OF CONCRETE COVER

E.J. Griesel and M.G. Alexander

Department of Civil Engineering, University of Cape Town,
P O Rondebosch, 7701, South Africa. E-mail: ejg@mweb.co.za

ABSTRACT

Durability properties of reinforced concrete are governed by the characteristics of the concrete cover layer, sometimes called the covercrete. Three durability indexes have been developed to quantify the properties of this layer, and include measures of oxygen permeability, chloride conductivity and water sorptivity of concrete specimens. However, the relationships between the various microstructural properties of the covercrete and these indexes are not yet fully understood.

A model is proposed which takes into account the dynamic interaction of cement hydration, microstructure formation and moisture transport. The hydration process is based on a multi-mineral hydration-heat model, and is dependent on sufficient pore moisture. Pore structure development is modelled as a function of the average degree of hydration, which is also used as a basis for moisture transport processes. The dynamic coupling of these models makes it possible to approximate microstructure development for arbitrary initial and boundary conditions.

This model is to be encapsulated into finite element computer code, which will be experimentally verified and used to investigate the influence of the various microstructural properties on the durability indexes.

Keywords: durability, durability indexes, hydration, microstructure, moisture transport, covercrete, drying, dynamic interaction.

1. INTRODUCTION

At present, there is sustained interest in problems of concrete durability, due to premature deterioration of many structures worldwide. Regarding reinforced concrete in particular, it is now realised that the primary determinant of durability is often the quality of the concrete cover layer, sometimes called the covercrete. The properties of this layer, and in particular its transport properties, govern the durability performance of the structure.

The need has arisen for practical design parameters that can be used for durability, in much the same way as the compressive strength test has been used up until now for quality control purposes. In response to this need, three durability index tests have been developed, which provide measures of oxygen permeability, water sorptivity and chloride conductivity of concrete specimens [1]. Thus far these tests have been researched extensively, and fledgling efforts are being made to incorporate them as design parameters into construction specifications. However, the influence of many important variables on the development of covercrete properties, including exposure conditions, is not yet fully understood. In the context of hot and dry climates such as exist in South Africa, it is particularly important to be able to characterise the influence of drying at early ages on the properties of the covercrete.

This paper considers the essential links between the microstructure of the cover layer and the engineering parameters describing its transport properties. It discusses the modelling of the microstructure and its development with time, using a multi-variable approach, based on fundamental relationships of cement chemistry and physics. The variables considered include cement (binder) type, mix proportions, exposure conditions, and time. Once this fundamental modelling is complete, the relationships between the microstructural properties and the engineering covercrete properties can be explored. This will aid in a better understanding of the important factors governing covercrete quality, and assist in arriving at improved specifications and construction practices so as to ensure long-term durability of concrete structures.

2. OVERVIEW OF DURABILITY INDEXES

The durability index tests provide measures for the chloride conductivity, water sorptivity and oxygen permeability of standard concrete samples [2]. These are cylindrical cores of 68 mm diameter and 25 mm thickness, which are oven dried at 50°C and 15% relative humidity prior to testing. Samples are dried until the change in mass is less than 0.1% over a 24 hour period.

2.1 Water Sorptivity Index Test

The samples are placed onto saturated layers of absorbent material in a plastic tray, and their mass gain monitored at prescribed time intervals. To ensure uniaxial absorption, the sides of the samples are sealed prior to testing. The water sorptivity index is calculated using the dimensions of the specimen, its porosity and the absorption rate, and is interpreted as the rate of penetration of the water front, in mm/ $\sqrt{\text{hr}}$.

2.2 Oxygen permeability index test

This test involves determining the rate at which oxygen permeates through a pre-conditioned concrete sample, using a falling head permeameter [2]. An initial oxygen pressure differential of approximately 100 kPa is applied across the sample. The pressure decay with time is measured, and the Darcy coefficient of permeability is determined. The oxygen permeability index is the negative logarithm of the coefficient of permeability.

2.3 Chloride conductivity index test

This test determines the conductivity of concrete samples, from their dimensions and electrical resistance. The samples are saturated with a 5 M NaCl solution prior to testing, by immersion under vacuum (-80 kPa) for 24 hours. The test procedure involves applying a potential of 10 V across the ends of the specimen and measuring the electrical current (DC) passing through, using a conduction cell filled with 5 M NaCl solution.

3. RELATIONSHIPS BETWEEN CAPILLARY POROSITY AND THE DURABILITY INDEXES

In a previous study a theory on concrete drying was formulated, which was based on the reduction of pore relative humidity (PRH) with time and depth from exposed surfaces, and its influence on cement hydration and subsequently the development of microstructural properties [3].

The influence of drying processes was obtained from an empirical expression formulated by Parrott [4], which described the changes in PRH with time and concrete depth, while cement hydration was roughly estimated from work done by Soroka [5]. The theory was based on the fact that hydration rates are very sensitive to changes in PRH, and that significant changes in porosity of the cement paste take place above 95% PRH [4]. Rough estimations were calculated on the variation of capillary and gel porosity with depth from exposed surfaces, and these were related to the results from the durability indexes.

Good correlations were found between the calculated capillary porosity and the durability indexes. These findings appeared promising enough to justify a more thorough investigation of early age development of the covercrete microstructure, and the influence thereof on the durability indexes.

4. MODELLING OF COVERCRETE PROPERTIES

Microstructure formation of concrete exposed to the environment is a complex problem, and incorporates a large number of variables. It is reasonable to assume that the potential service life of a reinforced concrete structure is largely established during the early stages of construction, typically within the first 10 days after casting [6]. At this stage the covercrete has a dynamic microstructure, which is highly sensitive to proper curing and initial exposure conditions [3].

The major processes involved in microstructure formation are cement hydration and moisture transport, which are dynamically linked, especially at early ages [3, 6]. Hydration is responsible for the development of the microstructure, and is very sensitive to the availability of sufficient pore moisture. The properties of the resulting microstructure, on the other hand, govern moisture transport processes, particularly drying, and thus the availability of pore water for further hydration. In order to model microstructure formation for arbitrary mix proportions and exposure conditions, it is necessary to take the dynamic interaction of these processes into consideration.

In a recent publication [6], analytical models were developed for microstructure formation, cement hydration and moisture transport, which are based on fundamental material models for the individual processes. Formulations are simplified as much as possible, for the purpose of integrating them into real-time computational schemes of heat and moisture transport of real-sized structures.

The hydration process is based on a multi-mineral hydration-heat model, and is dependent on sufficient pore moisture. Pore structure development is modelled as a function of the average degree of hydration, which is used again as basis for moisture transport processes. The dynamic coupling of these models makes it possible to approximate microstructure development for arbitrary initial and boundary conditions.

4.1 Cement Hydration

The hydration model in this study is based on the process of hydration-heat generation of cement in concrete, for any arbitrary temperature history, as quantified by Suzuki et al [7]. Hydration reactions in Portland cement are described for each clinker mineral, and interdependencies among them are evaluated separately. The total amount of hydration-heat is then obtained as the sum of the individual reactions, in proportion to the weight fractions of the clinker minerals. The cement minerals included are alite (C_3S), belite (C_2S), an aluminate phase (C_3A), a ferrite phase (C_4AF) and gypsum.

This approach makes it easy to include additional mineral components, e.g. in the case of blended cements. The extenders included in this model are fly ash (FA) and slag (SG), as single-phase hydration minerals. They are not classified like Portland cement, and it is assumed that the part reacting is only the glass phase at normal temperature, and is regarded as a homogeneous material [8]. The reactions of these extenders are described in terms of the amount of calcium hydroxide produced by hydration, and their delaying effect on hydration is taken into account. At this stage, the hydration of slag is assumed to be unaffected by the presence of gypsum.

The hydration process is described as the weighted sum of the individual mineral reactions, thus

$$\begin{aligned}
 H &= \sum p_i H_i \\
 &= p_{C_3A}(H_{C_3AET} + H_{C_3A}) + p_{C_4AF}(H_{C_4AFET} + H_{C_4AF}) + \\
 &\quad p_{C_3S}H_{C_3S} + p_{C_2S}H_{C_2S} + p_{SG}H_{SG} + p_{FA}H_{FA}
 \end{aligned} \tag{1}$$

where p_i = weight fraction of component i

H_i = heat-generation rate of component i

H_{C_3AET} and H_{C_4AFET} are both heat rates resulting from the formation of ettringite

It has been confirmed by Uchida and Sakakibara [9] and Suzuki et al [7] that Arrhenius's Law is applicable to cement hydration, and the heat generation rate (H_i) of each mineral component is described by the following equation:

$$\begin{aligned}
 H_i &= \gamma_i \beta_i \mu H_{i,T_0} e^{-\frac{E_i}{R}(\frac{1}{T} - \frac{1}{T_0})} \\
 Q_i &\equiv \int H_i dt
 \end{aligned} \tag{2}$$

where E_i = activation energy of component i

R = gas constant

Q_i = accumulated heat of component i

H_{i,T_0} = reference heat generation rate of component i at constant temperature T_0 , and is also a function of Q_i

γ_i = coefficient which expresses the delaying factor of organic admixtures

β_i = coefficient which expresses the reduction in heat generation due to the reduced availability of free water

μ = coefficient which expresses changes in heat generation with the concentration of calcium hydroxide

$-E_i/R$ = definition of the thermal activity of component i

The reference heat generation rate (H_{i,T_0}) is set as a material function for each reaction (Figure 1), with T_0 taken as 293 K, and is assumed to be under conditions where sufficient water (and calcium hydroxide for slag and fly ash) is available.

The hydration process is modelled as a step-wise function of time and temperature, using the above information. A time interval is chosen, and for each reaction (and time-step) a value for its accumulated heat is calculated from the relationship

$$Q_i = H_{i,T_0} t_{tot} \tag{3}$$

where t_{tot} = total time elapsed since the start of hydration (hours)

Figure 1. Reference heat generation rates of cement minerals

The value used for H_{i,T_0} in this calculation is obtained from the appropriate part of the curve in Figure 1. The degree of hydration for each reaction is calculated from

$$\alpha = \frac{Q_i}{Q_{i,\infty}} \quad (4)$$

where α = degree of hydration

$Q_{i,\infty}$ = maximum amount of accumulated heat for reaction i (Figure 1)

Using the calculated value for Q_i , the thermal activities of the individual reactions (E_i/R) are calculated from the relationships illustrated in Figure 2. Finally, coefficients γ_i , β_i and μ are calculated, and the final heat generation is obtained from Equation 1.

Figure 2. Thermal activities of component reactions

The system temperature used in Equation 2 (T) is calculated at the end of each time step, using the total amount of heat generated (Equation 1) and a heat conduction analysis to take environmental temperature into account.

4.2 Microstructure Formation

The degree of hydration and amount of chemically combined water, calculated from the hydration model, are used to calculate the development of the cement paste microstructure. This part of the model is based on the concept of cement particle growth, as computed from the state of maturity of the cement paste matrix, as illustrated in Figure 3 [6].

Figure 3. Cement particle growth

Important assumptions made here are that cement particles are spherical, uniform in size and uniformly distributed in the initial state of the mix. These may seem like gross approximations,

taking into account the fact that the particle size distribution (PSD) of commercially available cements varies over at least two orders of magnitude.

However, the dispersion characteristics of the cement paste are more important than the particle distribution itself [6]. For water:powder ratios in the normal range, it has been found that the distance between powder particles is of the same order of magnitude as the average particle size. In the case of flocculation of powder particles, the average size of flocculated clusters can be used as the representative size of particles. While a model that takes the entire PSD into account would be more accurate and theoretically preferable, the above assumptions make it possible to deal with any initial configuration of the dispersed system. Also, the evaluation of the microstructural properties of real structures can be evaluated without using extensive computational resources.

The porosity of the cement paste is subdivided into three categories, namely interlayer porosity, gel porosity and capillary porosity. These can be calculated from the degree of hydration, the volume of gel products, characteristic gel porosity and assumptions regarding interlayer thickness, interlayer specific surface area and the density of chemically bound water. The porosity of the inner products (Figure 3) is assumed to be constant, and the capillary porosity in the outer product is assumed to vary linearly (with the option to extend this to a polynomial function) from the particle boundary to the outer region of the expanding clusters.

This information is used to calculate the total amount of hydration products for any given degree of hydration, which is further used to obtain the volume of capillary and gel pores present in the cement paste. The specific surface areas (or surface area per unit volume of cement paste) of capillary and gel porosities are obtained next, in order to be able to formulate an expression for the pore size distribution (or porosity as a function of pore radius) of the cement paste.

It is assumed that moisture transport takes place only in the gel and capillary pores, because interlayer moisture is physically bound and unable to move under normal pressure gradients [6]. Therefore, the porosity distribution function takes the form

$$\phi(r) = \phi_{lr} + \phi_{gl}(1 - e^{-B_{gl}r}) + \phi_{cp}(1 - e^{-B_{cp}r}) \quad (5)$$

where $\phi(r)$ = porosity distribution

r = pore radius (m)

ϕ_{lr} = interlayer porosity

ϕ_{gl} = gel porosity

ϕ_{cp} = capillary porosity

B_{gl} = porosity parameter for gel pores

B_{cp} = porosity parameter for capillaries

The parameters B_{gl} and B_{cp} are obtained from an explicit relationship, which relates B_i as a function of S_i/ϕ_i [6].

4.3 Moisture Transport

Due to the dynamic nature of the developing cement paste microstructure, the hydration and microstructure formation described in the previous sections are included in the formulation of an expression for moisture transport. This implies that the rate of change of pore water content is not only a function of pore pressure gradients, but also of chemical fixation during hydration, as well as the rates of change of porosity, density of pore water and degree of saturation [6].

The authors of [6] used the conventional energy conservation principles to obtain an expression that describes concrete water content in terms of pressure gradients and diffusivity and permeability coefficients. This expression was further extended into a pore pressure based formulation (Equation 6), with an additional term to account for self-desiccation (Q_{hyd}) and porosity changes (Q_{pd}). This process is illustrated in Figure 4 [6].

$$\alpha_P \frac{\partial P}{\partial t} - \text{div}(D_P \nabla P) + Q_P = 0 \quad (6)$$

where P = pore pressure (Pa)

t = time (s)

α_P = specific fluid mass capacity parameter, and approximately equal to the amount of water the concrete can absorb (or release) for a unit change in the liquid pore pressure potential

D_P = macroscopic moisture (liquid and vapour) conductivity (m^2/s)

Q_P = rate of moisture loss due to hydration and microstructure formation

Figure 4. Schematic representation of the calculation of moisture conditions in concrete

In order to use the above expression for computational use, it was necessary to quantify a number of phenomena observed for moisture conditions in cementitious materials. These include the hysteresis effect observed during wetting and drying cycles, moisture retention under normal environmental conditions and simplified expressions for moisture conductivity coefficients.

4.4 Concrete as a composite material

The hardened cement paste matrix in concrete is but one of the three major components considered during moisture transport. The zone connecting the cement paste and the aggregates, called the interfacial transition zone (ITZ), is another important contributing component, while the role of the aggregates themselves become significant when considering high porosity aggregates (typically used for light-weight concretes or to compensate for self-desiccation at low water:binder ratios).

For any given aggregate grading, it has been found that there exists a crucial aggregate content, usually above 45%, at which percolation of interfacial transition zones (ITZ) occurs [6]. This means that neighbouring ITZs of different aggregate particles come into contact with each other, and form

at least one continuous path to exposed surfaces. These paths are generally more porous than the neighbouring cement paste matrix, due to insufficient packing of powder particles next to relatively large aggregate particles [6]. For normal mix proportions, the characteristics of the ITZ are crucial in defining the moisture transport behaviour in concrete.

In order to quantify the moisture transport in concrete, a multi-component model is considered. The assumption is made that thermodynamic equilibrium holds for moisture transport in each of the separate components of interest. These are evaluated individually and summed to obtain the net effect. Finally, expressions are evaluated and included in the result, to compensate for the interactions (or local moisture transfer) between individual components.

5. COMPUTER MODEL AND EXPERIMENTAL VERIFICATION

The theory as discussed above is to be encapsulated into a finite element computer model, in order to generate large quantities of microstructural data and investigate the influence of various covercrete properties on the durability indexes.

Firstly, however, the output generated by the model must be verified experimentally, and conditions that produce inaccurate results, identified. The purpose of the model is not to model extreme mix designs and environmental conditions, but rather to get a feel for the influence of 'normal' designs, construction practice and environments on the microstructural properties of the covercrete.

The calculated properties that will be verified experimentally include degree of hydration, porosity distributions and moisture distributions of fully cured samples, as well as samples exposed to controlled drying conditions. The latter might call for some sort of 'layered' experimental approach, where the covercrete is divided into several layers of uniform thickness, and evaluated separately. The experimental technique to be used has not yet been finalised.

6. CONCLUSIONS

Three durability indexes have been developed, providing measures of oxygen permeability, chloride conductivity and water sorptivity of concrete specimens. However, the relationships between the various microstructural properties of the covercrete and these indexes are not fully understood.

A model is proposed which takes the dynamic interaction of cement hydration, microstructure formation and moisture transport into consideration. Cement hydration is based on a multi-mineral hydration-heat model. Hydration reactions are described for each clinker mineral, and interdependencies among them are evaluated separately. The total amount of hydration-heat is then obtained as the sum of the individual reactions, in proportion to the weight fractions of the clinker minerals. The cement minerals included are alite, belite, an aluminate phase, a ferrite phase and gypsum. Fly ash and slag are included in the model as single-phase hydration minerals.

Microstructure formation is based on the concept of cement particle growth, as computed from the state of maturity of the cement paste matrix. The cement particles are assumed to be uniformly sized and distributed in the initial state of the mix. The porosity of the hydrating cement paste is sub-divided into interlayer-, gel- and capillary porosity. The amount of hydration products is calculated, and used to obtain the volume of capillary and gel pores present in the cement paste. This information is used to calculate the specific surface areas of the pores, and finally the porosity distribution of the cement paste.

A multiphase formulation is used to describe the combined transport processes of both liquid and vapour, and thus the overall moisture transport process is reduced to Fick's second law. This called for simplified expressions for moisture conductivity coefficients, and phenomena such as the hysteresis effect of moisture isotherms and moisture retention under normal environmental conditions were quantified [5].

In order to quantify the moisture transport in concrete, a multi-component model is considered. The assumption is made that thermodynamic equilibrium holds for moisture transport in each of the separate components of interest, which are the hardened cement paste, the aggregates and the ITZ. These are evaluated individually and summed to obtain the net effect. Finally, expressions are evaluated and included in the result, to compensate for the interactions (or local moisture transfer) between individual components.

A computer model is to be developed, experimentally verified and used to generate large quantities of data, in order to identify and quantify the microstructural properties that influence the durability indexes. The purpose of the model is to get a feel for the influence of general designs, construction practice and environments on the microstructural properties of the covercrete.

ABSTRACT

Concrete for use in sewers that are prone to the biological production of sulphuric acid needs to be manufactured using materials capable of resisting acid attack. The acid readily attacks certain constituents in the concrete, such as cements and calcareous materials, exposing the steel reinforcing, which can lead to collapse of the pipe.

Altering the nature of the binder can significantly improve the acid resistance of the concrete. The physical and chemical nature of the binder can be modified by incorporating mineral extenders into the mixture or by replacing the normal Portland Cement with Calcium Aluminate Cement.

Generally, acid-soluble calcareous aggregates are used in concrete mixtures to prolong the life of pipes exposed to acidic environments. The dissolution of the calcareous aggregate neutralises a mild sulphuric acid environment ($\text{pH} = 3,00$) and ensures that the acid attack is spread over the entire surface of the concrete, and is not only concentrated on the binder portion. It is speculated that the neutralisation of the acid environment not only slows down the rate of the sulphuric acid attack but also reduces the activity of the acid-loving thiobacillus bacteria, thus decreasing the rate of sulphuric acid production.

However, in aggressive sulphuric acid environments ($\text{pH} = 1,00$) the calcareous layer is dissolved rapidly. Under these conditions, Calcium Aluminate Cement is more effective in improving the acid resistance of the concrete. The chemistry of the Calcium Aluminate Cement is such that it is claimed to have a higher neutralisation capacity than Portland Cement, and the Calcium Aluminate Cement appears to be toxic to the thiobacillus bacteria. The acid resistance of the mixture is further improved by using a synthetic aggregate such as AlagTM in place of the calcareous aggregate.

1. INTRODUCTION

Concrete, the material conventionally used for manufacture of sewer pipes, performs poorly if subjected to a sulphuric acid environment such as that found in certain sewer systems. In areas having a flat topography and warm climate, sewer systems often cannot be designed to eliminate the factors responsible for the biological generation of sulphuric acid. The acid produced by the thiobacillus bacteria existing on the concrete above the sewage level attacks the alkaline constituents of the concrete exposing the steel reinforcing to the corrosive environment.

In such cases, the concrete must be modified to resist the sulphuric acid attack. A common practice is to use calcareous aggregates in the concrete mixture [1]. The acid-soluble calcareous aggregates ensure that the sulphuric acid generated by the bacteria is effectively neutralised and that the acid attack is spread over the entire surface of the concrete, and not only concentrated on the cement binder. It is speculated that the neutralisation of the sulphuric acid by the calcareous aggregate affects the metabolism and growth of the thiobacillus bacteria [2]. The bacteria are known to thrive best in an acidic environment, and as a result, the continuous neutralisation of the sulphuric acid stifles the growth of the bacteria.

Calcareous aggregate mixtures have proved to substantially increase the performance of concrete sewer pipes in mild sulphuric acid environments [2]. In aggressive acid environments, a sacrificial lining is sometimes cast on the inside of the concrete pipe to improve performance. In extreme circumstances, the sacrificial lining is insufficient, and alternative methods are sought to obtain a concrete that can resist the biologically-induced sulphuric acid attack in sewers.

The performance of concrete in acidic mediums is significantly improved by modifying the cement binder of the mixture. The addition of condensed silica fume improves the integrity of the Portland Cement (PC) binder in an inorganic acid medium, and in so doing, improves the performance of the concrete [3]. The silica fume reduces the amount of calcium hydroxide precipitated during the hydration of the PC, and leads to the refinement of pores in the hydrated cement binder. Calcium hydroxide is leached out of the cement binder in acidic mediums initiating the degradation of the concrete.

An alternative approach is to use Calcium Aluminate Cement (CAC) as a replacement for the PC to improve performance in a strong acidic environment. The hydrated CAC produces no calcium hydroxide [4,5], in contrast with PC. In addition, the CAC is stated to have a higher neutralisation capacity than PC [6]. The mineral phases formed during the hydration of the CAC are theoretically more effective in neutralising acidic mediums than the mineral phases formed during the hydration of PC.

CAC concrete is expected to perform better in biologically induced sulphuric acid environments. The higher neutralisation capacity of the CAC is reported to substantially reduce the aggressiveness of the sulphuric acid environment [6], thus reducing the metabolic rate and growth of the thiobacillus bacteria. It is speculated that the CAC is toxic towards the thiobacillus bacteria, which is of great significance in explaining the good performance of CAC in biologically-induced sulphuric acid environments.

The acid-resisting performance of CAC and PC mixtures is currently being investigated at the University of Cape Town (UCT). Results to date [3,7] have indicated that concrete containing CAC and a calcareous aggregate performs comparably to a PC/calcareous aggregate concrete, when immersed in hydrochloric acid solution at a pH of 1,00. On the other hand, concrete with CAC and a synthetic AlagTM aggregate better resists the attack of the hydrochloric acid solution [7]. These tests relate purely to attack of the concrete by strong mineral acids.

Investigations of bacterial attack on concrete are also being undertaken at UCT. Preliminary results indicate that concrete containing CAC shows no sign of attack compared to concrete with PC, over a period of several months in a bacterial chamber. Investigations in a sewer system having an extremely corrosive sulphuric acid environment show that concrete containing CAC and AlagTM is not attacked over a period of 16 months. Results of the on-going work will be reported subsequently.

2. CEMENT CHEMISTRY

The chemistry of cement plays an important role in determining the performance of concrete in chemical environments. The hydration products of cement are all compounds of relatively low solubility but are not stable when in contact with acidic mediums.

PC is composed mainly of lime (C) and silica (S) as well as a small portion of alumina (A) and iron oxide (F); refer to Table 1 [4]. The oxides interact with each other to form complex binary and ternary compounds, tricalcium silicate (C_3S), dicalcium silicate (C_2S), tricalcium aluminate (C_3A), and tetracalcium aluminoferrite (C_4AF). The major constituent in PC is calcium silicate. The reaction of PC with water mainly forms a hydrated calcium silicate gel ($C-S-H$) and calcium hydroxide ($CaO.H_2O$ or CH) is precipitated out of the pore solution due to its low solubility.

Table 1. Typical oxide composition of cements

<i>Compound</i>	<i>Portland (%)</i>	<i>Calcium Aluminate (%)</i>
CaO (<i>lime</i>)	64,1	37,7
Al ₂ O ₃ (<i>alumina</i>)	5,5	38,5
Fe ₂ O ₃ (<i>ferrite</i>)	3,0	12,7
FeO (<i>ferrous</i>)	-	3,9
SiO ₂ (<i>silica</i>)	22,0	5,3
MgO (<i>magnesia</i>)	1,4	0,1
SO ₃	1,75	0,1

CAC is composed essentially of equal portions of alumina and lime and a large portion of iron oxide; refer to Table 1 [4]. The binary and ternary compounds expected in CAC are $C_{12}A_7$, CA and C_2S . The major constituent in CAC is mono-calcium aluminate (CA). The reaction of CAC with water at normal temperatures forms alumina gel (AH_3), and the hydrates CAH_{10} and C_2AH_8 . The monocalcium aluminate hydrate and dicalcium aluminate hydrate are metastable hexagonal products that, on ageing of the cement, change into the more stable cubic tricalcium aluminate hydrate compound and alumina gel. The conversion leads to a volume change, and the expansive cubical form creates a marked loss in strength and increase in porosity of the converted cement.

3. INFLUENCE OF CEMENT CHEMISTRY ON INORGANIC ACID RESISTANCE

The hydration products of the cements indicate that CAC has the potential to be more resistant to acidic environments than PC. CAC contains mainly alumina gel, which only becomes unstable at a pH below 4. On the other hand, no hydrated compound of PC is stable at a pH below 11. It is stated that in practice, CAC materials have proved to be more resistant to soft water environments and weak acidic environments (pH > 4) than PC materials [4]. The poorer resistance of the PC is ascribed to the instability of the calcium hydroxide, which readily leaches out of the cement in soft waters and weak acidic environments. No conclusive evidence exists as to the cause of the good performance of CAC in weak acid environments but it is known that the increased porosity due to the conversion reaction that can occur in CAC may significantly reduce the performance of the CAC in aggressive environments.

In sewers, the sulphuric acid environment is either mild (pH of 2 to 4) or strong (pH < 2), and there is a lack of clarity on whether CAC materials are more resistant to such environments than PC materials. Test methods developed to study the resistance of concrete in mild and strong mineral acid solutions produce conflicting results as to whether a CAC material performs better than a PC material. The test methods are the subject of controversy since it is difficult to interpret the performance of a concrete in a biologically-induced sulphuric acid environment from these tests.

Mineral acid tests [6] indicate that CAC mortars perform better than PC mortars in mild sulphuric acid solutions having an initial pH of both 2 and 3. The results indicate that the CAC mortars consume more hydrogen ions than the PC mortars, thus reducing the corrosiveness of the mild sulphuric acid solutions at a faster rate with a correspondingly lower mass loss than the PC mortar. It is stated that CAC has the ability to neutralise an acid environment more effectively than PC. The calculated neutralisation capacity indicates that CAC neutralises approximately double the amount of hydrogen ions compared with equivalent amounts of PC. In addition, it is suggested that the alumina gel, which forms due to the reaction of the hydrogen ions with the CA hydrate, hinders the sulphuric acid attack at these pH levels.

Similar tests in a strong sulphuric acid solution having a pH of 1 showed that the CAC materials were more aggressively attacked [6]. The CAC mortars showed a higher mass loss and hydrogen ion consumption than the PC materials. In the same reference it is suggested that the abnormality observed at a pH of 1 is due to the slightly soluble by-product, calcium sulphate, which precipitates onto the PC mortar more readily in a strong sulphuric acid solution, thus stifling the acid attack. No calcium sulphate is precipitated onto the CAC mortar due to the absence of calcium hydroxide. In addition, the alumina gel formed during the acid attack is readily decomposed at a pH of 1.

A reliable test method, the hydrochloric acid resistance test [8] developed at the University of Cape Town, is used extensively to determine the performance of different materials in a hydrochloric acid environment at a pH of 1. The hydrochloric acid medium eliminates the effects of the calcium sulphate precipitating onto the samples tested and determines the ability of the materials to resist a corrosive inorganic acid solution. The test is more representative of actual acid attack on concrete sewer pipes in practice, since it better simulates the real mixtures and mimics both physical and chemical aspects of the problem. The concrete samples tested are prepared in a manner similar to that of concrete pipes. The heavy mechanical compaction produces a dense matrix largely impermeable to gases and fluids.

The hydrochloric acid tests indicate that concrete mixtures of CAC and Dolomite aggregates [3,7] are somewhat less resistant than similar PC mixtures in the mineral acid solution at a pH of 1. The percentage mass loss is highest for mixtures CAC and Dolomite aggregate (Figure 1), the values recorded for the 18 % cement and 23 % cement mixtures after 72 hours being 38,2 % and 37,8 % respectively. The PC mixtures with Dolomite aggregate are also readily attacked by the hydrochloric acid solution. The percentage mass loss of the 23 % PC mixture (32,4 %) is slightly higher than that for the 18 % PC mixture (30,0 %), presumably due to its higher calcium hydroxide content resulting in a greater mass loss. Noticeably, the mixture containing 23 % CAC and the synthetic AlagTM aggregate showed the greatest resistance to hydrochloric acid attack, the percentage mass loss after 72 hours being only 11,8 %, which is substantially lower than the other mixtures.

Figure 1. Percentage mass loss with time of concrete samples containing Dolomite aggregates at a pH of 1

The hydrogen ion consumption (Figure 2) of the mixtures follows similar trends to the percentage mass loss results. The exception is that the hydrogen ion consumption of the 23 % PC/Dolomite aggregate mixture ($3,12 \times 10^{-2} \text{ g/cm}^2$) was similar to the hydrogen ion consumption of the mixtures containing 18 % and 23 % CAC and Dolomite aggregate ($3,11 \times 10^{-2} \text{ g/cm}^2$ and $3,04 \times 10^{-2} \text{ g/cm}^2$ respectively). The increase in calcium hydroxide due to the higher PC content is probably responsible for the increased hydrogen ion consumption compared to the 18 % PC mixture ($2,62 \times 10^{-2} \text{ g/cm}^2$). The 23 % CAC/synthetic AlagTM aggregate mixture had considerably lower hydrogen ion consumption ($0,6 \times 10^{-2} \text{ g/cm}^2$) than the other mixtures.

The significant difference between the test procedures, other than the mineral acid medium, is in the samples tested. In the hydrochloric acid resistance test, the concrete samples consist of a large portion of Dolomite aggregate (77 %) and a smaller portion of cement (23 %). The mortar samples in the strong sulphuric acid solution test consist of a siliceous aggregate (67 %) and a larger portion of cement (33 %). The large portion of Dolomite stone in the concrete, which readily dissolves in the hydrochloric acid solution, can mask the effect that the neutralisation capacity of the CAC should have on the hydrogen ion consumption.

On the other hand, the hydrochloric acid resistance test shows that a CAC/AlagTM concrete is significantly more resistant to a strong acid environment than the CAC/Dolomite and OPC/Dolomite concrete. The CAC/AlagTM concrete should show the highest neutralisation capacity [7] but it has the lowest hydrogen ion consumption and corresponding mass loss. At this stage, conclusive reasons for the excellent acid resistance of the CAC/AlagTM mixture are not immediately evident. Tests to determine the acid resistance in granular form of the AlagTM aggregate may show a superior acid resistance of these aggregates. A further reason may be the creation of a good interfacial bond between the aggregate and the cement binder. The material is dense with a low porosity indicating that very durable concrete can be achieved with these materials.

Figure 2. H^+ ion consumption with time for concrete samples containing Dolomite aggregates, at a pH of 1

4. DISCUSSION

It is of concern that the results obtained from hydrochloric acid resistance testing do not entirely agree with the statements discussed in the literature. The hydrogen ion consumption does not show that CAC has a neutralisation capacity double that of PC, but that the values are similar. No calcium sulphate is precipitated on the PC materials in the hydrochloric acid solution as with the

strong sulphuric acid solution. The absence of the calcium sulphate allows a direct comparison to be made between the hydrogen ion consumptions of the two cement materials.

The calculated neutralisation capacity is based solely on the alumina and the lime composition of the cements [6]. In one kilogram of PC there is approximately 0,3 moles of alumina and 12,1 moles of lime. In comparison, one kilogram of CAC contains approximately 5,1 moles of alumina and 6,8 moles of lime. The higher alumina content in CAC is accountable for the more efficient hydrogen ion consumption. A mole of alumina reacts with 6 moles of hydrogen ions whereas a mole of lime only reacts with 2 moles, thus one kg of CAC neutralises 44 moles of hydrogen ions compared to 26 moles with one kg of PC.

Strictly, the theoretical neutralisation capacity calculation is incorrect since it is only based on the oxide composition of the cement. The properties of cement do not simply depend on the proportions of lime, magnesia, silica, alumina and other compounds contained in the ground clinker, but depend also on the stability of the hydration products formed from ternary and binary oxide systems of the cements. The neutralisation capacity and its effect on acid resistance of CAC at a higher pH are currently being investigated at UCT using the hydrochloric acid resistance test method. Work completed indicates that sewer pipe materials used in South Africa are resistant to a mineral acid solution at a pH of 2.

Further, much of the work reported in the literature has been done on materials that may not be representative of the physical and chemical properties of the mixtures as used in industry. The degree of mineral acid attack depends on the chemical and physical properties of the material, with the physical properties often being of equal importance to the chemical properties. If the material is not produced using materials and mixture proportions similar to those used in industry, or in a manner similar to that of industry, the acid resistance will not be representative of that occurring in reality. The sample preparation method is particularly relevant in the study of sewer pipe concrete made using the roller suspension method. The concrete pipes are heavily compacted often detrimentally affecting the integrity of calcareous aggregates in an acidic environment. The heavy mechanical compaction tends to fracture calcareous aggregates of low physical strength allowing rapid dissolution in acidic environments and deterioration of the concrete matrix.

5. VIRGINIA SEWER EXPERIMENTS

Investigations at UCT into the performance of concrete in biologically induced sulphuric acid environments are a major part of the research into the acid resistance of concrete for use in sewer pipes. The conditions in South Africa are such that biologically induced sulphuric acid environments having a pH of 1 are fairly common. An experimental sewer at Virginia in the Free State with these conditions has been used for various sewer experiments for over a decade, and is also being used in the current work. The hydrochloric acid resistance test simulates such environments, and together with the on-site testing at Virginia, reliable results are obtained within a short period. The Virginia experimental sewer site is an ideal location for accelerated biological acid testing. Preliminary investigations during summer revealed that within a period of 5 months, samples showed signs of thiobacillus bacterial growth, and pHs of less than one were recorded in the sulphuric acid environments present on some of the samples. The samples are placed directly above the maximum daily sewage level in a sewer environment having a hydrogen sulphide content of between 70 ppm in the cold winter months and 150 ppm in the hot summer months. The samples are kept continuously moist by the evaporation and condensation of the sewage. Literature [6] indicates that accelerated biological tests conducted in a laboratory can produce results within one year. The hydrogen sulphide of the laboratory environment reported in reference [6] is only 10 ppm, which occurs in many sewer systems throughout South Africa.

Information obtained from field studies on the Virginia test sewer in South Africa indicates that concrete materials containing 23 % cement similar to those tested in the hydrochloric acid resistance test show little signs of sulphuric acid attack, refer to Table 2. The materials are typical of those used for the lining of concrete sewer pipes in the Gauteng region. No mass loss is recorded for the CAC/Alag™ and CAC/Dolomite samples installed in the highly corrosive sulphuric acid environment over a period of 16 months. The percentage mass loss of the PC/Dolomite sample is small (2,9 %). The pH on the surface of the three samples is approximately 6,5 indicating that the sulphuric acid microenvironment is weak. Samples containing 18 % PC and 82 % Dolomite stone showed noticeable signs of sulphuric acid attack. The percentage mass loss recorded for these samples is approximately 5,0 %. The pH recorded on the surface of the samples is between 4,0 and 4,5 indicating that the sulphuric acid environment is mild and more corrosive. The most attacked samples installed in the sewer are samples containing 18 % and 23 % PC and siliceous aggregate. The pH on these samples is between 1,0 and 1,2 indicating that the sulphuric acid environment is strong and extremely corrosive towards concrete. The mass loss recorded for these samples is 5,3 % and 6,6 % respectively.

Observations at Virginia indicate that CAC and concrete containing Dolomite appear to retard the biological sulphuric acid attack. The CAC mixtures are expected to give good performance as the materials have the ability to effectively neutralise the biologically induced sulphuric acid environment. It is speculated that the CAC materials are toxic towards the thiobacillus bacteria curbing their growth. The good performance of the 23 % PC/Dolomite concrete is not fully understood, except that the material is expected to effectively neutralise the sulphuric acid environment. The poor performance of the PC/ siliceous concrete is related to the inability of the siliceous aggregate to dissolve in the biologically-induced sulphuric acid and as expected all the acid attack is concentrated on the small portion of the PC binder. Although the percentage mass loss is low, poor performance is noticeable in the protrusion of the siliceous aggregate from the attack surface compared to the smooth attacked surface of the Dolomite samples.

Table 2. Percentage mass loss of concrete samples in the Virginia Sewer Experimental Section, over a period of 16 months

<i>Samples</i>	<i>Mass Loss (%)</i>
23 % CAC/Alag™	0,0
23 % CAC/Gauteng Dolomite	0,8
23 % PC/Gauteng Dolomite	2,9
23 % PC/siliceous	6,6
18 % PC/Western Cape Dolomite	5,0
18 % PC/siliceous	5,3
18 % PC/Gauteng Dolomite	7,1

6. CONCLUSION

The performance of concrete in sulphuric acid environments such as those encountered in sewers can only be fully determined from tests done to ascertain the mineral acid resistance, and resistance to biologically-induced sulphuric acid environments. The tests must be conducted on materials similar to those used in industry and in conditions likely to be met in areas prone to the biological generation of sulphuric acid. Indications from work done thus far are that CAC materials perform better in biologically-generated sulphuric acid environments.

A MULTI-CHANNEL ISOTHERMAL HEAT CONDUCTION CALORIMETER FOR CEMENT HYDRATION STUDIES

L. Wadsö

Building Materials, Lund University, Box 118, 221 00 Lund, Sweden.

E-mail: lars.wadso@byggtek.lth.se

ABSTRACT

When cement hydrates heat is produced and different methods to measure this heat are interesting ways of studying the cement hydration process. There are essentially two types of calorimeters (heat measuring devices) used today: (semi)adiabatic calorimeters in which the temperature increase in an insulated sample is measured, and isothermal (conduction) and calorimeters in which the heat flow from a sample is measured. Although isothermal calorimeters have many advantages over the other type (more well defined conditions, less corrections needed etc.) such instruments have not been as widely used, at least partly because some such calorimeters have had large baseline drifts and other problems.

The paper presents the design of a new multi channel heat conduction calorimeter for cement hydration studies under essentially isothermal conditions. Each calorimeter within the multi channel instrument is both sensitive (precision $\pm 10 \mu\text{W}$) and stable ($< 20 \mu\text{W}$ over 24 h) so that it is possible to perform both long-term measurements (1 month) and use small samples ($< 1 \text{ g}$ of cement paste). The instrument is placed in an air thermostat that can operate between 5 and 60°C .

1. INTRODUCTION

The instrument described in this paper is a heat conduction calorimeter, i.e. the heat produced in the sample is conducted away from the sample into a heat sink. In this way the sample temperature does not increase and the calorimeter type is therefore also called an isothermal calorimeter. The heat production rate (thermal power; units: watts) is measured with a heat-flow sensor positioned between the sample and a heat-sink. It is actually not the heat flow that is measured, but the temperature difference over the heat flow sensor, but this is proportional to the heat-flow, so the result is an output signal that is proportional to the heat-flow from the sample. This gives much higher stability than if separate temperatures are measured in the sample and the heat sink.

All processes (physical, chemical, biological) produce heat. Calorimetry is therefore a very general method to study different kinds of processes. Isothermal calorimeters are therefore used in many different fields of science and technology, e.g.:

- To detect compatibility problems between products and packages.
- To monitor microbial growth in foodstuffs.
- To measure vapor sorption properties of materials.
- To study drug interactions in the pharmaceutical industry.
- To determine shelf life of active compounds.

In the field of cement and concrete isothermal calorimetry can also have many uses [1-4]:

- Measure total heat of hydration.
- Assess admixture retardation.
- Quality control of cement production.
- Determine cement-admixture incompatibility.

The instrument described in this paper has been commercialized by Thermometric AB (Järfälla, Sweden; www.thermometric.com) under the name TAM Air [4].

2. DESCRIPTION OF THE INSTRUMENT

As it is often of interest to run many samples simultaneously, e.g. to measure the retardation as a function of admixture concentration, the present instrument has eight calorimeters in one thermostat. Each of the calorimeters is easily assessable from the top of the instrument. Figure 1 shows a cut-away drawing of the instrument.

The heat flow sensors used are solid-state Peltier thermocouple plates that have a comparatively high voltage output for the very low temperature differences of the calorimeters. The sample and reference ampoules are placed in ampoule holders that are fastened to the topsides of the heat flow sensors. The calorimeters have two sensitivity ranges: ± 60 mW and ± 600 mW. The 600 mW range is advantageous to use for measurements of early hydration as one does not want the output signal to go out of range when a sample is charged into the calorimeter. The higher sensitivity is useful for long-term measurements of cement hydration.

The instrument is modular. Each calorimeter is manufactured as a unit of its own. In the instrument described here eight modules are used together, but it is possible to only use from just one module as a single-channel calorimeter up to as many modules as one can practically handle. A major advantage with modular design is that if a calorimeter needs to be serviced, one may remove only that module or directly exchange it for a new module.

Each calorimeter module has its own reference that is differentially connected to the sample, i.e. the output signal is the difference between the signal from the sample and the signal from the reference. The primary importance of a reference is to decrease the noise level. When a thermal disturbance enters the calorimeter it will reach both the sample heat-flow sensor and the reference heat-flow sensor at the same time, and if the thermal properties (mainly heat capacity) of the sample and the reference are similar, these disturbance signals will cancel out. The reference also makes the calorimeter react faster and in a more predictable way to rapid changes in heat production rate.

All heat conduction calorimeters have heat sinks into which the produced heat is deposited (before being transferred out into the thermostat). It is normally an advantage to have a large heat-sink as this will decrease the temperature variations and the noise. The drawback of a large heat sink is that the calorimeter will become larger, heavier and take longer time to thermostat to a new temperature. In the present design the calorimeters have a partially shared heat sink. The heat produced in a sample will first be conducted out into a small primary heat sink in that calorimeter and then further into to a larger secondary heat sink that is common for all the calorimeters in the instrument. By optimizing the sizes of the primary and secondary heat sinks one will get a rather small multi-channel instrument with low noise. This is further discussed in the next section.

Figure 1. A cut-away drawing of the instrument.

The eight calorimeters are shown in blue and white with two calorimeters cut open to show the ampoule holders (one of which has a sample in it). The grey box to the left of the calorimeters is the data logger. Below the calorimeter is the air thermostat equipment.

An air thermostat that can keep the calorimeter at temperatures between 5 and 60°C surrounds the multi-channel calorimeter. The heating and cooling is made by a Peltier heater/cooler, i.e. the same type of solid-state device that is used as a heat flow sensor in the calorimeters. The temperature stability of the air thermostat is ± 0.02 K.

3. PROPERTIES OF THE INSTRUMENT

3.1 Temperature increase in sample

Heat conduction calorimeters are essentially isothermal instruments and it is important that the heat produced in the sample is conducted away so that the temperature increases in the sample are low. Using a procedure described in reference[5] the temperature increase in the center of a cement paste sample has been calculated. At maximal thermal power (at the main peak) the center temperature will be elevated less than 0.3 K for a 5 g sample of cement paste. Smaller samples will have less over-temperature.

3.2 Time constant

The time constant of an ampoule with 5 g cement paste is in the order of 200 s, i.e. it takes 200 seconds for the output signal to drop from a value to 38% of that value (when there is no heat produced in the sample). The time constant (measured or calculated) may be used to correct the output signal for the thermal inertia of the calorimeter using the Tian equation[6]:

$$P = \varepsilon \left(U + \tau \frac{dU}{dt} \right) \quad (1)$$

Here, P (W) is the thermal power produced in the sample, U (V) is the voltage output of the heat-flow sensors, ε (W/V) is the calibration coefficient, and τ (s) is the time constant.

3.3 Cross-talk

As eight calorimeters are placed in contact with each other there is a risk that heat produced in one sample will influence the output from the other samples (cross-talk). The cross-talk may be minimized by a careful selection of references. A reference with closely matched heat capacity will substantially decrease the cross-talk. Figure 2 shows the result from a test of cross-talk. Computer simulations of the thermal behavior of the instrument have given similar results. If the references are well matched cross-talk is generally not a problem. However, charging of a room temperature sample into a calorimeter working at a very different temperature will give larger disturbances than shown in Fig. 2. Careful matching of heat capacities and pre-thermostating of samples and will decrease the cross-talk.

Figure 2. Result from a test of cross-talk in an instrument in which all calorimeters have about 14% difference in heat capacity between the sample and the reference sides.

In Figure 3, the red curve shows the output from a calorimeter that was charged with a sample with an excess heat of 13 J at about 1.7 h. The output from the calorimeter closest to that calorimeter (black line) is slightly disturbed (the maximal deviation is about 17 μ W).

The temperature of the thermostat having been changed before this measurement causes the sloping baselines.

3.4 Baseline stability

At the higher amplification (max 60 mW) the least significant bit of the A/D-converter is about 1 μ W and the short-term baseline (less than 1 hour) is usually within a few microwatts when the instrument is working at close to room temperature. Over a longer time period (e.g. 1 week) the baseline will be within ± 3 μ W. The baseline values are very constant and do not change (e.g. over a period of a year). The above values are when the calorimeter is working near room temperature; at higher or lower temperatures one will see a slight deterioration of performance. The manufacturer guarantees a sensitivity (precision) of ± 10 μ W and a 24-hour stability of better than 20 μ W under all conditions.

3.5 Calibration coefficients

Calibration coefficients are determined from electrical calibrations with heaters that are either fixed in the ampoule holders or inserted into ampoules. The instrument should be calibrated regularly; more often if it is used for different types of measurements, at different temperatures, or placed in a dusty environment. Under normal laboratory conditions the calibration coefficients are very stable. A change in a calibration coefficient indicates a broken calorimeter.

4. TYPICAL USES OF THE INSTRUMENT

Below are given some typical types of measurements that can be made with the present instrument.

4.1 Measuring the total heat produced

By charging the samples into the calorimeter as soon as possible (typically 200 s) after water and cement has been mixed (or mix water and cement inside the calorimeter) it is possible to measure the total heat produced during seven days (or any other time period), a value that should be equal to the result from the standardized solution calorimeter. An advantage with the isothermal calorimeter is that it gives not only the total heat, but also the thermal power as a function of time during the seven days. A Tian correction (Eq. 1) may be applied to correct for the influence of the time constant.

4.2 Measurements at different temperatures

From measurements of cement paste or mortar hydration at different constant temperatures the rate of hydration as a function of temperature and degree of hydration (defined as the ratio between the produced heat and the maximal heat produced) may be determined [3]. The activation energies may also be evaluated. From such data the temperature field during hardening of a massive construction may be calculated with less calculations than is needed when (semi)adiabatic measurement results are used.

Figure 3 shows the specific thermal power (watts per gram cement) as a function of produced heat (joules per gram cement). This is both a convenient and illustrative way to compare calorimetric cement hydration curves. The produced heat Q (J/g(cement)) on the x-axis can be seen as the extent of reaction ξ (g(reacted cement)/g(cement)); more produced heat means that the hydration reaction has preceded further:

$$\xi = \frac{Q}{\Delta h} \quad (2)$$

Here, Δh (J/g(reacted cement)) is the specific reaction enthalpy. The specific thermal power P (W/g(cement)) on the y-axis is proportional to the rate of reaction v (g/s):

$$v = \frac{P}{\Delta h} \quad (3)$$

These relations are useful in modelling the cement hydration process as solid-state kinetic models usually have the form:

$$v = f(\xi) \quad (4)$$

This can easily be rewritten using the calorimetrically measured parameters P and Q [7, 8]:

$$Q = f_2(P) \quad (5)$$

Figure 3. Three different ways of viewing the results from measurements at three temperatures (green: 10°C; blue: 20°C; red: 30°C). At each temperature the results from four measurements with samples from the same mix are shown. The left subplot shows the primary result from the calorimeters; the middle subplot shows the same result integrated; the right subplot essentially shows reaction rate as a function of extent of reaction.

Data from a calorimetric measurement can therefore be used to test kinetic models. A problem with this use of these equations is that the reaction enthalpy Δh may have different values at different times of the hydration process. Note that the 30°C-results in the right subplot are slightly shifted to the left, indicating there is a change in reaction path when the temperature is increased.

4.3 Assessment of retardation

Many admixtures retard the hydration process. By making measurements on cement paste or mortar with different percentages of an admixture it is possible to construct a diagram of retardation (time) as a function of admixture content [9]. Figure 4 shows an example of such a measurement. It is also possible to make a measurement with different recipes (cement, filler, admixtures etc.) to see when the main hydration process starts.

Figure 4. An example of the influence of an admixture on the hydration kinetics of a cement. From left to right the curves are from samples with 0, 0.1, 0.15, 0.20, 0.30, 0.50% of an admixture.

A MULTI-CHANNEL ISOTHERMAL HEAT CONDUCTION CALORIMETER FOR CEMENT HYDRATION STUDIES

Lars Wadsö

Building Materials, Lund University, Box 118, 221 00 Lund, Sweden.

E-mail: lars.wadso@byggtek.lth.se

Dr. Lars Wadsö is a senior researcher at Building Materials at Lund University in Sweden. His thesis was on wood-water relations, but his main current scientific interest is in development of calorimetric instruments and methods. He has designed a number of isothermal calorimeters and methods for such calorimeters for use in various fields. He is also engaged in the indoor air quality field through the industrial research school The Building and Its Indoor Environment at Lund University.

WORK TOWARDS A STANDARD FOR ISOTHERMAL (CONDUCTION) CALORIMETRY FOR CEMENT HYDRATION

Lars Wadsö

Building Materials, Lund University, Box 118, 221 00 Lund, Sweden.

E-mail: lars.wadso@byggtek.lth.se

ABSTRACT

This paper presents work done to prepare a draft for a Nordic (NORDTEST) standard for measurement of the heat of hydration with isothermal (conduction) calorimetry. The main aim of the work is to produce a standard for measurements of 2-, 3- and 7-day (isothermal) heats as an alternative to (semi) adiabatic calorimetry and solution calorimetry. It is also thought that large parts of the standard may be used when planning other types of experiments with isothermal calorimetry.

1. INTRODUCTION

When cement hydrates, heat is produced and different methods to measure this heat are interesting ways of studying the cement hydration process. There are essentially four different calorimetric techniques used today to study cement hydration:

1.1 Isothermal calorimetry

The heat production in the sample is monitored while the sample temperature is unchanged. This type of calorimeter is usually a heat conduction (flow) calorimeter in which the heat produced in the sample is measured as it is conducted out from the sample through heat flow meters. There are today several types of commercial instruments used in the pharmaceutical industry and elsewhere (references [1, 2] discuss different uses of isothermal calorimetry), and some instruments that are limited to cement science. No cement standards exist for isothermal calorimetry, although Cembureau have issued recommendations how to use it [3] and there have been (and are) a few manufacturers of such instruments. Figure 1 shows a schematic description of a twin heat conduction calorimeter and Fig. 2 shows the instrument used in the present study (TAM Air, Thermometric AB, Järfälla, Sweden).

1.2 Adiabatic calorimetry

In this type of calorimetry the sample is perfectly insulated so that all heat produced is used to heat the sample. The temperature increase of the sample is measured and the rate of temperature increase is a measure of the heat production rate in the sample. So-called adiabatic shields are usually used to stop the heat from leaving the sample

1.2.1 Semiadiabatic calorimetry

This is an insulated calorimeter in which the insulation is not perfect so a certain fraction of the heat produced is allowed to escape from the sample (how much may also be measured by measuring the temperature gradient through the insulation). In practice the sample is placed in an insulation made of polystyrene. There are several standards on semiadiabatic calorimetry.

Figure 1. A schematic drawing of a heat conduction calorimeter. When heat is produced in the sample the temperature of the sample is slightly increased. The temperature difference between the sample and the heat sink will then generate a signal from the heat flow sensor (a thermocouple plate positioned between the sample and the heat sink). An identical reference side contains an inert reference sample (water or dry sand) with the same heat capacity as the sample. The sample and reference heat flow sensors are differentially connected so that disturbances entering the calorimeter will be reduced (because they will influence the sample and reference sides in similar ways). The whole calorimeter is placed in a thermostat.

Figure 2. A cut-away drawing of the TAM Air instrument (Thermometric AB, Järfälla, Sweden) that was used in the present study. The calorimetric block contains eight separate isothermal calorimeters, each with a baseline-stability better than 10 microwatts. The data logger is placed in the thermostat and connected to the serial port of a computer. The air thermostat and the 50 mm polystyrene insulation give a temperature stability of 0.02 K.

1.2.2 Solution calorimetry

In this method, which is actually a type of semi-adiabatic calorimeter, the total heat of hydration at a certain time is determined as the difference between the heat liberated when an un-hydrated sample and the sample under investigation are dissolved in mixtures of hydrofluoric and nitric acid. The use of this old standardised technique is decreasing because of the hazardous materials used.

This paper is about a proposal for a standard for isothermal calorimetry of cement hydration. Isothermal calorimeters, often called heat conduction calorimeters, have seen significant development the last decades and they have a wide use in science and industry. Such instruments have many advantages over the standardized and presently used (semi) adiabatic calorimeters:

- Isothermal calorimeters directly measure the heat production rate that is proportional to the rate of the reaction (adiabatic calorimeters measure temperature (change) that is recalculated to give heat produced).
- In isothermal calorimetry it is not necessary to know the heat capacity of the sample, as is required in adiabatic calorimetry.
- For the evaluation of isothermal measurements it is not necessary to know the activation energy; on the contrary isothermal calorimetry can be used to measure activation energies.
- Isothermal calorimeters are very stable and seldom need to be calibrated more than a few times a year (adiabatic calorimeters are often calibrated before each run).
- Isothermal heat conduction calorimeters for cement hydration studies are more sensitive than adiabatic calorimeters and have a higher time-resolution of events taking place. Measurements may therefore be made on much smaller samples than are used in (semi) adiabatic calorimetry.
- The temperature never increases to unrealistic temperatures in an isothermal calorimeter (final temperatures during measurements in adiabatic calorimeters can be very high, e.g. 80°C; far above what is desirable in real construction).
- Isothermal calorimetric experiments are easy to perform and need little operator training and operator time (in contrast especially to the solution calorimetric method described above).
- Isothermal calorimeters are widely used in science and industry and one may therefore expect that such instruments have higher performance/cost-ratios than instruments made specifically for the cement or concrete market.

Isothermal calorimetry has many advantages over conventional cement calorimetry, but a possible drawback is that only small samples may be used. For measurements on large samples of concrete one therefore needs adiabatic or semi-adiabatic calorimeters. However, most measurements can be made on cement pastes, mortar or micro-concrete since normal coarse aggregate does not influence the heat development in the cement paste (approx. 30% of the concrete volume).

Testing of concrete is costly and time-consuming, both because of the large quantities of material that have to be handled and because many of the measurement techniques, e.g. strength measurements, are work-intensive. Some of the measurements that today are made on concrete could instead be done in a much smaller scale on cement paste in isothermal calorimeters. Testing for unwanted excessive retardation is one example. Mixing and charging eight cement paste samples with different concentrations of an admixture into an isothermal calorimeter takes about one man-hour.

Adiabatic and semi-adiabatic calorimeters are sometimes advocated because the temperature increases during a measurement, just like it does in a massive construction. However, this is not of any real advantage since there are very different temperature increases in different parts of a massive construction. The isothermal measurement is the most well defined calorimetric measurement, and to completely describe the hydration of a cement paste or a mortar the best way is to take isothermal hydration measurements at different temperatures.

2. THE PRESENT STANDARDISATION PROJECT

NORDTEST, a Nordic organisation for development of test methods and conformity assessment (www.nordtest.org), is funding an effort to develop a standard for cement hydration measurements by isothermal calorimetry. The project group has the following partners:

1. Building Materials, Lund University, Sweden (Lars Wadsö, coordinator)
2. The Norwegian Building Research Institute, Norway
3. SP, The Swedish National Testing and Research Institute, Borås, Sweden
4. Cementa AB, Sweden
5. Grace Construction Products, USA

The project has two parts. In the first part, parts of which are reported here, the present author at Building Materials at Lund University, Sweden tested different aspects of isothermal calorimetry. In the second ongoing part, the following different types of calorimetric measurements will be performed on two cements:

- Isothermal calorimetry with and without fine aggregate (partners 1, 3 and 5).
- Semi-adiabatic calorimetry (partners 2 and 3).
- Solution calorimetry (partner 4).

The aims of the project are:

- To investigate different aspects of isothermal calorimetry of cement hydration.
- To compare the result of isothermal measurements with those from semi-adiabatic and solution calorimetry.
- To draft a standard for 2-, 3- and 7-days heat of hydration measured by isothermal calorimetry.

Isothermal calorimetry is a very versatile and general measurement technique that can have dozens of uses within the fields of cement and concrete. We have, however, chosen to write a standard only on the determination of 2-, 3- and 7-day heat of hydration. The reason for this is that this type of measurement is today made with semi-adiabatic and solution calorimetry and it is therefore possible to compare our isothermal results with results with these methods. As the standard text will be rather detailed and discusses different aspects of isothermal calorimetry (e.g. calibration and choice of instrument) it may also be used as a base for developing methods for other purposes, e.g. assessment of retardation, determination of activation energy, indicating false set etc.

The standard text will be written in such a way that different models of isothermal calorimeters can be used, but it must also clearly define which properties such a device should have to work well. In the present project all isothermal calorimetry is done in TAM Air calorimeters (Thermometric AB, Järfälla, Sweden; www.thermometric.se). This is a newly developed eight-channel isothermal heat conduction calorimeter which is well suited for cement hydration studies.

3. ASPECTS OF ISOTHERMAL CALORIMETRY OF CEMENT HYDRATION

In this section I discuss some aspects of isothermal calorimetry that were investigated in the first part of the NORDTEST project. Some of these issues discussed concern isothermal calorimetry in relation to present standardised techniques, e.g. measurements of strength. It is obvious that it is necessary to strictly control the use of aggregate when making samples for strength measurement, as the strength of a mortar is dependent on the properties of the aggregate. Present standards therefore prescribe the use of an expensive standardised sand. It would then be natural to suggest

that one also use this sand when making isothermal calorimetry specimens. However, it is not obvious that the aggregate has much influence on the rate of cement hydration, and if one could use cement paste without sand one would decrease the cost and simplify the measurement procedure.

Note that all the results are given in watts per gram cement or joules per gram cement. By this it is possible to directly compare measurements of mortar and cement paste. Also note that not all aspects discussed below may or can be incorporated into the draft standard.

3.1 Sample size

There are two aspects of sample size to be discussed in connection with isothermal calorimetry:

1. In isothermal calorimetry the sample size is limited because if the sample becomes too large it will no longer be at isothermal conditions. This is discussed below (subsection 3.9).
2. Sample size may also have a direct effect on the result of a heat conduction calorimetric experiment as it may change the heat loss paths from the sample, e.g. with a larger, and therefore higher, sample an increased fraction of the heat produced may be conducted away without passing through the heat flow sensor. For good isothermal calorimeters this is not a problem, e.g. with the TAM Air used in the present project we see no differences between results (expressed as mW/g(cement)) from cement paste samples in the range 2-10 g. In the present study I have used about 5 g of cement paste and 10-15 g of mortar in the experiments and have found that this gives reproducible results.

3.2 Aggregate influence (paste vs. mortar)

Some types of calorimetry (semi-adiabatic) are usually made on concrete with large aggregate, whereas other types (solution calorimetry) require cement paste without any aggregate. In the isothermal calorimeters we have used, it is possible to include aggregate up to about 5 mm in diameter. The spread in data will, however, increase if 5 mm aggregate is used.

We have made measurements of cement paste hydration with and without fine sand and only found minor differences. This is natural as it is in the cement paste that the reaction takes place; the aggregate can usually be considered to be inert. In isothermal calorimeters it is therefore often possible to leave out the aggregate and work with cement pastes. This facilitates sample preparation.

However, note the following:

- It is possible to include some sand to decrease segregation at high water-cement ratios or high plasticiser concentrations, but it is in many cases also possible instead to decrease the water-cement ratio if one can accept a slightly longer time until the main reactions start.
- When sand is included, the start of the main hydration reaction is often slightly more rapid than without the sand. This is probably because the sand grains can act as seeds for the hydration reaction. For 2-7 days heat of hydration this is of no importance.
- It is probable that filler materials like silica fume and finely ground limestone will influence hydration. Such materials can be incorporated without any problem in a measurement.
- If one expects that a large size aggregate could influence hydration by substances/contaminants on its surface one may, for test purposes, wash these off into the mixing water.

3.3 Glass ampoules (vials)

In heat conduction calorimetry it is essential that there is good contact between the sample and the heat flow sensors and one normally uses ampoules of stainless steel or glass that tightly fits into an ampoule holder in the calorimeter. For cement hydration studies disposable glass ampoules (chromatographic vials) are the most rational choice. However, the very alkaline pore solution of

cement paste may partly dissolve the surface of a glass ampoule. Will the heat from this reaction influence the measurement of the heat from the cement hydration reaction? To test this I made parallel measurement with cement paste in glass ampoules and in polyethylene bags placed into glass ampoules. The result was both integrated for the total heat and examined visually and there was no observable trend in any direction. The relative standard deviation of the integrals up to 40 h was about 3% for the whole data set, as well as for the samples in glass ampoules and the samples in polyethylene bags, respectively. The conclusion is that the glass-cement paste reaction does not significantly influence the result of the calorimetric measurements.

3.4 Deriving the total heat

When the result from a calorimetric measurement is to be integrated so that one can compare it with solution calorimetric results it is important that the measurement is started as soon as possible after the water is mixed with the cement. I have found that it is no problem to charge samples into the calorimeter in less than 180 seconds after the water was added.

When the sample is charged into the calorimeter it is never at exactly the same temperature as the calorimeter. There will therefore be an initial disturbance, most of which can be removed by the application of the Tian equation [3]:

$$P = \varepsilon(U + \tau \frac{dU}{dt}) \quad (1)$$

The Tian equation is useful for processes with rapidly changing heat production to find the true shape of the $P(t)$ -curve from the U -output from the heat flow sensors, but for calculating the true *integral* a simpler approach may be used. The heat Q is the integral of the thermal power P :

$$Q = \int_{t=t_1}^{t_2} P dt = \varepsilon \int_{t=t_1}^{t_2} U dt + \varepsilon \tau \int_{t=t_1}^{t_2} \frac{dU}{dt} dt \quad (2)$$

Here, t_1 is the start of the integration a few minutes after the water was added and t_2 is the end of the integration, typically 2, 3 or 7 days after water was added. The second integral is trivial and Eq. 2 can be rewritten as:

$$Q = \varepsilon \int_{t=t_1}^{t_2} U dt + \varepsilon \tau (U(t_2) - U(t_1)) \quad (3)$$

Normally, $U(t_2)$ is very small compared to $U(t_1)$ and we finally arrive at the following simplified expression for the heat integral from a isothermal calorimetric measurement:

$$Q = \varepsilon \int_{t=t_1}^{t_2} U dt - \varepsilon \tau U(t_1) \quad (4)$$

The time constant τ needed for the Tian correction may be determined from calibrations or calculated from knowledge of the thermal properties of the calorimeter and the sample. The most practical way is probably to calculate it as the ratio of the sum of the heat capacities of the sample components (cement, sand and water), the ampoule and the ampoule holder divided by the thermal conductivity of the heat flow sensor. Such a procedure will probably give a value within 10% of the true value.

3.5 Influence of the mixing procedure

In mortar standards the mixing procedure is important and particularly when one is interested in measuring the total heat with isothermal calorimetry the mixing has to be quick. We have tested mixing small amounts of cement paste and mortar by hand. Typically, we mix about 50 g of cement paste or about 100 g of mortar by hand in a plastic cup or glass cup. Mixing is usually done with a stainless steel teaspoon and takes about 15 seconds. We have found that hand mixing is efficient and we see no differences between samples mixed for 30 seconds and samples that are mixed for a longer time. Mixing with an electrical hand mixer (household type) may possibly be more reproducible and can be made in as short time as hand mixing. Note that it is essential that the sample be efficiently mixed for some time after the last dry cement is gone. Also note that it is probable that samples containing fine fillers like silica need more aggressive mixing than hand mixing.

3.6 Calibration

Isothermal calorimeters are normally calibrated electrically by sending a known current through a resistor (heater) that is placed close to where the samples are placed. Calibrations may be made with built-in heaters (usually attached to the sample holders) or with heaters that are placed in ampoules. It is probable that the placement and construction of such heaters to some extent will influence the result of a calibration [4], but this has not been specifically investigated for the types of calorimeters used in this project.

Calibration should be done regularly and the generated calibration coefficients and baselines (offset) should not differ substantially from calibration to calibration. Rules for calibration intervals and acceptance of calibration results need to be discussed. Monthly calibration is advisable, particularly when a calorimeter is used continuously. Our experience from the Thermometric TAM Air is that its calibration coefficients and baseline offsets are very stable with time.

3.7 Test experiments

Test experiments are experiments designed to test the whole measurement procedure, i.e. the instrument, the calibration coefficient, the mixing and charging procedures etc. For a multi-channel calorimeter like the TAM Air we recommend the following experiment. Make a mix of 100 g cement and 50 g water. Charge between 3 and 8 g into each of the eight calorimeters and measure until the main hydration peak has passed. The test experiment is successful if the curves look similar and all peak values are within $\pm 5\%$ of the mean peak value. This test measurement takes less than one day and confirms that the whole measurement procedure works as intended.

3.8 Measurements at different temperatures

When measuring the total heat of hydration it is important that the measurement is started soon after the mixing. When the measurement is made at a temperature that is different from that of the room where the mixing is made, the sample may carry a substantial amount of (positive or negative) heat into the calorimeter making it go out of range for a time during which data about the heat production is lost. This is mostly a problem at elevated temperatures where the reaction rate is higher. It is therefore recommended that one uses pre-heated ingredients and work in such a way that the sample has approximately the measurement temperature when it is charged into the calorimeter. One can for example test how much one has to pre-heat the water to get a final ampoule temperature that is the same as that of the calorimeter temperature.

3.9 Temperature changes in an isothermal calorimeter

Heat conduction calorimetry is often referred to as isothermal calorimetry because one tries to keep the temperature of the sample constant by removing the produced heat by conduction (cf. (semi) adiabatic calorimetry in which one insulates the sample in order to be able to measure its temperature increase). Heat conduction calorimetry is, however never perfectly isothermal as there

will always be a small temperature difference between the sample and the thermostat. The present author [5] has given a procedure to calculate the temperature increase in a sample during a measurement in a heat conduction calorimeter. A cement hydration standard for heat conduction calorimetry should demand that the temperature increase caused by the heat production in the sample should be limited, e.g. below 0.5 K, during a measurement.

4. DISCUSSION AND CONCLUSIONS

Isothermal calorimetry is a useful method to solve problems in cement and concrete science and technology, but its use has been limited by the lack of standardised method for its use in the cement and concrete field. The aim of this work is to propose a Nordic standard for measurements of total heat of hydration (usually 2, 3 or 7 days) with the following limitations:

- Temperature 20°C.
- Water-cement ratio 0.5.
- Cement paste (no sand)

The procedures stated in this standard can then be modified and used also for other types of measurements of cement hydration. For example, if one wants to quantify retardation as a function of admixture concentration one can modify the standard procedure so that one adds the admixture with the mixing water. If this needs to be done at different temperatures one can modify the temperature conditions in the standard.

The first stage of this work has been to test if a number of procedures required by other standards are necessary to implement in the new standard. The main result of this was that:

- Samples of 5g cement paste give reproducible results.
- The influence of the aggregate is very small (fillers are probably an exception).
- Glass ampoules may be used.
- The total heat can be derived with a simplified Tian-expression.
- Hand mixing produced reproducible results.

5. NOMENCLATURE

P	thermal power	W
Q	heat	J
U	voltage*	V
ε	calibration coefficient*	W/V
τ	time constants	s

* The output from a heat conduction calorimeter is normally a voltage

MONITORING EARLY CEMENT HYDRATION BY RHEOLOGICAL MEASUREMENTS

F. Winnefeld¹ and L. Holzer¹

¹Swiss Federal Laboratories for Materials Testing and Research, Section Concrete/Construction Chemistry, 8600 Dübendorf, Switzerland. E-mail: frank.winnefeld@empa.ch

ABSTRACT

This contribution focuses on the structural changes of cement paste from mixing to setting, determined by rheological measurements and ESEM-observations. Initially after adding of water, the cement starts to hydrate. During the induction period the rate of hydration is very low. The cement paste is still workable and behaves like a fluid. At the beginning of the acceleration period, the structure of the cement paste changes, it stiffens. By measuring the rheological properties during cement hydration, information on the structural growth during the hydration process can be obtained. But it is important that the structure of the paste is not influenced by the measurement itself. Cement paste before setting is a flocculated suspension that is very sensitive to the applied shear. Its microstructure breaks down very easily. The usual rheological techniques - for example flow curves - are not suitable for a continuous monitoring of cement hydration, as the yield stress of the paste is exceeded during measurement, causing a structural breakdown. With a special dynamic measurement technique, low-amplitude oscillatory shear, the structural growth of cement pastes can be studied continuously from mixing until setting. As an application example of the method the influence of superplasticizers was examined. The results correlate well with ESEM and calorimetry data.

1. INTRODUCTION

Rheology is defined as the science of flow and deformation of matter. Regarding fresh cement paste, mortar and concrete, it is a powerful tool to determine their workability properties. Viscometric flow of a homogeneous liquid is usually explained using the two plate model (Figure 1). The sample is placed between two parallel plates. The upper plate is moved with a constant velocity, the force needed is F . The lower plate is fixed. If the liquid adheres to the plates, a laminar flow in x -direction occurs. Shear stress and rate of shear are given by the equations shown in Figure 1. In commercial rheometers, the simplified plate geometry is replaced by a rotating plate-plate-, cone-plate- or concentric cylinder-geometry.

Figure 1. Two plate model - definition of rheological parameters

Usually, the flow behavior of a liquid or a suspension is characterized by a flow curve. The sample is sheared at different levels of rate of shear and the resulting stress is measured. The opposite, different preset levels of stress and measuring the resulting rate of shear is also possible. The flow curve, usually stress versus rate of shear, shows a typical behavior, depending on the tested material. For Newtonian liquids such as water, stress is proportional to rate of shear. The slope of the curve is the viscosity. Cement pastes, mortars and concretes are approximately Bingham- or Herschel-Bulkley-fluids with a yield stress [1], there are some other models reported in literature [2,3]. The flow behavior of these materials is strongly dependant on mixture composition, e. g. type and amount of cement, aggregate, admixture, but also water/cement-ratio, temperature and intensity of the previous mixing process.

The rheology of cement paste (as well as mortar or concrete) is also depending on hydration time. Like in other suspensions, the cement particles start to form agglomerations via diffusion-induced collisions [4] immediately after mixing. The cause of the flocculation process is interparticle (van der Waals-) forces. If the particle concentration is low, the aggregates will settle. At higher concentrations, the flocculation process forms a network that is quite stable with regard to sedimentation. This material behaves to small amplitude deformations like an elastic solid. At later hydration times, the cement particles begin to interact also mechanically due to the formation of hydration products.

It is obvious that the change in rheological properties can provide information on the hydration progress and workability time. Hydration causes an increase in viscosity and especially in yield stress [1]. However, the measurement of sequential flow curves on the same sample with a rheometer or of the shear stress as a function of the rate of shear are not suitable methods. Their disadvantage is, that the material is influenced by the measurement itself. Therefore, a non-destructive rheological method is needed that measures the structural strength of cement paste without allowing it to flow, at stresses below the yield point. A special dynamic method, low-amplitude oscillatory shear, can be applied. Again, the two plate model is useful to explain the method (Figure 2).

Figure 2. Two plate model - oscillatory shear experiment

Strain (or stress) is oscillated according to a sine function (Figure 3):

$$\gamma(t) = \gamma_A \cdot \sin(\omega \cdot t) \quad (\text{with } \omega = \text{angular frequency}) \quad (1)$$

The resulting stress (strain resp.) and the lag between applied stress and resulting strain (phase angle) is measured:

$$\tau(t) = \tau_A \cdot \sin(\omega \cdot t + \delta) = \gamma_A \cdot [G' \cdot \sin(\omega \cdot t) + G'' \cdot \cos(\omega \cdot t)] \quad (2)$$

(with the complex shear modulus $G^* = G' + i \cdot G''$)

For an ideal elastic solid, strain and the resulting stress are in phase. For an ideal viscous liquid, however, the stress sine curve is delayed by a phase angle of 90° compared to the strain sine curve. Viscoelastic substances such as cement paste show a behavior that ranges between an ideal liquid and an ideal solid. The lag between strain and stress curve is $0 < \delta < 90^\circ$. δ is called the phase or the loss angle. The storage modulus G' calculated from the data represents the elastic (or solid-like, reversible) response of the material to a strain or a stress, the loss modulus G'' describes the viscous (or liquid-like, irreversible) response. The ratio $G''/G' = \tan(\delta)$ represents the ratio of viscous and elastic properties. Therefore, the measurement of G' and G'' of cement paste can provide information on the structural growth during the first hours of cement hydration. There are only few reliable data in world-wide literature on the application of this method to cement pastes [6-11], because the material is so very sensitive to shear.

2. EXPERIMENTAL

2.1 Materials

An Ordinary Portland cement CEM I 42.5 N according to European Standard EN 197-1 with a specific of $2840 \text{ cm}^2/\text{g}$ (Blaine method) was used. The chemical composition is given in table 1.

Table 1. Chemical composition of the used Ordinary Portland cement CEM I 42.5 N

CaO	MgO	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	Na ₂ O	K ₂ O	SO ₃	CO ₂	L.O.I.	free lime
wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%	wt.-%
63.2	2.1	19.5	5.3	3.1	0.13	1.1	3.1	2.1	2.7	0.43

The influence of admixtures on cement hydration was examined using three superplasticizers with different chemistry (Table 2). The adsorption of the admixtures on the cement was studied preparing pore solutions under nitrogen atmosphere (glove box). Cement and distilled water containing the superplasticizer were mixed by hand for one minute. The dosage of admixtures was 0.45% referred to cement, water/cement ratio was 0.40. The pore solution was extracted by suction filtration after 5 min and in a second series after 30 min of hydration.

Table 2. Properties of the used superplasticizers

abbreviation	chemistry	solid content	adsorption of admixture (dosage 0.45%, w/c = 0.40) on cement	
			after 5 min	after 30 min
PC	Polycarboxylate	approx. 35%	52 %	59 %
NS	Naphthalene sulfonate	approx. 35%	84 %	85 %
LS	Ligno sulfonate	approx. 35%	70 %	71 %

2.2 Rheology

A rheometer (Paar Physica MCR 300) that enables both stress- and strain-controlled experiments was used. A cylindrical measuring geometry according to ISO 3219 with a cup and a rotating bob was used (Searle geometry), the measuring gap was 1.13 mm. The measuring system was connected to the rheometer by an air bearing. A special, newly developed technique (direct strain oscillation [11]) was applied that allows measurements at very low torques ($< 0.1 \mu\text{Nm}$) and very small deflection angles ($< 0.1 \mu\text{rad}$). Such a high sensitivity is necessary due to the very low torques and deflection angles that have to be measured for the examination of very weak structures.

Cement pastes were prepared with w/c ratio of 0.40. The admixtures were dissolved in the mixing water. Mixing was done according to EN 196-3. The paste was transferred into the rheometer cup with a spoon. The measuring bob was then slowly lowered into the paste. The cup was covered with a solvent trap to keep relative humidity above the paste to over 90%. The temperature of the sample was maintained to 20°C by means of a circulating water bath. The measurement started 5 min after the addition of water to cement. In the hydration experiments, data were collected every 60 seconds.

2.3 Heat flow calorimetry

The heat flow during hydration of the cement pastes was determined by means of isothermal conduction calorimetry. Water/cement ratio and dosages of superplasticizer were the same as described in 2.1.

2.4 Electron microscopy

To determine whether changes in rheological properties are related to microstructural changes of the cement pastes, the morphology of the hydration products was studied using an environmental scanning electron microscope (ESEM). Pastes were prepared under nitrogen as described in 2.1. At different hydration times (30 min, 2 and 5 hours) the pore solution was separated. A sample of the filter residue was then immediately transferred into the ESEM.

3. RESULTS

3.1 Determination of the linear viscoelastic region

The prerequisite of the oscillatory shear experiments is, that the strain level during measurement stays below a critical strain in the so-called "linear-viscoelastic region" (LVR), so that the structure of the flocculated network will not be disturbed. Higher stresses outside the LVR will cause a structural breakdown of the paste. The sample then begins to flow like a liquid. To determine the LVR, a strain sweep with increasing strain amplitude and an angular frequency of 2.5 s^{-1} was performed (Figure 4).

Within the LVR in the low-strain region, the G' - and G'' -curves are both independent of the strain level. That means, that the microstructure of the suspension is not disturbed. G' (14 kPa) is higher than G'' (7 kPa), indicating that the paste shows mainly a gel-like or solid-like behavior. The critical strain is 6×10^{-5} . Above the critical strain, a structural breakdown occurs, G' and G'' decrease rapidly. The critical strain corresponds to the yield stress. Actually, yield stresses can be determined in a more accurate way by oscillatory stress or strain sweeps than by calculation from flow curves with

the Bingham- or the Herschel-Bulkley-model. The critical stress of all examined samples was between 5×10^{-5} and 2×10^{-4} . This corresponds well with the data from [5,6]. In [8] a critical strain of $1.3 \cdot 10^{-4}$ for C_3S -pastes with w/c ratio of 0.50 is reported. For the further hydration experiments in 3.2 and 3.3. a strain amplitude of $\gamma = 5 \times 10^{-5}$ was used.

Figure 4. Strain sweep of Portland cement paste with w/c = 0.40; angular frequency = 2.5 s^{-1}

Figure 5. Change of storage modulus, loss modulus and loss angle during early hydration of Portland cement paste with w/c = 0.40; strain = 5×10^{-5} , angular frequency = 2.5 s^{-1}

3.2 Time behavior of Portland cement paste

Figure 5 shows the time behavior of a Portland cement during an oscillatory shear experiment. At the beginning of the measurement (5 minutes after the addition of water to the cement), the paste shows a both liquid- and solid-like behavior with $\tan(\delta)$ at about 1. The values for G' and G'' are approximately 2 kPa. Then G'' and especially G' increase rapidly, because the structure of the paste

recovers from the structural breakdown due to the mixing process. The flocculation of the cement particles is responsible for this thixotropic effect. The increase in G' is stronger than the increase in G'' , the character of the paste becomes more solid-like. At the end of this period after 30 minutes of hydration, the values for G' are 150 kPa and for G'' 25 kPa.

After this thixotropic structural gain, the increase of G' and G'' gets slower, with a linear gradient in relation to the logarithmic scale of G . This indicates that the paste slowly begins to stiffen. At about 110 min hydration time, the increase of the storage modulus and also of the loss modulus gets stronger. The reason for the increase of G' is the increasing amount of solids in the suspension due to hydration, but also the interaction of the hydration products [5]. This workability loss occurs at an earlier time compared to the initial setting determined by the Vicat test method according to European Standard EN 196-3. This can be explained by the fact that the result of the Vicat test is caused by a certain, quite high viscosity or stiffness of the paste and not by a significant shift of the structural development.

After the beginning of this strong increase in G' and G'' , the measurement had to be stopped. The stiffness of the sample caused first an increasing scattering of the data, then very low values for G' were measured. It can be suggested that the measuring bob had lost adhesion to the cement paste and wall slip occurred. The reproducibility of the oscillatory shear experiments is quite good [12], indicating that no problems like wall slip occurred, as discussed in [10]. This could be expected because of the narrow gap used and the very low strains applied in the experiments. The experimental data is quite comparable to those determined by [5-7], considering the first 90 minutes of hydration. The decrease in G'' reported in their papers, however, could not be observed. It can be suggested that this decrease is an artifact due to the increasing stiffness of the paste, as discussed in [6]. A rapid rise in G' and G'' at the beginning of the acceleration period was determined by [13]. Other authors report much lower (1/100) values for G' and G'' for oilwell cement slurries with high w/c ratios around 1.0 [14]. In [14], the authors did not find the decrease in G'' . But in the last two cases it is very uncertain, if they worked within the linear viscoelastic region.

3.3 Influence of superplasticizers

The influence of a polycarboxylate-based superplasticizer (PC), commonly used in self-compacting concrete, was tested (Figure 6). Generally, the storage modulus is lower with increasing dosage of the superplasticizer at a certain hydration time. The paste has less structural strength and is more fluid. The rise of the storage modulus after the initial thixotropic structural gain is also less strong in the case of the superplasticizer-containing pastes. G'' shows the same effect as G' . The greater fluidity of the superplasticizer-modified pastes is caused by the adsorption of the polymer on the clinker surfaces leading to steric and to a less extent electrostatic repulsion between the cement grains [15]. The more superplasticizer added to the paste, the more the workability time increases. The adsorption of the polymer on the cement also causes this prolongation of workability time. The retarding effect of the polycarboxylate-based superplasticizer was also confirmed using a conduction calorimeter. A good correlation was found between the end of workability time determined by oscillatory shear and the end of the dormant period measured by calorimetry (Figure 7).

Figure 6. Influence of polycarboxylate-based superplasticizer on storage and loss modulus depending on hydration time; $w/c = 0.40$; strain = 5×10^{-5} , angular frequency = 2.5 s^{-1}

Figure 7. Comparison between rheological and calorimetric data on the hydration progress of PC-containing cement pastes

The microstructures of the pure cement paste and the paste with 0.45% PC were investigated in the environmental scanning electron microscopy (ESEM) at hydration times 30 min (end of thixotropic structural gain, 2 hours (beginning workability loss of pure cement paste) and 5 hours (beginning workability loss of the paste with 0.45% PC).

Figure 7. ESEM-micrograph of Ordinary Portland cement paste with w/c 0.40 without admixture (left) and with 0.45% PC (right) after 30 min of hydration

Figure 8. ESEM-micrograph of Ordinary Portland cement paste with w/c 0.40 without admixture (left) and with 0.45% PC (right) after 2 hours of hydration

Figure 9. ESEM-micrograph of Ordinary Portland cement paste with w/c 0.40 without admixture (left) and with 0.45% PC (right) after 5 hours of hydration

Figure 7 shows the microstructure of the two pastes at an age of 30 minutes. In both cases initial hydration products have formed on the surface of the cement clinker grains. The hydration products, however, are not big enough to connect the larger cement particles. At a hydration time of two hours (Figure 8), larger crystals can be found on the clinker surfaces. The hydration products now start to bridge the space between the particles, causing the workability loss determined by the oscillatory shear measurements. The paste with PC however shows after two hours mainly the same structure than after 30 minutes of hydration. The beginning of a significant bridging of the space between the particles can be observed at a hydration time of five hours (Figure 9.). In comparison to that, the particles in the paste without admixture are connected by a network of hydration products.

Beside the polycarboxylate-superplasticizer, two other products based on naphthalene sulfonate (NS) and on ligno sulfonate (LS) were tested at a dosage of 0.45%. Figure 10 shows the results of the oscillatory shear experiments in comparison to the data for the pure and the PC-modified pastes. It is obvious, that in spite of the greater adsorption on the cement grains both products are less effective in plastification of the cement paste compared to the polycarboxylate. The decrease in storage modulus compared to the control mix is less compared to the polycarboxylate. The increase of G' at the end of workability time marking strong structural gain, is remarkably earlier, 150 min for 0.45% NS and 140 min for 0.45% LS, compared to 270 min for 0.45% PC-superplasticizer. This effect corresponds to data obtained from the Vicat-test, heat flow calorimetry and ESEM experiments.

Figure 10. Influence of polycarboxylate-based superplasticizer on storage and loss modulus depending on hydration time; $w/c = 0.40$; strain = 5×10^{-5} , angular frequency = 2.5 s^{-1}

4. CONCLUSIONS

It could be shown that oscillatory shear experiments are a suitable method for studying the structural growth of cement paste during early hydration. Storage modulus G' and loss modulus G'' , representing solid- and liquid-like behavior, can be measured continuously without influencing the very shear-sensitive structure of the paste. The experiments have to be carried out in the linear viscoelastic region below a critical strain. The critical strain for the examined cement pastes ranges from $5 \cdot 10^{-5}$ to $2 \cdot 10^{-4}$.

Freshly mixed cement paste with water/cement-ratio of 0.40 shows both solid- and liquid-like behavior, with values for G' and G'' of approximately 2 kPa. The greatest increase in storage modulus G' occurs on one hand within the first 30 minutes of hydration due to thixotropic effects caused by flocculation of the cement particles. On the other hand, the end of workability time is marked by a strong increase of G' at about 110 min of hydration in the case of the examined Ordinary Portland cement paste without admixture.

The influence of three different superplasticizers was studied. Effects like workability time, plastification or retardation could be determined. The end of workability time could be linked on one hand with the end of the dormant period measured using a heat flow calorimeter, on the other hand with structural changes observed in the ESEM.

ABSTRACT

During cement hydration chemical processes and structural changes in nano- and micrometer ranges induce a specific physical behaviour of the material on a macroscopic scale. In the ideal case a profound understanding of the link between these aspects enables the design of materials with specific characteristics. In order to improve such an integral understanding of the hydration process, fresh Portland cement pastes are investigated during the early hydration period (1 minute to several days) by means of various complementary methods: rheology, calorimetry, glove-box experiments, ESEM-investigations of the microstructure, Backscattered imaging (BSI) on polished sections, X-ray powder diffraction (XRD) and analysis of pore solution chemistry. The comparison of the different results, calibrated to the same timescale, helps to clarify the relationships of micro and macroscopic aspects and explains some connections between physical properties and chemical or mineralogical processes, which dominate the hydration process of fresh cement pastes.

1. INTRODUCTION

Most important material properties of cementitious materials such as workability, setting behaviour, strength but also durability qualities are strongly related to the hydration process [1]. Therefore a profound understanding of the early hydration period is a prerequisite for a specific material design. However the link of physical properties with the microstructural development is difficult for several reasons: Firstly, the elaboration of relationships at different scales is a challenge. C-S-H and gelpores are nanoscale structures [2]. The very fine hydration products form networks on a μm - to mm-range. Aggregates reach diameters of several cm, while concrete structures are generally in the range of several meters. Thus, for a thorough understanding of the system a wide range of meter scales has to be taken into consideration. Secondly, the change from a suspension to a solid material leads to variable measuring conditions, for which no single and simple method of characterisation can be applied. The dynamic aspects of the process must be encountered by methods with a sufficient time resolution. Thirdly, the wet or moist system is prone to produce artefacts. Hydration products may become unstable during the investigation (e.g. in high vacuum). During the investigations uncontrolled reactions may take place between the highly concentrated pore solutions and reactive cementitious components [3]. Because of its complexity, an integral view of the cement system is very difficult. Many studies are based on single characterisation methods and thus the interest is often focused on isolated aspects of cement hydration. In this study, we try to correlate information from different methods, which were applied to fresh paste. Based on an internally consistent set of data from several methods an integral description of the hydration process arises.

2. MATERIALS AND METHODS

All experiments are carried out with pastes from ordinary Portland cement (OPC) CEM I 42.5 with a water/cement(w/c)-ratio of 0.5. The composition of the cement is given in Table 1.

Table 1. Composition of OPC, CEM I 42.5

Chemical analysis		Normative phase composition (modified after Bogue)	
	g/100g		g/100g
SiO ₂	20.60	C ₃ S	48.23
Al ₂ O ₃	4.80	C ₂ S	22.67
Fe ₂ O ₃	2.70	C ₃ A	10.41
CaO	63.60	C ₄ AF	8.22
MgO	1.90	CaSO ₄	4.09
Na ₂ O	0.10	(K,Na) ₂ SO ₄	1.38
K ₂ O	1.00	CaO	0.58
CaO (free)	0.58	CaCO ₃	3.53
CO ₂	1.55	Bogue calculations according to [1]	
SO ₃	3.12		
Total	99.95		

The following section is a summary of methods used. The methods are described in more detail in [4].

2.1 Rheology

Viscoelastic properties of fresh paste are measured with a Paar Physica MCR 300-rheometer that enables dynamic measurement of low-amplitude oscillatory shear [5], [6] with a cylindrical measuring geometry. Measuring conditions: Temp. 20°C, RH>90%, pre-shearing: 1 minute/100s-1 shear rate, strain amplitude: 5*10⁻⁵, angular frequency: 2.5s⁻¹, measuring rate 1/min, dynamic measurement during the first 220 minutes.

2.2 Calorimetry

Hand mixed pastes are measured in a calorimeter under isothermal conditions at 20°C. The evolution of heat flow as a response to exothermal hydration reactions is documented over the first 60 hours.

2.3 Glove box experiments

Hydration experiments are performed in a glove box under nitrogen gas atmosphere in order to prevent carbonation. For each hydration step (1, 20, 30 min. 1, 1.5, 2, 4, 6 hrs. 1, 2, 7, 28 days) a batch of paste is mixed separately. For hydration steps less than 1 day, hydration is stopped by pore solution extraction with vacuum filtration through a 0.45 µm membrane filter. Subsequently filter residues and pore solutions are prepared for further investigations. For samples older than 6 hours, hydration is stopped by evaporation of free water at 50 °C.

2.4 ESEM (Environmental Scanning Electron Microscope; Philips XL30 FEG) [7]

Microstructural aspects are investigated qualitatively by Secondary Electron Imaging (SEI) [8], [9], [10], [11], [12] on fractured surfaces from filter residues, which are transferred from the glove box in a moist state immediately after pore solution extraction. For each time step phase fractions of hydrates are estimated relative to the total of the hydration products. Conditions in ESEM: H₂O vapour pressure 3-6 mbar, Temp <10°C, RH 60-95%.

2.5 ESEM: Back Scattered Imaging (BSI)

From one part of each filter residue polished sections are prepared (drying 110°C, impregnation, lapping, polishing [13]). From BSI the degree of hydration is estimated and EDX analyses are performed (the latter are not presented in this paper).

2.6 X-ray powder diffraction (XRD) and soluble calcium ("free lime")

Material from fresh filter residues (<1day) and from crushed samples (>1day) are washed with acetone twice, then filtered (<63 μm) and dried at 50°C for 24 hours. From these samples XRD-patterns are determined with a Siemens D500 (5-65° 2 θ , 1.2°/min.). For each spectrum the major peaks are summarized. From this, relative peak intensities of the different crystalline phases are calculated. In addition "free lime" is determined after the method of Franke [14]. Thereby soluble calcium is extracted with ethylene glycol mainly from portlandite and from calciumoxide in clinker.

2.7 Chemical composition of pore solution

OH⁻ concentrations are determined with a combined pH-electrode. Concentrations of Al, Ca, Fe, Mg, Na, K, SO₄ and Si are determined by ICP-OES.

3. RESULTS AND DISCUSSION

3.1 Rheology and Calorimetry

During the transformation of fresh paste from a suspension to a solid material four characteristic periods are generally distinguished. The induction period during the first few minutes is characterised by an exothermal peak (see Figure 1, **heat flow**), which is attributed to the dissolution of soluble cement components (compare section 3.4: pore solution chemistry).

Figure 1. Changing properties of fresh paste, consisting of ordinary PC (CEM I 42.5, w/c-ratio 0.5), monitored by the measurement of **heat flow in an isothermal calorimeter** and of **visco-elasticity in a rheometer** by lowamplitude oscillatory shear method.

For the dormant period significantly lower heat flow indicates strongly reduced reaction rates. This is also reflected by slow changes of the rheological properties (see Figure 1, **G'** and **G''**). The **storage modulus G'** represents the elastic (reversible, solid-like) response of the material to the oscillating strain. The **loss modulus G''** describes the viscous (irreversible, liquid-like) response [5]. In the dormant period **G'** and **G''** show an increasing gradient, which indicates a slow stiffening of the paste. The start of the acceleration period is then characterised by an exponential increase of **G'** and **G''** which reflects a more "rigid" behaviour due to the interaction of newly formed hydration

products. The faster growth of G' compared to G'' indicates that the paste becomes more solid-like. This stiffening, which is not correlated with significant development of compressive strength, is called setting and it is not a strictly defined physical state. In our experiments setting can be attributed to the time span between first hindrance of Vicat-indentation at 150 ± 10 min. and the "rheometer wall slip" after 219 min. A further typical feature of the acceleration period is the strong increase of heat evolution between 2.5 and 12 hours which reflects faster hydration rates. Afterwards decreasing hydration rates lead to a thermal relaxation in the retardation period. Strength development slowly starts after the setting, is relatively fast during the first days and slowly continues for months and years.

3.2 Microstructural Investigation

3.2.1 Estimation of hydration rates and degree of hydration

In a paste with ordinary PC (eg. CEM I 42.5) only a few % of the clinker grains are transformed into new hydration products during the first hours. It is thus very difficult to quantify the degree of hydration in young cement pastes with a satisfying accuracy [15]. By means of Back Scattered Imaging (BSI) the progress of hydration can be documented qualitatively (See Figure 2):

Figure 2. Back Scattered Imaging (BSI) in ESEM: Growth of hydration products in a paste with ordinary PC (CEM I 42.5), w/c-ratio 0.5. Legend: black=porosity, dark grey=hydration products, bright grey=unhydrated clinker, IP=Inner Product, OP=Outer Product.

2(a) after 2 hours: Dissolution preferentially attacks edges and cracks. This leads to a fragmentation of yet unhydrated clinker grains. **2(b)** after 2 hours: The thickness of the hydration layer is below $0.5 \mu\text{m}$. **2(c)** after 6 hours: Clinker grains are covered by $0.5\text{-}1 \mu\text{m}$ C-S-H (VI), called Inner Product. Less than 5 % of the clinker are transformed into hydrate phases. **2(d)** after 24 hours: The IP layer reaches a thickness of $1\text{-}2 \mu\text{m}$. In the interstitial space OP is formed. The degree of hydration is estimated to 0.2.

Within the first minutes dissolution is the dominating process [1]. Thereby cement grains are not uniformly dissolved. “High energy sites” along edges or cracks are preferentially eroded. This leads to a fragmentation of those clinker grains with a lot of inherited cracks (Figure 2a). At this stage the cement grains are hardly hydrated and there is only a thin hydration layer of a few 100 nm recognisable (Figure 2b). Within the next hours the hydration layer is growing constantly and it reaches a uniform thickness of 0.5 to 1 μm after 4 to 6 hours (Figure 2c) and 2 μm after 24 hours (Figure 2d). Based on the microstructural observations the degree of hydration is estimated to <0.05 after 6 hours and to 0.2 after 24 hours.

The evolution in the degree of hydration based on two simple hydration models with a constant (0.833 %/hr) and variable hydration rates (0-4 hrs: 0.417 %/hr, 4-12 hrs: 1.666 %/hr, >12hrs: 0.417 %/hr) is shown in Figure 3.

Figure 3. Two models for the degree of hydration as a function of time: **Red squares:** constant hydration rate. **Blue diamonds:** variable hydration rate The hydration rates of the corresponding periods are given below.

Both curves are forced through the estimated degree of hydration of 0.2 after 24 hours. This value reflects an estimation which is based on BSI (Figure 2). The curves for the degree of hydration obtained from the two models are not significantly different during the early hydration period.

3.2.2 Description and quantitative estimation of hydration phases

C-S-H is the main hydration phase in ordinary PC. Various models exist for the nanoscale structure [16], [17], [18], [19], [20]. Although nuclei with a crystalline structure are generally accepted, C-S-H has an amorphous behaviour with respect to X-rays. The quantification of C-S-H by means of XRD is therefore difficult. An alternative approach for an approximate quantification of hydration products is the estimation of phase fractions based on ESEM-investigations (Figure 4).

During the first 20 minutes clinker grains are covered by a very thin layer (Figure 5a) of amorphous C-S-H (IV) (C-S-H types according to [21]). Within this gel layer tiny crystals of short prismatic ettringite (average length: 300 nm) can be observed (Figure 5b). In the first 4 hours amorphous C-S-H (IV) (80%) and ettringite (20%) are the dominant hydration products (Figure 4). After four hours locally a new type of C-S-H (II) with a spongy appearance is observed (ca. 7%) (Figure 5c). At the same time also first flakes of portlandite precipitate (ca. 3%).

Figure 4. Volumetric fractions of hydration phases in the cement matrix as a function of time. The estimated compositions are based on microstructural observations in the ESEM.

After six to seven hours the amount of spongy C-S-H (II) increases (max. 30%), together with the formation of a new, fibrous or needle like type of C-S-H (I) (Figure 5d). Obviously a transformation of C-S-H types occurs between 4 and 24 hours. The amorphous C-S-H (IV) is dominant during the dormant period. A transitional spongy type C-S-H (II) grows during the setting and early acceleration period. Finally, fibrous C-S-H (I) becomes the dominant phase in mature pastes (up to 80 %). However, no strict stability fields can be defined for the different C-S-H types, which can also be formed contemporaneously. A new generation of long prismatic ettringite ($> 1.5 \mu\text{m}$) is formed between 6 and 24 hours. At the same time the relative amount of portlandite is increasing constantly and is then stabilising after 24 hours at approximately 10 % of the total amount of hydration products.

Figure 5. Morphology of typical hydration products in a paste of ordinary PC (w/c 0.5), observed in ESEM with gaseous Secondary Electron Imaging (SEI) under 60 to 95 % relative humidity.

5(a) After 20 minutes: A thin layer of amorphous C-S-H (IV) covers the cement grains. **5(b)** After 2 hours: Hexagonal ettringite prisms (~300 nm length) embedded in a layer of amorphous CS-H (IV). **5(c)** After 4 hours: Spongy type of C-S-H (II). **5(d)** After 24 hours: Fibrous type of C-S-H (I).

Figure 6. Volumetric phase fractions of hydration products, normalised by the degree of hydration at the corresponding time. (100 % = total of solid phases). Quantitative estimation of phase fractions from Figure 4, multiplied by the degree of hydration from Figure 3 (constant hydration rate).

3.2.3 Inner Product (IP), Outer Product (OP) and Hollow shell hydration

According to the geometric relationship with unhydrated clinker grains, two different types of hydration products can be distinguished: Inner Product (IP) and Outer Product (OP) as documented in Figure 7.

Figure 7. Inner Product (IP), Outer Product (OP) and Small Intersitital grains (SIG) in a paste of ordinary PC (w/c 0.5) observed in ESEM.

7(a) BSI after 6 hours: The IP layer covering unhydrated cement grains has a uniform thickness of less than 1 μm . In this locality first fibrous OP is observed. **7(b)** BSI after 6 hours: Locality without OP. Small interstitial grains (SIG) between larger cement grains form an interstitial meniscus. **7(c)** and **7(d)** SEI after 24 hours: Part of the IP is broken away and gives insight to the unhydrated clinker core. Within the hollow space between IP shell and clinker core, ettringite and portlandite are precipitating. The surface of IP is covered by fibrous C-S-H (I). Amorphous C-S-H (IV) is also present.

The IP partially or fully replaces the formerly unhydrated cement grains. After the first two hours only a thin gel layer ($<500\text{ nm}$) covers the cement grains. From this boundary layer the IP grows concentrically towards the center. After 4 to 6 hours the IP has a uniform thickness of 1 μm (Figure 7 a and b). Between the IP shell and the unhydrated clinker core empty space is formed (Fig. 7 c and d). Dissolution of the clinker core thus seems to be faster than the growth of the IP.

This phenomena is termed "hollow shell hydration" [22], [23]. Within the hollow space ettringite and portlandite are precipitating (Fig. 7 d) before the space is filled with C-S-H. As a result IP replaces the initial clinker grains by forming a dense pseudomorph.

Initially the interstitial space between the clinker grains is filled with pore solution. In a mature paste the interstitial space is overgrown by porous and heterogeneous hydration products, i.e. the OP. First local accumulations of OP are observed after 6 hours (Figure 7a). This is contemporaneous with the first appearance of fibrous C-S-H (I). In contrast to the short fibrous C-S-H (I) in IP (Length $\sim 200\text{ nm}$), OP is characterised by longer C-S-H fibres ($>500\text{ nm}$). After 24 hours the fibrous OP forms an interstitial matrix in which portlandite, ettringite but also small interstitial cement grains (SIG) are embedded.

In summary the terms IP and OP reflect a concept for the description of the cement microstructure on a μm - to mm-scale. The size of most hydrate phases however is below 1 μm and what is considered as IP or OP, frequently represents a mixture of C-S-H with other phases like portlandite, ettringite or C-A-H. In summary, the boundaries of IP and OP are not strictly defined [24]. It is often impossible to distinguish IP of small cement grains from the surrounding OP-matrix. IP and OP should therefore not be considered as distinct phases with fix properties (porosity, density, chemistry). These properties depend on the composition and structure on a sub- μm scale, where IP and OP are heterogeneous.

3.2.4 Small Interstitial Grains (SIG)

As shown in Figure 2, small interstitial cement grains (SIG) with a diameter below 5 μm react faster than larger cement grains ($>10\text{ }\mu\text{m}$). Already after 2 hours the small cement grains are embedded in a diffuse gel layer. The apparent higher reactivity of small cement grains can be explained by a higher surface/volume-ratio. As a consequence the gel layer covering SIG is relatively voluminous compared to the distinct IP-layer on large cement grains (Figures 8a and 8b).

In addition SIG tend to form multi-grain agglomerations which act as a connecting meniscus between larger cement grains (Figure 7b). After 4 to 6 hours spheroids with a typical diameter of 2 μm are frequently observed (Figure 8c and 8d). It is suggested that the reactive multi grain agglomerations (initially consisting of SIG) represent precursors or nuclei of the spheroids.

Together with the slowly precipitating OP these reaction products represent the major connecting elements between the larger cement grains during the first hours of hydration. At this stage the small interstitial products may be a dominant factor with respect to the interparticle forces. This should be taken into consideration when microstructural aspects are discussed in relation to properties of fresh paste (rheology, stiffening, setting and early strength development).

Figure 8. Agglomeration and hydration of Small Interstitial Grains (SIG) observed in ESEM.

- 8(a)** after 2 hours: Small clinker grains with a diameter of $1\mu\text{m}$ (or less) form agglomerations. The small grains are embedded in a diffuse hydration layer consisting of amorphous C-S-H (IV).
8(b) after 6 hours: A large number of fully hydrated grains, typically with a diameter of $2\mu\text{m}$ form agglomerations in the interstitial space between larger cement grains. The "2 μm spheroids" are connected by a massive gel of C-S-H (IV). **8(c)** after 6 hours: Numerous "2 μm spheroids" form an interstitial matrix which connects the larger cement grains. **8(d)** after 24 hours: Due to the fibrous C-S-H (I) the spheroids become a hedgehog-appearance.

3.3 X-Ray powder diffraction (XRD) and soluble calcium

The results from X-Ray diffraction are summarised in Figures 9 and 10. During the induction and dormant periods (first 4 hours) the relative intensities of the clinker phases remain nearly stable. Only for C3A a slight decrease is indicated within the first minutes. C3S shows a significant decrease between 6 and 24 hours (acceleration period). Between 6 hours and 28 days 80 to 90 % of C3A are decaying. For C2S and C4AF only little changes can be recognised even after 28 days.

Hemihydrate is the most reactive sulfate carrier. Within the first 30 minutes it disappears completely. A part of it seems to be transformed into gypsum, which increases significantly during the first two hours. Between 4 to 6 hours and one day gypsum and anhydrite are almost completely dissolved.

The first reaction product, which precipitates after 1 minute, is ettringite. Between six hours and 7 days a second generation of ettringite is formed. Small quantities of portlandite ($\text{Ca}(\text{OH})_2$) can be detected after 4 hours and in the following period it is growing constantly. This is compatible with the concentrations of soluble calcium ("free lime") which are determined after the method of Franke [14]:

hydration time:	1min	0.5	1	1.5	2	4	5	6	hrs
"free lime":	0.59	0.57	0.59	0.63	0.66	0.99	1.41	1.82	wt-%

From the comparison of the two methods it follows that the detection limit of Ca(OH)_2 in XRD corresponds to 0.6 - 1.0 % soluble calcium.

Figure 9. XRD results showing relative peak intensities as a function of hydration time for the following crystalline phases:- C3S: alite, C2S: belite, CH: portlandite.

Figure 10. XRD results for:- C3A: aluminate, C4AF: ferrite, CSH2: gypsum, CSH0.5: hemihydrate, Cs: anhydrite, AFt: ettringite.

3.4 Pore Solution Chemistry

Pore solution was collected using the vacuum filtration technique during the first 8 hours. A comparison with published pore solution data from more mature OPC pastes [25], [26] indicates comparable ion-concentrations, except for K, Na and SO_4 , which vary with the corresponding cement compositions. The comparison of different sets of data indicates that the temporal development of pore solutions generally follows similar trends. Data from the literature [25, 26] data are therefore used in Figure 11 to extrapolate from the measured pore solution compositions (8 hours) to concentrations at longer hydration times.

The changes of ionic concentrations in solution are related to dissolution and precipitation of solid phases (compare Figures 9, 10 and 11). K, OH^- and SO_4 show the highest concentrations in pore solutions from fresh paste, while Na, Ca and Si are present at somewhat lower concentrations.

Figure 11. Measured concentrations in the pore solution of ordinary PC as a function of time. Data given in [25] and [26] were used to draw the approximate development of pore solution compositions at hydration times longer than 8 hours.

The relatively high concentrations of K and Na after a few minutes are largely due to the dissolution of alkali-sulphate phases (K_2SO_4 , $3K_2SO_4 \cdot Na_2SO_4$) in cement. Over time the concentrations of alkalis increase complementary to the hydration rate of clinker phases. The release of K and Na is attributed mainly to the dissolution of C3A and gypsum.

Similarly, the high initial sulphate concentrations stem from the ready dissolution of the alkali-sulphate phases as well as from the presence of the Ca-sulphate phases. Sulphate concentrations slowly decrease during the first hours of hydration due to the precipitation of ettringite. After 1 to 2 days, sulphate concentrations in OPC pore solutions decrease drastically. At this time gypsum and anhydrite disappear, while the precipitation of ettringite continues until the sulphate present in solution is consumed (see Figures 10 and 11).

The hydroxide concentrations increase constantly from initially 90 mmol/L (1 min.) over 150 mmol/L (6 to 8 hours) to 300 mmol/L in mature pastes. Measured calcium concentrations increase from initially 15 mmol/L to 20-25 mmol/L after 4-6 hours. Afterwards calcium decreases again because portlandite is limiting its solubility with increasing OH^- concentrations.

Silicate and magnesium concentrations are low and little changes can be observed during the first hours of hydration. The concentration of Al and Fe are below the respective detection limits ($Al < 0.04$ mmol/L; $Fe < 0.01$ mmol/L), as the precipitation of ettringite and Fe-bearing phases efficiently removes Al and Fe from the pore solution.

4. CONCLUSIONS

There is no single method which can describe the different aspects of hydration processes sufficiently. For physico-chemical investigations of cement hydration a correlation between complementary methods has to be applied. Major changes of early paste properties such as stiffening and setting are related to very small changes of the hydration products. The degree of hydration during setting is below 0.05. These minor changes are difficult to measure quantitatively. However they can be documented by qualitative microstructural investigations with ESEM.

The main hydration product is C-S-H which can be described as a solid phase with characteristics of

a gel [27]. C-S-H is a non-stoichiometric phase for which the following morphological types can be distinguished: structureless/amorphous (IV), spongy-type (II) and fibrous (I). During the dormant period structureless C-S-H prevails. In mature pastes C-S-H mainly consists of a fibrous type.

From the microstructural investigations it follows that changes of the material properties are not exclusively determined by the amount and type of hydration phases. Of major importance are structural elements, such as small interstitial grains (SIG) which form a meniscus of hydration products between larger cement grains. Because hydration rates of small particles are faster, SIG can form agglomerations of hydration products in the interstitial space within a short time. In this way SIG influence the interactions between the cement particles significantly and therefore they are interpreted as dominant factors which control physical properties in fresh pastes, eg. viscoelasticity.

Another view on the hydration processes considers chemical solid-liquid interactions. The chemistry of pore solutions during the first hours is dominated by the dissolution of reactive cement phases such as alkali-sulphate phases in clinker or $\text{CaSO}_4 \cdot 0.5\text{H}_2\text{O}$ and the simultaneous precipitation of ettringite, gypsum, portlandite and the C-S-H phases. Significant changes of the pore solution chemistry during the acceleration period can be correlated with the dissolution of C3A, C3S and gypsum and the precipitation of ettringite, portlandite and C-S-H. However, the low solubility of SiO_2 puts limitations on the link with microstructural observations on C-S-H. In summary, most significant changes of the pore solution chemistry occur subsequent to the setting, contemporaneous with important compositional changes, as observed with XRD. In this period considerable reaction volumes are affected by the hydration process which can be linked on a macroscopic scale with the increase of strength. In contrast, properties of fresh, viscous pastes depend on minimal volumetric changes, which are difficult to show by chemical measurements and phase quantifications. Thus for the early hydration period qualitative investigations of the microstructure with ESEM are of major importance.

ACKNOWLEDGEMENTS

This study was financed by Swiss Federal Institute of Materials Testing and Research (EMPA) and by MBT (Schweiz) AG. The authors would like to thank L. Brunetti for assistance with glove box experiments, M. Guecheva for ICP-OES- and U. Gfeller for XRD-measurements. Fruitful discussions with J. Kaufmann contributed a lot to this paper.

1. INTRODUCTION

Some compounds among the group of layered Calcium aluminate hydrates are important for the process of cement manufacturing. Their chemical composition can be described by the following general formulae:

Structurally they consist of positively charged layers of $[\text{Ca}_2\text{Al}(\text{OH})_6]^+$ and negatively charged interlayers of $[\text{OH} \cdot n\text{H}_2\text{O}]^-$. Detailed structural studies were done with Monosulfate ($3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$) and Monochloride ($3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$). The structure is shown in Figure 1.

Figure 1. Structure of α -Monochloride

Tetra Calcium Aluminate Hydrate with the formula $C_3A \cdot Ca(OH)_2 \cdot nH_2O$ is especially suitable as storage mineral, because of its layered structure^[2,3,4,5,6]. It is widely used to incorporate efficiently for example heavy metals, because the OH-group in the interlayers can be exchanged for 1^+ - or 2^+ -anions (Figure 1).

Tetra Calcium Aluminate Hydrate with the formula $C_3A \cdot Ca(OH)_2 \cdot nH_2O$ is especially suitable as storage mineral, because of its layered structure^[2,3,4,5,6]. It is widely used to incorporate efficiently for example heavy metals, because the OH-group in the interlayers can be exchanged for 1^+ - or 2^+ -anions (Figure 1).

It is well known that chromates are capable of accelerating cement hydration. Chromate is the reason for the so called “Cement- or Bricklayer-eczema”. Formation of these lamellar calcium aluminate hydrates (in connection with hydration of calcium aluminates) can proceed under variable conditions:

1. Formation in concrete due to harmful substances in the environment.
2. Formation due to additives controlling cement hydration
3. Formation under controlled conditions as storage minerals

Monosulfates also form in nature, as was shown by Pöllmann, who described natural Monosulfate (“Kuzelite”) as alteration products in basalts (i.e. Zeilberg by Maroldsweisach in Lower Franconia/Germany)^[7].

2. METHODS

Mixtures with different loading agents and BFD in various parts were investigated:

fresh heated lime + technical calcium aluminate : BFD =

0.5	:	1 M%
1	:	1 M%
1	:	0.5 M%

The amounts were filled into polyethylene vials and reacted with distilled water (solid-to-liquid ratio = 1:15) for variable times. After 1, 5, 10 and 24 hours the samples were filtered. The filtrates were analyzed for their chromate content with ICP, the insoluble residues were investigated with XRD and SEM.

3. RESULTS

3.1 Investigation of the chromate content in the filtrates after reaction with agents

The chromate content in the component ratio is:

0.5	:	1	=	17.34 [mg/l]
1	:	1	=	35.11 [mg/l]
1	:	0.5	=	68.99 [mg/l]

The content of chromate in the filtrates after different times is shown in table 1.

Table 1. Content of chromate in the filtrates after different times. 0.03 [mg/l] ≈ detection limit

mixture	Chromate content (mg/l)		
	1 : 0.5	1 : 1	0.5 : 1
time (h)			
0h	17.34	35.11	68.99
1h	0.08	16.86	49.82
5h	≤0.03	0.17	39.94
10h	≤0.03	≤0.03	0.12
24h	≤0.03	≤0.03	≤0.03

3.2 Investigation of the insoluble residues by X-ray diffraction

Figure 2 shows the XRD diagrams of residues after different periods of reaction.

Figure 2. XRD diagrams of residues after different times of reaction

3.3 Examination of the storage minerals and reaction products in the residues by SEM

Figure 3 shows a Cryo-SEM picture of a residue after a reaction time of 24 h. Portlandite and lamellar Calcium aluminate hydrate (storage mineral) can be seen as hexagonal platy crystals near phases of BFD.

Figure 3. Cryo-SEM image of a residue, reaction stopped after 24h, scale bar = 10 μm

4. DISCUSSION AND CONCLUSION

Amounts of chromium (VI) in mixtures with BFD originally containing 70 mg/l, were less than 0.03 mg/l after conversion of TCAH into a lamellar storage mineral like Monochromate. Suitable procedures can be transferred from laboratory scale to the scale of technical industry processing. TCAH can be synthesized through stoichiometric compositions of various educts.

The possibility for chromate removal from BFD-solutions and for recycling is illustrated in the following scheme^[8]:

ABSTRACT

Lamellar Calcium aluminate hydrates are hydration products in ordinary Portland cements and play an important role in the hardening process. Due to the fixation ability of organic and inorganic ions the technical features of lamellar phases are important as reservoir minerals for pollutants. Formation of these hydrates can proceed under variable conditions:

- Formation in concrete due to harmful substances in the environment
- Formation due to additives controlling cement-hydration
- Formation under controlled conditions as storage minerals

1. INTRODUCTION

Some compounds among the group of layered Calcium aluminate hydrates are important for the process of cement manufacturing. Their chemical composition can be described by the following general formula: $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaX} \cdot n\text{H}_2\text{O}$ and $3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaY}_2 \cdot n\text{H}_2\text{O}$ with $\text{X} = \text{SO}_4^{2-}$, CO_3^{2-} , CrO_4^{2-} , ... and $\text{Y} = \text{OH}^-$, Cl^- , NO_3^- , [1,2,3]. Structurally they consist of positively charged layers of $[\text{Ca}_2\text{Al}(\text{OH})_6]^+$ and negatively charged interlayers of $[\text{OH} \cdot n\text{H}_2\text{O}]^-$.

Detailed structural studies were done with Monosulfate ($3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4 \cdot 12\text{H}_2\text{O}$) and Monochloride ($3\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaCl}_2 \cdot 12\text{H}_2\text{O}$).

Tetra Calcium Aluminate Hydrate (TCAH) with the formula $\text{C}_3\text{A} \cdot \text{Ca}(\text{OH})_2 \cdot n\text{H}_2\text{O}$ is especially suitable as storage mineral, because of its layered structure. It is widely used to incorporate efficiently for example heavy metals, because the OH-group in the interlayers can be exchanged for 1^+ - or 2^+ -anions [4,5].

Storage minerals can be used or added for the immobilization of inorganic and organic substances in contaminated water, gas and soil. The composition of the harmful substance to be immobilized depends on the structure and the kind of the compounds. The immobilization of toxic substances is based on the crystallo-chemical fixation and physical aggregation due to the crystallization of metal-metal-hydroxy salts. These compounds offer a great possibility for diadochism of cations and anions. The fixation of non-polar and polar molecules is guaranteed by additional bonding mechanisms (hydrogen bond, residual bond, etc.) and crystallo-chemical replacement.

The idealized composition of the metal-metal-hydroxy salts are :

The following cations and anions can be partially or completely replaced:

1. :	Cu ²⁺	2. :	Co ³⁺	4. :	CrO ₄ ²⁻	BrO ₃ ⁻	MnO ₄ ⁻	Mo ₇ O ₂₄ ⁶⁻
	Ni ²⁺		Mn ³⁺		SeO ₄ ²⁻	Br ⁻	CN ⁻	Fe(CN) ₆ ³⁻
	Zn ²⁺		Ga ³⁺		SeO ₃ ²⁻	CO ₃ ²⁻	HCOO ⁻	Fe(CN) ₆ ⁴⁻
	Ca ²⁺		Cr ³⁺		SiO ₃ ²⁻	ClO ₄ ⁻	OCN ⁻	
	Cd ²⁺		Al ³⁺		ClO ₃ ⁻	SO ₃ ²⁻	S ₂ O ₃ ²⁻	
	Mg ²⁺		Fe ³⁺		B(OH) ₄ ⁻	NO ₃ ⁻	WO ₄ ²⁻	
	Fe ²⁺		In ³⁺		OH ⁻	J ⁻	C ₆ H ₅ -(CH ₂) _n -COO-	
	Co ²⁺		Ni ³⁺		NO ₂ ⁻	SCN ⁻	(CH ₃) _n -(CH ₂) _n -COO-	
	Mn ²⁺		Ga ³⁺		Cl ⁻	SO ₄ ²⁻	-OOC-(CH ₂) _n -COO-	
					JO ₃ ⁻	Al(OH) ₄ ⁻	H ₂ W ₁₂ O ₄₀ ⁶⁻	

3. : Adsorption of (in)organic, (non)polar molecules
 5. : Fixation instead of H₂O
 6. : Additional fixation of e.g. : Na₂SO₄, KClO₄, Na₂CrO₄, etc.
 7. : Additional incorporation of (non)polar molecules

This paper shows the examination of the fixation of NO₃⁻, SO₄²⁻ and Cl⁻ in TCAH as a function of different educt concentrations. In addition an estimate is presented on the fixation in TCAH under the influence of the cations Na⁺ and K⁺ (in variable concentrations) /6/.

Detailed statements about the disturbing effects of the cations on the anions in different concentrations in solution are given, with regard to preferred immobilisation of the anions in the crystalline residue.

2. METHODS

Stoichiometric amounts were filled into polyethylene vials and reacted with CO₂-free water under a protective gas filling for 14 days. The mineral phases studied are eager to exchange CO₂ for any other anions. Therefore care was taken to use CO₂-free water. Reactions, drying and further sample preparation were done in a glove-box filled with nitrogen.

X-ray diffraction techniques were used to identify the reaction products and to determine their lattice parameters. In order to inhibit carbonate formation during x-ray analysis, the counting was done at 100% humidity, without air inside a TTK camera, which was flushed with nitrogen gas of technical quality. A wet piece of cloth inside the chamber during the measurements guaranteed almost 100% humidity.

3. RESULTS

Various concentrations of the cations just mentioned have a substantial influence on the formation of TCAH containing nitrate, chloride and sulphate in the presence of the anions NO₃⁻, SO₄²⁻ and Cl⁻.

Nitrate containing lamellar phase

Comparison of the fixation of nitrate, chloride and sulphate in [ppm] as a function of the conc. of sodium:

Comparison of the fixation of nitrate, chloride and sulphate in [ppm] as a function of the conc. of potassium:

4. CONCLUSIONS

- Fixation behaviour of sulphate, chloride and nitrate in presence of sodium or potassium:

1.0 mol Sodium	:	Chloride > Nitrate > Sulphate
0.5 mol Sodium	:	Chloride > Nitrate > Sulphate
0.1 mol Sodium	:	Sulphate > Chloride > Nitrate
1.0 mol Potassium	:	Chloride > Nitrate > Sulphate
0.5 mol Potassium	:	Chloride > Nitrate > Sulphate
0.1 mol Potassium	:	Sulphate > Nitrate > Chloride
- High sulphate contents disturb the crystallisation of lamellar calcium aluminate hydroxy salts.
- Lower sulphate contents give preferential the crystallisation of nitrate and chloride containing lamellar phases.
- Chloride containing lamellar phases were identified in the presence of primary crystallised sulphate-ettringite and near gypsum
- A chloride containing lamellar phase in the presence of sulphate-ettringite exclusively forms at high sulphate and low chloride concentration.
- In comparison to sodium, potassium prefers the fixation of sulphate in sulphate-ettringite by different concentrations of nitrate, chloride and sulphate.

ABSTRACT

Three different groups of lamellar calcium aluminate sulfonate hydrates were purely synthesized. Metric parameters were refined and structural properties of the new Afm – phases were discussed. The influences of different relative humidities in the range of 100...35 % and the influence of different temperatures on the stability of the Afm – salts was studied in detail. In addition, binary systems of $C_3A \cdot Ca(OH)_2 \cdot nH_2O$ - $C_3A \cdot Ca(X)_2 \cdot nH_2O$ were investigated at different r.h. in order to determine phase compositions and the crystal chemistry of newly formed Afm-phases.

1. INTRODUCTION

In Ordinary Portland Cements (OPC) the aluminate phase of the clinker reacts together with $CaSO_4 \cdot nH_2O$ and water to ettringite (Aft-phase) and in a second step to monosulfate, which belongs to the family of lamellar calcium aluminate hydrate (Afm-phases). Calcium Aluminate Cements (CAC) crystallize C_2AH_8 and AH_3 as reaction products of CA at intermediate temperatures. C_2AH_8 itself belongs to the group of Afm – phases. In comparison to monosulfate, $Al(OH)_4^-$ ions are fixed in the so called interlayer of the structure. As indicated, Afm-phases [1], [2], [3] are based on layered structures, built up of main layers $[Ca_2Al(OH)_6]^+$ and interlayers $[X \cdot nH_2O]^-$ or $[1/2 Y \cdot nH_2O]^-$ ordered in the direction [001]. X and Y are placeholders for inorganic or organic anions. In the main layer Al-atoms form a distorted brucite lattice. The octahedral sites are occupied by Ca-atoms. Whereas the coordination of Al is 6 the coordination of Ca is 7, which results in an additional coordination with an O-atom of a water molecule of the interlayer. The interlayer is a fragile area, built up of weakly bonded water – anion frameworks. Water molecules can be easily removed and the anion exchanged against further inorganic or organic anions. Because of the application of different additives in cement chemistry to manipulate the properties of the cement paste and the concrete, the kinetics of the hydration process and rheology were influenced [5], [6], [7]. The presented investigations deal with the influence of additives on the influence on the crystal chemistry of Afm-phases.

2. EXPERIMENTAL

2.1 Synthesis of the reactants

CaO was synthesised by sintering pure $CaCO_3$ (Merck p.a.) at 1000°C for 1h. The loss of ignition of $\gamma-Al_2O_3$ was determined at 1000°C for 1h, in order to correct the concentration of $\gamma-Al_2O_3$ for the

synthesis of CA. For the synthesis of CA, stoichiometric concentrations of CaO and Al₂O₃ were sintered at 1350°C several times for 1h with ball milling in between.

2.2 Synthesis of different Calciumsulfonatehydrates

Principally, stoichiometric concentrations of CaCO₃ and different sulfonic acids (Table 1) reacted in moist atmosphere. CaCO₃ was mixed with water to obtain a slurry. The sulfonic acid was added drop wise. After the combination of CaCO₃ and acid the solution became transparent under the formation of CO₂. In order to accelerate the reaction the synthesis was performed at 40°C and was stirred carefully. The measured pH-value at the end of the reaction CaCO₃ + sulfonic acid was 7. Afterwards the solution was evaporated in a drying oven at 30-40°C. After 5 days, transparent idiomorphic crystals were obtained and the chemical composition was determined, immediately.

Table 1. Sulfonic acids

Chemical formula	Description
Alkanesulfonic acids	
CH ₃ SO ₃ H	Methane sulfonic acid
C ₂ H ₃ SO ₃ H	Ethane sulfonic acid
C ₃ H ₃ SO ₃ H	Propane-1-sulfonic acid
C ₄ H ₃ SO ₃ H	Buthane -1-sulfonic acid
Benzene sulfonic acids	
C ₆ H ₅ SO ₃ H	Benzene sulfonic acid
C ₇ H ₇ SO ₃ H	Toluene-p-sulfonic acid
C ₈ H ₉ SO ₃ H	Xylene sulfonic acid
C ₉ H ₁₀ SO ₃ H	Mesitylene sulfonic acid
Naphthalene sulfonic acids	
C ₁₀ H ₇ SO ₃ H	Naphthalene-1-sulfonic acid
C ₁₀ H ₇ SO ₃ H	Naphthalene-2-sulfonic acid

2.3 Instrumentation

The XRD measurements were performed on a SIEMENS 5000 Diffractometer with CuK_α radiation. For the temperature and humidity controlled measurements a TDK camera from PAAR was used. During the measurements the interior of the camera was purged with N₂. In order to install different relative humidities the N₂ was pumped slowly through saturated salt solutions. The following parameters in Table 2 were used for the measurements.

Table 2. Parameters for XRD measurements

Parameters	Values
2Theta [°]	3...80
Voltage [kV]	40
Current strength [mA]	30
Step 2Theta [°]	0.01
Count time [s]	1
Scatter- and Antiscatter slit	Variable

In order to determine the loss in weight and to determine the onset temperatures of the different dehydration reactions a TG/DTG 320CU and a DSC 220 of SEIKO were used. For the specific determination of the water concentrations Karl-Fischer instrument of Methrom with an oven was applied. Chemical analyses of the different lamellar calcium aluminate sulfonate hydrates were performed by AAS and ICP/OES. The sulfonic compounds were directly determined by the total organic carbon method.

3. RESULTS

After synthesis of 4 months, the precipitates of all samples were filtered under N_2 -atmosphere in the glove box and investigated immediately at 100 % r.h. by XRD. For the studies the salts were dried step by step to 35% r.h. and the chemical composition of each salt was determined.

The habit of the crystals showed in the case of the fixation of benzene- alkane- or naphthalenesulfonic acid anions in the crystal structure idiomorphic well crystallized individuals with the typical platy hexagonal habit. Especially calcium aluminate alkanesulfonate hydrates crystallize as platy aggregates (Figure 1).

Figure 1. SEM image of $C_3A \cdot Ca(CH_3SO_3)_2 \cdot 15H_2O$

3.1 Metric parameters of lamellar Calcium aluminate sulfonate hydrates

3.1.1 Metric parameters of lamellar calcium aluminate alkanesulfonate hydrates

The least-squares-refinements of the metric parameters of Afm phases (Table 3) is based on the structures of calcium aluminate sulphate hydrate [1] and the monoclinic calcium aluminate chloride hydrate [2]. Lamellar calcium aluminate alkanesulfonate hydrates crystallized in the trigonal system with possible space groups $R\bar{3}$, $R\bar{3}m$ and $R\bar{3}m$. The unit cell contained 6 sequences $[Ca_2Al(OH)_6]^+[X \cdot nH_2O]^-$ (X = alkanesulfonic ion) perpendicular $[00l]$ at 100 % and 35 % r.h.

On the basis of the hexagonal setting of the unit cell the lattice parameter $a_0 = b_0$ varies in the region 0.577 ± 0.002 nm. Due to the chemical fixation of different long chained alkanesulfonic acid ions the layer distance $c' = c/6$ will be increased approximately linearly (Figure 2). STERN et al. (1996) showed that the chemical fixation of alkanesulfonic acid ions $C_nH_{2n-1}SO_3^-$ with $n > 4$ in the interlayer let the interlayer distance c' approach a saturation value for $n = 12$ at approximately 22 nm.

3.1.2 Metric parameters of lamellar calcium aluminate benzene sulfonate hydrates

At 100 and 35% r.h, calcium aluminate benzene sulfonate hydrate and calcium aluminate toluene-p-sulfonate hydrate crystallized on the basis of a hexagonal primitive unit cell with a sequence $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{X}\cdot n\text{H}_2\text{O}]^-$ per unit cell perpendicular $[001]$. However the fixation of xylene sulfonic ions in the interlayer of the Afm-phase forced the formation of a salt with a trigonal lattice, comparable to the lattices of lamellar calcium aluminate alkane sulfonate hydrates. In opposition, calcium aluminate mesitylene sulfonate hydrate crystallized monoclinic. The refined metric parameters of the different investigated lamellar calcium aluminate benzene sulfonate hydrates are summarized in Table 3. At 100 and 35% r.h, calcium aluminate benzene sulfonate hydrate and calcium aluminate toluene-p-sulfonate hydrate crystallized on the basis of a hexagonal primitive unit cell with a sequence $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{X}\cdot n\text{H}_2\text{O}]^-$ per unit cell perpendicular $[001]$. However the fixation of xylene sulfonic ions in the interlayer of the Afm-phase forced the formation of a salt with a trigonal lattice, comparable to the lattices of lamellar calcium aluminate alkane sulfonate hydrates. In opposition, calcium aluminate mesitylene sulfonate hydrate crystallized monoclinic. The refined metric parameters of the different investigated lamellar calcium aluminate benzene sulfonate hydrates are summarized in Table 4.

3.2 Stability of Afm-phases

3.2.1 Influence of variable relative humidities r.h. on the crystal chemistry of Afm - phases

In the interval 100...35% r.h. the salts were dried to 95%, 86%, 75%, 55% and 35% r.h. On each hydration level they were investigated by XRD. The water concentrations of the phases were determined by thermogravimetry (TG/DTG) and the Karl-Fischer Method. It could be proved that calcium aluminate buthane-1-sulfonate hydrate started dehydrating with the decrease of the relative humidity. Further dehydration reactions occurred hand in hand with lower r.h. atmospheres. Consequently, the layer distance decreased nearly linearly as a result of lower H_2O concentration in the interlayer region. According to the dehydration of butane-1-sulfonate containing Afm-phase, the processes of further investigated calcium aluminate alkanesulfonate hydrates took place. (See Figure 3)

The influence of variable relative humidities on the group of different calcium aluminate benzene sulfonate hydrates in the interval [100...35] caused a totally different behaviour against variable relative humidities (Figure 4). In opposition to the dehydration of calcium aluminate alkanesulfonate hydrates, the layer distances of calcium aluminate benzene sulfonate hydrates remained stable. Thermal analysis performed on the salts at different relative humidities gave the result, that the same H_2O concentrations always remained in the interlayer. Because of the stronger O – H bondings between H_2O molecules and the hydrogen atoms of the benzene ring and its CH_3 -substituents the water molecule were more strongly fixed than in the interlayer of calcium aluminate alkanesulfonate hydrates.

Figure 3. Variation of the interlayer water concentration of calcium aluminate alkanesulfonate hydrates as a function of r.h.

Figure 4. Variation of the interlayer water concentration of different calcium aluminate benzene sulfonate hydrates as a function of r.h.

3.2.2 Thermal stability of Calcium aluminate sulfonate hydrates

Thermal investigations of Afm - phases are divided into the dehydration processes of the interlayer $X \cdot nH_2O$ X = sulfonic acid ion and the main layer $[Ca_2Al(OH)_6]^+$. All 3 groups, calcium aluminate alkane-, benzene- and naphthalenesulfonate hydrates started dehydrating at 30-35°C. The interlayer water was released in several steps. According to the properties of the crystal structure of each salt, the major concentration was dehydrated as separate reactions between 30...120°C. More strongly fixed water molecules resisted the temperature increase until 150 °C. FISCHER (1982) [8] postulated, that these strongest bonded interlayer water molecules are the 7th coordination of calcium atoms of the main layer.

The main layer $[Ca_2Al(OH)_6]^+$ of the crystal structure dehydrated at higher temperatures approximately 250°C. It could be proved, that the dehydration process contained one or several reactions; hence not all of them were determined by TG/DTG because of the simultaneous dehydration processes and exothermal pyrolysis of the organic compound. Therefore, two dehydration processes should be discussed.

The interlayer area of calcium aluminate xylene sulfonate hydrate dehydrates in 4 steps (interlayer) at 34°C, 66°C, 86°C and 161°C. The main layer dehydrated in 1 step according to the loss in weight of the TG graph, water molecules were removed from the interlayer of the structure during heating. The chemical composition of the interlayer changed from $[(C_8H_9SO_3)_2 \cdot 8H_2O]^{2-}$ to $[(C_8H_9SO_3)_2 \cdot 5.5H_2O]^{2-}$, $[(C_8H_9SO_3)_2 \cdot 4H_2O]^{2-}$, $[(C_8H_9SO_3)_2 \cdot 2H_2O]^{2-}$ and consequently to $[(C_8H_9SO_3)_2 \cdot 0H_2O]^{2-}$. Therefore the layer distance decreased from originally 1.633nm to lastly 1.434nm (Figure 5).

As a further example the dehydration process of calcium aluminate naphthalene-1-sulfonate hydrate $[Ca_2Al(OH)_6]^+[C_{10}H_7-1-SO_3 \cdot 14H_2O]$ should be discussed. This salt dehydrated in the range of 25...100°C and 125...150°C. The dehydration of the main layer started at 217°C. However the c' values refined on the basis of temperature controlled XRD measurements, did not agree with the loss in weight and the heat flow (DSC). The interlayer dimension c' was not changed systematically as a function of increased temperature. Naphthalene-1-sulfonic acid anions changed slightly with increasing temperatures their orientation in the interlayer until a certain threshold value of the H_2O

concentration was reached. At approximately 112 °C the layer distance shrank drastically, the orientation of the naphthalene-1-sulfonic acid anions changed and the layer distance c' became extremely low (Figure 6).

Figure 5. Refinement of c' of temperature controlled XRD measurements of $\text{Ca}(\text{C}_8\text{H}_9\text{SO}_3)_2 \cdot 14\text{H}_2\text{O}$

Figure 6. Refinement of c' of temperature controlled XRD measurements of $\text{C}_3\text{A} \cdot \text{Ca}(\text{C}_{10}\text{H}_7\text{-1-SO}_3)_2 \cdot 14\text{H}_2\text{O}$ at 35 r.h.

3.3 Investigations in systems $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{OH} \cdot n\text{H}_2\text{O}]^-$ - $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{C}_{10}\text{H}_7\text{SO}_3 \cdot n\text{H}_2\text{O}]^-$

In the systems $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{OH} \cdot n\text{H}_2\text{O}]^-$ - $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{X} \cdot n\text{H}_2\text{O}]^-$ no solid solution $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{xX} \cdot (1-\text{x})\text{Y} \cdot \text{H}_2\text{O}]^-$ (X = sulfonic acid anions, Y = OH^-) in the range of 10...90 mole-% X were detected. At 100 % r.h., an Afm phase, identified as a pure calcium aluminate sulfonate hydrate on the basis of powder patterns determined during the investigations of pure Afm-phases, was identified by XRD. With the Afm-phase a Gel phase stood in chemical equilibrium and recrystallized at lower r.h to pure calcium aluminate hydroxide hydrate (Figure 7).

Figure 7. System $C_3A \cdot Ca(OH)_2 \cdot 12H_2O$ - $C_3A \cdot Ca(C_9H_{11}SO_3) \cdot 15H_2O$ at 35 % r.h.

However, in the system calcium aluminate hydroxide hydrate – calcium aluminate naphthalene-2-sulfonate $[Ca_2Al(OH)_6]^+[OH \cdot nH_2O]^-$ - $[Ca_2Al(OH)_6]^+[C_{10}H_7SO_3 \cdot nH_2O]^-$ at 100 and 35% r.h. a intermediate phase beside the pure phases was stable in the concentration range 10-70 mole-% $C_{10}H_7SO_3^-$. The composition of the intermediate phase varied respectively the concentration ratio $C_{10}H_7SO_3^-/OH^-$. The chemical formula is $[Ca_2Al(OH)_6]^+[xOH \cdot (1-x)C_{10}H_7SO_3 \cdot nH_2O]^-$. The structure of the phase is built up of 2 different sequences $[Ca_2Al(OH)_6]^+[C_{10}H_7SO_3 \cdot nH_2O]^-$ and $[Ca_2Al(OH)_6]^+[OH \cdot nH_2O]^-$. Because of the immiscibility of inorganic and sulfonic acid ions in the crystal structure, the interlayer contained only naphthalene-2-sulfonic or hydroxide ions in one layer. The systematic distribution of hydroxide and naphthalene-1-sulfonic acid ions in separate interlayers caused the formation of a superstructure. (Figure 8)

Figure 8. System $C_3A \cdot Ca(OH)_2 \cdot 12H_2O$ - $C_3A \cdot Ca(C_{10}H_7SO_3) \cdot 14H_2O$ at 35 % r.h.

4. DISCUSSION AND CONCLUSIONS

Pure phases of lamellar calcium aluminate alkanesulfonate hydrates, calcium aluminate benzene sulfonate hydrate and calcium aluminate naphthalenesulfonate hydrates were synthesized by paste reaction under equal conditions in the range of 4 months. All salts are built up of a layered structure based in most cases on a trigonal or hexagonal metric. Just calcium aluminate mesitylene sulfonate hydrate crystallized in the monoclinic crystal system. The unit cells of the synthesised phases contain one or 6 sequences of $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{X}\cdot\text{nH}_2\text{O}]^-$ X = sulfonic anion perpendicular c_0 .

The central point of these investigations dealt with the weak bondings between H_2O and the sulfonic anions in the interlayer of the structure. Water molecules and sulfonic ions built frameworks, where the molecules were kept together by O-H bondings. In the interlayer of calcium aluminate benzene sulfonate hydrates, water molecules were stronger bonded due to O-H of the benzene and CH_3 - substituent than in interlayer with chemically fixed alkanesulfonic acid anions. Not only the relative humidity, but also variable temperatures decrease the H_2O concentration in the interlayer. As a result the layer distance decreased. Therefore it was possible to detect and identify different stable hydration stages. In the other case the naphthalene-1-sulfonic ion kept its orientation in the interlayer during the dehydration process and the layer distance could not be applied as an indicator for dehydration activities. Thus the layer distances of the different hydration stages were not refined. The phase composition and the crystal chemistry of the phases were investigated in binary systems $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{OH}\cdot\text{nH}_2\text{O}]^-$ - $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{X}\cdot\text{nH}_2\text{O}]^-$ X = sulfonic ion. It could be proved that two different salts, the "inorganic" calcium aluminate hydroxide hydrate and the "organic" calcium aluminate sulfonate hydrate were stable. No solid solution series were determined in any of the investigated binary systems. Only in the system $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{OH}\cdot\text{nH}_2\text{O}]^-$ - $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{C}_{10}\text{H}_7\text{-2-SO}_3\cdot\text{nH}_2\text{O}]^-$ at 100 and 35% r.h. naphthalene-2-sulfonic acid anions and hydroxide ions are chemically fixed systematically in separate layers in one phase. The distribution of the different ions resulted in the formation of a superstructure $[\text{Ca}_2\text{Al}(\text{OH})_6]^+[\text{x OH (1-x)C}_{10}\text{H}_7\text{-2-SO}_3\cdot\text{nH}_2\text{O}]^-$.

ABSTRACT

Through an addition of CaCl_2 to an ordinary Portland cement clinker, an alinite phase originates instead of alite [Number]. And the temperature of clinker formation could be reduced by 400-500°C. A cement, based on these cement phases, has been produced commercially in the previous USSR by burning the raw-mix at 1150°C after adding 6-25% CaCl_2 as a sintering aid to an ordinary Portland cement clinker [1]

This paper will demonstrate that through an appropriate mixing of industrial residues (copper slag, municipal solid waste incineration residues (MSWI) and limestone fines) and thermal treatment a synthesis of alinite can take place.

1. INTRODUCTION

The copper mining industries in the Mansfeld area have left a lot of waste dumps. About 50 million tons of applicable copper slag which are remains of the 800 years of copper production are stored in the area of Eisleben/Helbra (Germany) [2]. From an environmental technical point of view, the copper slag of Mansfeld do not cause any harm if utilized properly. So far, the application of this copper slag is limited to use in road stone constructions [3].

On the other hand, there are a lot of other industrial wastes (residues) which are detrimental to the environment if not treated correctly. Therefore, it is the aim of this research to contribute to this idea, that is: to synthesise, among others, a hydraulic substance, alinite in this case, out of mainly industrial residues. During the hydration of alinite a C-S-H-gel appears which can enable the incorporation of detrimental elements [4]. This leads to an improvement of the leachability behaviour and accordingly to the possibility of immobilizing hazardous substances by using hydraulic binders.

Oberste-Padtberg & Neubauer [5] carried out experiments in 1989 to synthesise Alinite-cement out of industrial-residues. Neubauer [4] gave the chemical formula of Alinite as $\text{Ca}_{10}\text{Mg}_{1-x/2}\square_{x/2}[(\text{SiO}_4)_{3+x}(\text{AlO}_4)_{1-x/2}/\text{O}_2/\text{Cl}]$; ($0,35 < x < 0,45$; \square = lattice vacancy). A typical Alinite cement contains the following main mineralogical phases: alinite (65%), belite (20%), mayenite ($\text{C}_{11}\text{A}_7\cdot\text{CaCl}_2$; 10%) and C_4AF (5%)

2. EXPERIMENTAL METHODS

2.1 Synthesis

An appropriate mixing of a copper slag from the Mansfeld area (Germany) (Table 1), municipal solid waste incineration (MSWI) (Table 2) residues and correction of the raw mix by adding

limestone fines and a subsequent thermal treatment of the mixture leads to the synthesis of alinite cement (hydraulic binder) (Table 3).

Table 1. Chemical composition of copper slag from Mansfeld (Germany)

Oxides [weight %]		Oxides [weight %]		Oxides [mg/Kg]		Oxides [mg/Kg]	
SiO ₂	49,10	BaO	0,41	Fe ₂ O ₃	50900	PbO	257

Al ₂ O ₃	3,6	LOI (1000°C)	32,8	Cd	109
Na ₂ O	1,7	LOI (700°C)	19,5	Pb	2016
K ₂ O	2,4			As	2
				Total	98%

In order to make the synthesis of alinite a reality, an alinite cement was synthesised first from pure chemical components which were gradually replaced, during the course of the investigation, by the above-mentioned industrial wastes (residues) and treated thermally by various temperatures and durations, as well, so as to optimise the synthesis parameters. All compositions were fired in Corundum crucibles.

Table 3. Composition of typical Alinite cement [1]

	Alinite
CaO	45-55%
SiO ₂	13-19%
Al ₂ O ₃	9-12%
Fe ₂ O ₃	4-10%
MgO	1-10
CaCl ₂	6-18

3. CHARACTERISATION

3.1 X-ray Diffraction Analysis

The phase compositions of the synthesised sample were determined using a Philips powder diffractometer D5000. Operating conditions were 40kV accelerating voltage and 30 mA beam

current on a copper anode. Diffractograms were taken in increments of $0,04^\circ$ with a counting time of 2s.

3.2 Heat Flow Calorimeter Analysis

The calorimetric measurements were done using a heat flow calorimeter which was constructed and later developed in the institute of Erlangen (Germany) [6]. Three samples can be measured simultaneously with this equipment against an empty reference-cell and the resulting data can be collected online on a PC. During the measuring process, the samples and the reference-cell are protected from exposure to air.

4. RESULTS

4.1 X-ray Diffraction Results

Figure 1 shows the x-ray diffraction pattern of the sample B19 on which alinite (main phase), chlorellestadite and chloromayenite (both are primary mineral-reservoirs) are illustrated. The minerals, chlorellestadite and chloromayenite, are capable of fixing detrimental elements like heavy metals in their lattice. This behaviour is very useful, taking the composition of the constituents we have into consideration. As already mentioned above, during the hydration of alinite (Figure 2) there originates $\text{Ca}(\text{OH})_2$ (portlandite), $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$ (Friedel's salt -monochloride-) and C-S-H gel (which enables also to incorporate heavy metals [4]). This is another important side of alinite, which is the behaviour of fixing detrimental substances in its structure during the hardening process by immobilising them.

Figure 1. X-ray powder diffraction pattern of B19.

Figure 2. X-ray powder diffraction pattern of hydrated and unhydrated sample (B19).

4.2 Heat flow calorimeter results

The hydraulic properties of the sample -B19- were measured using the above-mentioned heat flow calorimeter at a water/solid ratio (w/s) of 1 and by a hydration time of 24 hours.

Figure 3 shows the heat evolution curve for sample B19 which was fired at different temperatures for one hour. It can be seen from the diagram that the tendency to hydraulicity in all samples exists. The hydration process occurs during the first two hours which is very fast in comparison to that of an ordinary Portland cement and it ceases after approximately four hours.

Figure 3. Hydration heat evolution of sample B19

An image, produced using a cryo-transfer scanning electron microscope (cryo-SEM), of the hydrated sample of B19 after a hydration time of 10 minutes is shown in Figure 4.

Figure 4. Cryo-SEM image of a hydrated sample of B19
(w/z = 0,5; after a hydration time of 10 Min.)

Regarding the strength development of the sample, it behaves like those cements which contain alimite (after a hydration time of 1d ~ 17 N/mm² ; 7 days ~ 24 N/mm²) [7] and it is believed that 1-3% boric acid (H³BO³) or tartaric acid (C⁴H⁶O⁶) can influence the setting time of alinite.

4.3 Results of the leaching behaviour test

The leaching behaviour of the sample was examined according to the German standard DEV-S4 test in which a finely ground sample is mixed with water in a ratio of 1:10 (sample : water) and shaken for 24 hours. After filtrating the solution, it is then examined using ICP-OES for possible heavy metalcontent.

Table 4. Element contents of B19 in ppb

	Pb	Ni	Cd
B19	3200	20	340
B19A (900°C/60 Min.)	2500	10	290
L of B19A	*	*	*
TA-Kl. 2	<1000	<1000	<1000

TA-Kl.2 = German regulation for technical instructions on waste handling

* = below detection limit; B19 = not thermally treated; B19A = thermally treated by 900°C/60 Min.; L of B19A = Leachate of B19A

Table 4 shows that the leaching of heavy metals in the leachate (L of B19A) is almost non-existent. This is an indication of the incorporation of these metals in the minerals like alinite, chlorellestadite and chloromayenite.

5. CONCLUSIONS

From the above results, it can be seen that through an appropriate mixing of Industrial residues such as copper-slag, municipal solid waste incineration (MSWI) and correcting the mixture by adding limestone fines and sintering it at an adequate temperature as well duration, the synthesis of a hydraulic substance like alinite is possible. This is demonstrated by the results of the heat flow calorimeter- and powder diffraction-analysis.

The results of the heat flow calorimeter show that the hydration of alinite is very fast and it takes place during the first hour and is finished after approximately four hours. The powder diffraction analysis of the hydrated sample delivers a result which shows the formation of hydrated phases such as $\text{Ca}(\text{OH})_2$ and $\text{C}_3\text{A} \cdot \text{CaCl}_2 \cdot 10\text{H}_2\text{O}$; chlorellestadite ($\text{Ca}_{10}(\text{SiO}_4)_3(\text{SO}_4)_3\text{Cl}_2$) remains unchanged. And the leaching behaviour of the sample shows that the content of heavy metals in the leachates is almost zero which gives an indication to their incorporation in the mineral phases formed.

SYNTHESIS OF ALINITE-CEMENT OUT OF COPPERSLAG AND MUNICIPAL-SOLID-WASTE-INCENERATION (MSWI) RESIDUES

ABSTRACT

The hydration of a CAC (Secar 51) with and without 0.01 m LiCO_3 was monitored with a modified Heat-Flow calorimeter at 25, 30, 35, 40 and 45°C. Beside acceleration and retardation of the cement hydration kinetics the heat liberation of the cement pastes as a function of the temperature was detected. Furthermore the phase formation of different pastes was investigated online at higher temperatures and the efficiency of the X'Celerator detector for detecting very fast hydration reactions was proven.

1. INTRODUCTION

In 1983 a new Heat Flow calorimeter based on semiconductor elements was developed by KUZEL [3]. The instrument improved the determination of the heat of reactions of cements, mortars, lime and other cement based materials. In the following years the calorimeter was equipped with a computer controlled data collection and an online data calculation [4].

Cements and especially formulated systems based on the reciprocity of their compounds are highly specialized products and should always guarantee the same performance. However, different climates, with cold or hot temperatures influence the properties of such building products. Hydration reactions will be retarded or accelerated. In order to control the quality and properties of building products the heat flow calorimeter the, was remodelled and combined with a thermostat to perform measurements at different temperature levels in the range of 5...80°C.

This paper demonstrates the capability of the improved calorimeter in combination with an X'Pert Theta-Theta Diffractometer plus the new X'Celerator on the determination of hydration reactions and the phase formation at different temperatures with and without admixtures.

2. EXPERIMENTAL

2.1 Construction principles and sample preparation for Heat-Flow calorimetry

The heat flow calorimeter [2], [3] [5] consists of an aluminium block, sited in an isolated box with a cover. The aluminium block contains 4 openings for the measuring cells, a construction of a copper plate with BiTe- semiconductors sited below. Three cells can be used for the measurement of the sample heat-flow and one cell is occupied by the reference. In this case 1g of a hydrated CAC cement, Secar 51, (w/s = 0.5) for 20 days at 40°C was used as a reference. Just after the combination of the water with the cement, the heat of reaction (exothermic reactions) is measured in difference with the reference to exclude background heat effects. Heat values were detected as mV per time by a multimeter of PREMA 5017 multimeter, which was able to scan three channels in a

certain preinstalled time interval. The raw data stored on the hard drive of a personal computer(PC) was afterwards plotted and analysed. The online measurement program used to direct PC, multimeter, and calorimeter was OMI (Online Measurement and Interpretation) written by ECKER [6].

For the detection of the course of hydration at different temperatures, the construction of the calorimeter was improved. An RM6-thermostat from LAUDA was used to condition the water temperature, and this was pumped through a channel system in the aluminium block and the aluminium top.

The samples for the measurement were produced the following way. 1g cement powder was weighed into the copper pot. Top and cover pot were closely sealed using a commercial Vaseline. The samples were put onto the copper plates of the cells. In order to improve the heat transport between copper vessel and the copper plate of the cell special water free oil was introduced between the two parts. Finally the aluminium cover was put on the aluminium block and the water was filled into syringes on the surface of the aluminium cover to equilibrate cement powder and water on the same temperature for 12h. In order to determine the heat flow quantitatively for a certain time range the raw data must be multiplied by the calibration factor. Because, the calibration constant is depended on the temperature, K must be determined for every temperature separately [2].

For the measurement of the heat flow of the cement paste, the parameters in Table 1 were used.

Table 1. Parameters for the determination of the heat flow by calorimetry

Parameters	Values
Temperatures [°C]	25, 30, 35, 40, 45
Time interval [min]	1
Activity of the channels [s]	20
Data collection [s]	20

2.2 Parameters and sample preparation for X-ray analyses

In order to determine the phase formation of the Secar 51 pastes, freshly prepared samples were mixed with water or admixture and immediately shrink-wrapped in a PE film. The pastes could not dehydrate during the hydration process. In order to make XRD measurements the samples were fixed and heated in a HTK-16 camera from PAAR. The X'Pert Theta-Theta Diffractometer with copper radiation $\text{CuK}\alpha$ from Philips was equipped with a new X'Celerator detector. It made it possible to make measurements in the range of 3...40 degrees 2 Theta with a step of 0.017 degrees 2 Theta and a count time of 10s in 6 minutes. For the investigations of the course of hydration of pastes Secar 51 + 0.1 mole/l Li_2CO_3 measurements between 3...40 degrees 2 Theta, with a step of 0.033 degrees 2 Theta and a count time of 5s were used. The measurement took approximately 49s. Therefore fast non-ambient measurements made it possible to determine fast hydration reactions, especially at 40°C.

3. RESULTS

3.1 Determination of the calibration values K at different temperatures

For each temperature the calibration constant was determined three times in order to reproduce the results. The most important point was to bring the calorimeter to equilibrium. Under a calibration time of 12 h at constant temperatures, the reproducibility of the calibration values was not sufficiently good. In Figure 1 K was plotted against the temperature. It is quite clear that K will decrease linearly with high temperatures and increase with low temperatures. Now, a precise determination of K for different temperatures makes it possible to calculate further K values by the regression equation.

Figure 1. K values plotted against the temperature

3.2 Determination of the heat flow of Sec. 51+H₂O at 25...45 °C by isoperibolic calorimetry

The induction period decreased with increased temperatures during the hydration process (Figure 1). In the calorimeter curve Sec. 51 + H₂O T = 25 °C the induction period took approximately 18 h and was finally decreased step by step to less than 20 minutes. The maximum values of the main hydrations were shifted to lower times with increased temperatures. Figure 3 described an approximately linear correlation. Especially at low ambient temperatures 25...30 °C small differences of the hydration maxima positions were detected although the pastes hydrated under comparable conditions. Thirdly, the course of the heat-flow as a function of the temperature changed completely. At 25°C heat was immediately set free at approximately 20h as one peak. Higher ambient temperatures caused the formation of different separately detectable heat processes before the start of the main hydration and as a long fade out of the heat evolution at the end of the main hydration. This effect was firstly visible in the calorimeter curve heated at 30°C of a Secar 51+H₂O. The heat evolution during the main hydration occurred in a smaller time interval, which resulted in a sharper heat evolution. This tendency was reinforced with the increased temperatures.

Figure 2. Calorimeter curves: Sec.51+ H₂O w/s = 0.5 T = 25, 30, 35, 40, 45°C

Figure 3. Hydration maxima variation of calorimeter curves: Sec.51+ H₂O w/s = 0.5 as a function of the temperature

The phase formation of cement pastes heated at 25 °C showed the typical course of phase formation (Figure 4). CA reacted with water to CAH₁₀ after 18h and to C₂AH₈ + AH₃ after 16h of hydration [7]. Higher ambient temperatures at 30 and 35°C hindered the formation of CAH₁₀. C₂AH₈ crystallized as the predominant reaction product together with AH₃ of CA. At 30 °C, two different hydration stages of the calcium aluminate hydrate, the C₂AH₈ and C₂AH_{7,5} were stable. C₂AH_{7,5} was transformed after approximately 14 h to C₂AH₈ indicated by the shift of the (006) peak to lower 2 Theta values in the XRD pattern (Figure 5). At 40 °C, CA reacted very fast with water to C₂AH₈. After approximately 2.5h first (006) and (0012) reflections were detected with a net area of 2 and 3 cps·deg respectively. Just 4 h later, the net area of the (006) counted 70.3 cps·deg. After 9...10 h, the (211) peak at 17.29 2 Theta indicated the formation of C₃AH₆.

On one side C₃AH₆ resulted in the conversion reaction $3C_2AH_8 \Rightarrow 2 C_3AH_6 + 2AH_3 + 9H$ and on the other side hydrogrossularite crystallized primarily according to the reaction: $3CA + 12H \Rightarrow 2 C_3AH_6 + 2 AH_3$ [7]. Monocarbonate C₃A·CaCO₃·11H₂O crystallised after approximately 6.6h. Monocarbonate crystallized due to the substitution of Al(OH)₄⁻ ions in the interlayer of C₂AH₈ by CO₃²⁻ ions of the paste. As part of the conversion reaction, AH₃ crystallized (Figure 6). Due to the conversion of C₂AH₈ to monocarbonate and C₃AH₆ the intensity of both, the (006) peak and (0012) peak of C₂AH₈ decreased.

Figure 4. Phase formation Sec 51+ H₂O w/s =0.5 T = 25°C

Figure 5. Change of the hydration stage $C_2AH_8 - C_2AH_{7.5}$ at $30^\circ C$ during the hydration

Figure 6. Phase formation Sec 51+ H_2O w/c = 0.5 $T = 40^\circ C$

3.3 Determination of the heat flow of a Secar 51 + 0.01 mole/l Li_2CO_3 at $40^\circ C$ by isoperibolic calorimetry

The application of different Lithium salts like LiCl or Li_2CO_3 [1] used as a set accelerator were widely investigated.

Figure 7 shows the heat evolution of Secar 51 pastes mixed with 0.1...0.001 mole/l at a w/s ratio of 0.5 and $T = 40^{\circ}\text{C}$. The addition of Li_2CO_3 concentrations > 0.01 m accelerated the CAC (calcium aluminate cement) hydration vigorously. Neither an induction period, nor the main hydration is fully visible in the plot of the calorimeter curves.

The detection of the phase assemblage per time for such fast hydration reactions by XRD, was always a problem because of high count times per step 2 Theta and long measuring times in order to obtain a suitable pattern. The application of an X'Celerator improved the determination of the hydration phase formation.

The addition of 0.01 mole/l Li_2CO_3 accelerated the formation of C_2AH_8 drastically. Just after 1 minute of mixing Secar 51 with 0.1 m Li_2CO_3 solution, a small peak at 8,11 degree 2-Theta indicated the formation of C_2AH_8 in the cement paste (Figure 8). After 1 minute the determined net area of the (006) peak of C_2AH_8 had a value of 5.9 cps/deg and after 59 minutes of hydration the net area value of the (006) peak was 95.2 cps/deg. At higher hydration times until 1.5 h the hydration seemed to be retarded, because, the intensity of the monocarbonate and C_2AH_8 peaks did not grow. In contrast, the earliest detected formation of C_2AH_8 occurred in Li_2CO_3 -free pastes (Secar 51 + H_2O paste, heated at 40°C) after 2.4h! Furthermore, the formation of C_3AH_6 was not detected in between 0...1.5h of hydration. Monocarbonate was formed at approximately 40 minutes, as a result of the carbonation process of C_2AH_8 . $\text{Al}(\text{OH})_4^-$ ions were substituted by carbonate ions in the inter layer of the C_2AH_8 structure and $\text{Al}(\text{OH})_3$ was formed with a low degree of cristallinity.

Figure 7. Heat flow calorimetry: Sec 51 + 0.01 m Li_2CO_3 w/c = 0.5

Figure 8. Early phase formation (1h): Secar 51 + 0.01 m Li_2CO_3 w/s = 0.5 $T = 40^{\circ}\text{C}$

Figure 9. Intermediate phase formation (1-11h): Sec 51 + 0.01 m Li_2CO_3 w/s = 0.5 T = 40 °C

4. CONCLUSIONS

Calorimetric studies demonstrated that increased temperatures shortened the distinct induction period from approximately 16.7h (Sec.51.H₂O 25°C) to 0.2h (Sec.51.H₂O 45°C). Increased temperatures shifted the maxima of the main hydration to lower hydration times and the heat flow during the main hydration was set free in a shorter time interval.

At 25 °C, the exothermic hydration of Secar 51 reacted with water was detected as one sharp peak between 19...33h. Higher temperatures manipulated the heat evolution systematically. In the calorigrams of Sec51 + H₂O at 30, 35, 40 and 45 °C the main reactions were split into 2 reactions, a smoother exothermic reaction, just after the end of the induction period and a following stronger hydration reaction. The heat liberation at the end of the main hydration of Sec51. + H₂O at 30, 35, 40 and 45 °C did not approach values near zero, but faded out as a function of the temperature.

Briefly said, all facts pointed out that the increase of temperature from 25°C to 40°C accelerated the overall cement hydration of the Secar 51 pastes, but distributed the heat liberation over a larger time range. The phase assemblage of the heated pastes, investigated by time resolved XRD, changed. $\text{CAH}_{10} + \text{C}_2\text{AH}_8 + \text{AH}_3$ crystallized at 25°C as reaction product of CA. At 30°C $\text{C}_2\text{AH}_8 + \text{AH}_3$ crystallized as the main hydration product. At 40 and 45 °C, $\text{Al}(\text{OH})_4^-$ ions of the C_2AH_8 inter layer were substituted by carbonate ions due to increased temperature. Monocarbonate and additional AH_3 crystallized. Furthermore, C_3AH_6 crystallized after 10 h and C_2AH_8 was converted to C_3AH_6 , the stable phase in the system $\text{CaO-Al}_2\text{O}_3\text{-H}_2\text{O}$.

Variable high temperature, did not only change the phase assemblages, but accelerated the crystallisation of the hydration phases. At 25 °C the (006) reflection of C_2AH_8 was first detected at approximately 12h. In the XRD pattern of a Secar 51+ H₂O paste, heated to 40°C, the (006) reflection was present after approximately 2.4h.

In order to analyze the hydration of Sec 51 + H₂O to 40 °C with 0.01 m LiCO_3 solution the application of heat flow calorimetry was not sufficient, because the reaction was too fast to resolve the 3 main phases of hydration, the heat of wetting, the induction period and the period of main hydration. However XRD measurements with the new X'Celerator made it possible to follow the incredibly fast hydration of CA to C_2AH_8 and AH_3 and at later times to monocarbonate.

MANGANESE IN HIGH ALUMINA CEMENT

H. Pöllmann and R. Oberste-Padtberg

ABSTRACT

Manganese can be used in two different ways for HAC-applications : Manganese ore can be added to the raw meal, but manganese sulphate can also be added to HAC's to form stable hydrated mineral assemblages.

Manganese is not normally used in HAC production because the similar phase to monocalcium aluminate (CA), Ca_2MnO_4 (marokite) crystallizes in a distorted spinel structure type and shows no hydraulic behaviour.

New investigations have shown that the addition of manganese ore to the raw meal composed of bauxite and lime leads to the formation of highly reactive HAC's. Lowered production temperatures and lower costs of raw material are also obtained.

Depending on the composition of the raw materials, clinkering temperature and handling, new phases are formed, but also solid solutions with brownmillerite, monocalciumaluminate and larnite can occur.

The hydration of manganese containing HAC's leads to the formation of hydrates incorporating manganese in their crystal lattices. In technical applications, when calcium sulphate is added the formation of manganese containing ettringites may occur. The use of manganese sulphate instead of calcium sulphate leads to the formation of shigaite.

Keywords: High Alumina cement, manganese, manganese sulfate, shigaite

1. INTRODUCTION

In the past manganese seemed to have no impact on HAC production because the phase chemically analogous to monocalciumaluminate (CA), CaMn_2O_4 (marokite) crystallizes in a distorted spinel structure type and is therefore not hydraulic. In the meantime new investigations proved that the addition of manganese oxides to the raw meal of a typical HAC leads to the formation of highly reactive HAC's. Obviously lowered production temperatures and lower costs of raw materials are added advantages. Depending on the raw materials and the temperature applied the new formed phases are solid solutions of manganese with the primary minerals of a HAC, like CA and C_4AF , but also calcium manganates and different Ca-Al-Si-Fe-Mn-oxides with varying stoichiometry are formed.

The hydration of these primary minerals leads to different new hydrates partially also incorporating manganese in their crystal lattices.

In technical applications of HAC's calcium sulfate is often added. In the course of hydration of these systems ettringite is formed. The use of MnSO_4 , instead of gypsum leads to the formation of shigaite, a lamellar metal-metal hydroxysalt with good water binding capacities.

It is possible to create optimal HAC and manganese sulfate mixtures for use in the building industry.

2. RESULTS

The formation of manganese containing HAC is based on mixtures of raw materials like limestone, bauxite and manganese ore as sources for calcium, aluminium and manganese. But other raw materials and wastes can also be used. In manganese-free High Alumina cements the overall composition lies close to a ratio of $\text{CaO}/\text{Al}_2\text{O}_3 = 1.0$ with varying contents of Fe_2O_3 . The iron-content is normally provided by the Fe-content of the bauxites used. In Figure 1 the raw materials for the production of manganese-containing cements are shown.

Figure 1. Bauxite (left), limestone (bottom) and manganese ore (middle) – the raw materials for production of manganese containing cements

The chemical composition for the production of manganese-containing cements can be illustrated within a tetrahedron $\text{CaO} - \text{Al}_2\text{O}_3 - \text{Mn}_2\text{O}_3$ and Fe_2O_3 (Figure 2). The content of manganese should be below 50 %, otherwise the non-hydraulic phases dominate and only poorly reacting mixtures are crystallizing.

Figure 2. Tetrahedron $\text{CaO} - \text{Al}_2\text{O}_3 - \text{Mn}_2\text{O}_3 - \text{Fe}_2\text{O}_3$ with the region of hydraulic manganese-containing mixtures including classic HAC

2.1 Synthesis of manganese containing cement

By using the raw materials in different compositions and after sintering at different temperatures from 1050°C to 1350°C, various HAC-clinkers were obtained composed of various cementitious minerals with various tendencies for hydraulicity. The mixtures were also investigated due to varying sintering times from 0.5 hours to 10 hours.

Different calcium aluminates and calcium aluminium ferrites crystallizing in HAC-systems are shown in Table 1. Due to increasing contents of manganese other phases and solid solutions are additionally formed.

Table 1. Phases of High Alumina cement

Name	Simplified Formula	Formula	Limits
Monocalcium -aluminate	Ca	$\text{CaAl}_{2-x}\text{Fe}_x\text{O}_4$	$0 \leq x \leq 0,2$
Mayenite	C_{12}A_7	$\text{Ca}_{11}\text{Al}_{14}\text{O}_{33} \cdot \text{CaX}_2$	$\text{X} = \text{F}^-, \text{Cl}^-, \text{OH}^-, \text{etc.}$
Grossite	CA_2	$\text{CaAl}_{4-x}\text{Fe}_x\text{O}_7$	$0 \leq x \leq 0,4$
Gehlenite	C_2AS	$\text{Ca}_2\text{Al}_{2-x}\text{Fe}_x\text{SiO}_7$	$0 \leq x \leq 0,4$
Brownmillerite	C_4AF	$\text{Ca}_2\text{Al}_{2x}\text{Fe}_{2-x}\text{O}_5$	$0 \leq x \leq 0,8$
Pleochroite	$\text{C}_{20}\text{f}_3\text{A}_{13}\text{S}_3$	$\text{Ca}_{20}\text{Al}_{32-2x}(\text{Mg},\text{Fe})_x\text{Si}_x\text{O}_{68}$	$2,5 < x < 3,5$
Magnetite	fF	$(\text{Fe},\text{Mg})(\text{Fe},\text{Al})_2\text{O}_3$	
Wüstite, Iron	f	FeO, Fe	
Larnite		C_2S	
Perovskite	CT	CaTiO_3	
Ye'elimite	$\text{C}_4\text{A}_3\text{S}$	$\text{Ca}_4\text{Al}_6\text{O}_{12}\text{SO}_4$	
Corundum	A	$\alpha\text{-Al}_2\text{O}_3$	
Lime	C	CaO	

In the presence of manganese other hydraulic phases are formed like:

$\text{CA}_{(\text{ss})}$, $\text{C}_4(\text{A}, \text{Mn}, \text{F})$, $\text{Ca}(\text{Mn}, \text{Fe})\text{O}_{3-x}$, $\text{C}_x(\text{A}, \text{Mn})\text{S}_y$, $(\text{C}_{12}\text{A}_7)$, $\text{C}(\text{A}, \text{Mn})_2$, minor phases containing (Si, Ti).

Depending on the mineralogical compositions, different hydraulic behaviour is obtained. It is highly important to avoid compositions with high amounts of calcium manganates with perovskite or spinel structure types, because these phases are only poorly hydraulic. The hydraulic behaviour of manganese-containing cements with different contents of manganese is shown by heat flow

calorimetric measurements, but also the strength development of mortars using manganese-containing cements was investigated.

Different ratios of $\text{CaO}/\text{Al}_2\text{O}_3/\text{Mn}_2\text{O}_3$ were homogenized and treated thermally at 3 different temperatures. The ratios were varied according Figure 2, whereas the times of treatment varied between 0.5 hours up to 10 hours with intermediate grinding. Pt- and Al_2O_3 -crucibles were used for the heat treatment. All mixtures were sintered at 1350°C , 1250°C and 1100°C .

The clinkers were ground and investigated by heat flow calorimetry. As can be seen from Figure 3 depending on oxide ratios, different grades of hydraulicity occur, depending on the phase assemblage formed. In presence of Iron oxide in manganese-containing cements the sintering temperatures are lowered drastically to less than 1100°C . Due to these reduced temperatures optimised clinkers can also be produced. Less energy is necessary to sinter these clinkers (Figure 4). Different quaternary eutectica were found.

Figure 3. Heat flow calorimetry of different ratios $\text{CaO} / \text{Al}_2\text{O}_3 / \text{Mn}_2\text{O}_3$

Figure 4. Heat flow calorimetry of different ratios of $\text{CaO} / \text{Al}_2\text{O}_3 / \text{Mn}_2\text{O}_3 / \text{Fe}_2\text{O}_3$

2.2 Phase formation in pure systems

The complicated phase formations were investigated mainly based on complex solid solutions of the brownmillerite type structures. The presence of other manganese-containing phases like perovskites and spinels must be avoided because they do not react with water. The lower the content of the clinker is in perovskites and spinels, the better is the reactivity with water. The results on the ternary phase diagram is shown in Figure 5 (Zötzl & Pöllmann).

Figure 5. Phase relations in the pseudoternary diagram C_2F – “ C_2A ” – C_2Mn

The dark area is characterized by ternary solid solutions of the brownmillerite structure, whereas in the other fields different other phases coexist, some of these are not hydraulic in any case. In area A only solid solutions of brownmillerite are crystallizing with varying contents of iron, manganese and aluminium. In area B brownmillerite and $C_{12}A_7$ and/or C_3A are coexisting. Area E can be characterized by the coexistence of brownmillerites and coexisting perovskites and marokite, depending on the amount of manganese and conditions used. On the rims of the triangle the phases and their amounts are given schematically with increasing and decreasing tendency.

The complex phase relations are being investigated, but it is already obvious that there are upper limits of the addition of manganese at approximately 50 % to the mixtures to obtain a useful hydraulic clinker and also that the oxidation control of the sintering conditions can play a very important role to avoid crystallization of inert phases.

3. HYDRATION CHARACTERISTICS

The replacement of Al by Mn in HAC influences the reaction characteristics of HAC/water suspensions, and, as can be seen from Figure 6, the hydration intensity (determined by the total heat development due to the hydration) is affected by this substitution:

The commercial HAC without Mn-substitution showed initial hydration after 13 hours, whereas the HAC with a 20 wt-% Mn-substitution showed, after 8 hours, a beginning of hydration, the maximum hydration intensity (i. e. the maximum heat flow) being lower than that of the former one. The HAC with a 50 wt.-% Mn-substitution showed the highest heat flow, whereas the total heat evolution of all the three samples were in the same order of magnitude.

The HAC without Mn-substitution showed initial hydration after 10 hours, whereas the HAC with a 20 wt-% Mn-substitution showed, after 13 hours, the beginning of hydration, the maximum hydration intensity (i. e. the maximum heat flow) being lower than that of the former one. The HAC with a 50 wt.-% Mn-substitution showed the highest heat flow, whereas the total heat evolution of all the three samples were in the same order of magnitude.

(Pöllmann, H. & Oberste-Padtberg, R.).

Figure 6. Hydration characteristics of Cements as compared a typical HAC to cements where the aluminium is replaced by manganese up to equivalent ratios of aluminium and manganese

3.1 Hydration behaviour of cements and building mixtures using MnSO_4

The manganese –cement systems were designed in the form such that the anhydrous active matter consisted uniquely of pure classic HAC (HAC component minerals) or with newly synthesized manganese-substituted cements (new manganese-containing components) on one hand, and , on the other hand, they consisted of so-called ternal systems, consisting of HAC, Ca- or Mn-sulfate and a CaO-containing material (either $\text{Ca}(\text{OH})_2$ or ordinary Portland cement). The hydration of these mixtures are controlled by the addition of organic retarders such as citric acid, sodium gluconate or –tartrates.

Applications and use of these ternal mixtures are mortars which were designed on the basis of sand (0 – 8 mm) at a sand/active matter-ratio of 4 : 1 and a water/active matter ratio (equivalent to water/cement-ratio) of 0,44 : 1.

The hydration behaviour was investigated using a calorimeter (Pöllmann, H., Kuzel, H.-J. & Meyer, H.)

As can be seen from Figure 7, the hydration characteristics, i. e. the hydration velocity as well as the hydration intensity in ternal systems, containing conventional HAC and MnSO_4 , can significantly be influenced by the amount of manganese sulfate:

Here, a powder, consisting of (70 parts HAC, 15 parts OPC, 1.5 parts sodiumcarbonate, 2 parts organic retarders, and 23 parts of Ca-sulfate, partly being replaced by Mn-sulfate), was mixed with water (water/solid: 0,44 : 1) and then permitted to hydrate in an isothermal calorimeter. As can be seen from Figure 7, the above mentioned powder mix showed the fastest heat evolution, when it contained 11 parts of Mn-sulfate. Increasing and decreasing manganese contents led to a retardation of the hydration and to a decrease in hydration intensity. The control of hydration can be followed directly due to the amount of manganese sulfate added. The main peak of heat evolution can be followed very precisely showing acceleration and retardation due to the amount added.

Figure 7. Influence of the amount of MnSO_4 on the hydration velocity of ternal HAC-mixes

Basically these mixtures have a complicated hydration chemistry and various hydrates form, including crystalline and amorphous phases. In manganese-free systems the main newly formed hydrate is ettringite. In manganese-containing mixtures ettringite and the mineral shigaite, a lamellar metal-metal hydroxy salt were identified.

The time of maxima of heat evolution is strongly dependant on the amount of sulfate and type of sulfate (calcium sulfates, manganese sulfate) added (Figure 8). It must be mentioned, that other metal sulfates, besides calcium sulfate do not have a similar effect on the hydration.

Maximum of Main peak of Hydration

Figure 8. Time of maxima from peaks of heat evolution as a function of manganese sulfate content of the ternary mixtures

The hydration characteristics were also determined in the above mentioned ternary systems, where the HAC was Mn-substituted. As an example in comparison to an ordinary manganese-free HAC, other HAC's, with an Al/Mn-ratio of 4:1 and 1:1 were tested.

As can be seen from Figure 9, the Mn-substituted HAC's had a slight retardation of hydration but, especially the HAC with an Al/Mn-ratio of 4:1 showed within the first 10 hours of hydration the maximum amount of heat evolution.

Figure 9. Heat evolution of ternary mixtures using manganese-containing HAC's

3.2 Strength Development

The development of the strength was determined in mortars on the basis of the above mentioned ternary systems (HAC, Ca-sulfate, Mn-Sulfate, OPC and organic retarders). These mortars were mixed with sand (0 - 8 mm) and water (water/cement = 0.41 : 1).

Table 2 shows the formulation of the different binders, which were created because their compositions are close to actual binders using calcium sulfate as a component, whereas Figure 10 shows the results of the strength development in the mixes tested.

Table 2. Formulations whose strength development is shown in Figure 10

	HAC	OPC	Ca-sulfate	Mn-sulfate	Na-carbonate	org. additives
Mix 1	64	11	22	0.0	0.3	2.7
Mix 2	62	11	6	18	0.3	2.7
Mix 3	65	11	0.0	21.3	0.0	2.7

Figure 10. Compressive strength development (in N/mm²) at 20° C/65 % r. h. of mixes 1- 3 from Table 2

As can easily be seen from Figure 10, a substitution of a part of the CaSO₄ – content in the ternal mixes (closely related to technical mixes in the case of gypsum addition) by MnSO₄ leads to an increase in compressive strength development of mortars. In the case of MnSO₄ a mixture is given without Na-carbonate, so that no influence of a potential activator is included.

3.3 Stability of newly formed hydrates

In order to determine the leachability of different ternal HAC-systems, the binders of Table 3 were mixed with water (water/solid = 0.44 : 1) and then permitted to harden for 7 days. The hardened materials were then crushed and sieved at 1 mm, and the fines were leached for 1 week with water (ratio 10 wt.-parts of water : 1 part of crushed material) and then analysed for Mn. In all the cases, the Mn-content was below the detection limit of << 0.1 ppm.

Table 3. Composition of HAC-Mixes for the determination of Mn-leachability (see text)

	HAC	OPC	Org. additives	MnSO ₄	CaSO ₄
HAC-mix 1	64	12	2		22
HAC-mix 2	64	12	2	22	
HAC-mix 3	64	12	2	16	6

The advantages of manganese for production of HAC's can be summarized as follows :

- 1) Lowered sintering temperatures (by 100 °C – 300 °C) (due to high amounts (20-30%) of manganese present, own phases are formed and no additional fluxes were used)
- 2) Use of widely available and cheap raw materials
- 3) High strength development
- 4) High early strength development
- 5) Weathering stability
- 6) High water bonding capacity due to phase formation of metal-metal hydroxy salts with high water bonding capacities
- 7) Complex use of this cement in construction industry possible due to good strength development
- 8) Use of this cement in environmental applications for immobilization of soluble manganese salts to form insoluble hydrates
- 9) High chemical resistance, low leaching rates
- 10) Workability at low temperatures possible due to high heat evolution
- 11) Admixture control of hydraulic properties in applications possible similar to HAC

ABSTRACT

The main purpose of this investigation was, to demonstrate how different admixtures (benzene sulfonic acids and alkanesulfonic acid sodium salts) systematically change the setting times of ordinary Portland cement pastes (OPC) due to different concentrations, systematic changes of chain lengths of alkanesulfonic acids sodium salts and systematic variations in number and orientation of CH₃ - substituents on the benzene ring. Furthermore the crystallisation of OPC pastes under the influence of these admixtures was investigated. The course of hydration of the OPC pastes was determined by isoperibolic heat-flow calorimetry. For the investigation of the bulk phase composition of the cement pastes, differential scanning calorimetry (DSC) and X-ray powder diffraction techniques (XRD) were applied.

Both, alkanesulfonic and different benzenesulfonic acid anions showed retardation or acceleration effects on the hydration process depending on the variation of the chain-length or the molecular structure of the different benzenesulfonic acid anions. Under the presence of admixtures newly Afm-phases crystallized containing alkanesulfonic or benzenesulfonic acid anions in the crystal structure.

1. INTRODUCTION

There is widespread use of admixtures in cement chemistry. It is estimated that more than 80% of the concrete production in North America contains one or more admixtures. Today organic and inorganic substances are added to the concrete batch immediately before or during mixing. They are used to modify the properties of the cement paste or concrete, to make them more suitable for particular applications and to save energy for economic purposes. Different effects like acceleration or retardation of the setting times, decreased water requirements without a change in workability, durability enhancements, and increased rate of strength development and many more effects are provided by admixtures. The different properties of admixtures are defined by different standards and specifications provided by RILEM, ACI, ASTM or CSA [1].

The raw materials for most admixtures are by-products or waste materials resulting from technical processes. For example the retarding effect of Calcium- or Sodium lignosulfonates depends on their sugar impurities. Sugar-free lignosulfonates are poor retarders and sugar rich lignosulfonates are good retarders.

In this work, pure benzene sulfonic acids and different sodium alkane sulfonates were applied to investigate the direct effect of the systematic variation of the molecular structure on the cement or concrete hydration.

The following parameters were raised:

- Variation of number and orientation of CH_3 - substituents on the benzene ring of different benzene sulfonic acids
- Variation of the chain length of alkanesulfonic acids sodium salts $\text{C}_n\text{H}_{2n-1}\text{SO}_3\text{Na}$ $n = 1, 3, 5, 7, 8, 9$

2. EXPERIMENTAL

For the investigations on the effects of sulfonic acids and sodium salt additions, a commercial OPC CEM I 32,5 R with a measured specific surface of $3870 \text{ cm}^2/\text{g}$ was used. The composition of the main phases in the clinker is summarized in Table 1. As admixtures, commercial alkanesulfonic acid sodium salts and different benzene sulfonic acids (Table 2) were used.

Table 1. Composition of the OPC (Clinker phases and Calcium sulphate dihydrate)

C_3A [wt.-%]	C_2S [wt.-%]	C_3S [wt.-%]	C_4AF [wt.-%]	Gypsum [wt.-%]
7.5	9.8	72.5	2.6	3.0

Table 2. Admixtures: Different sulfonic acids and sodium salts

Alkane sulfonic acid Sodium salts	
$\text{CH}_3\text{SO}_3\text{Na}$	Methane sulfonic acid sodium salt

$\text{C}_7\text{H}_7\text{SO}_3\text{H}$	Toluene-p-sulfonic acid
$\text{C}_8\text{H}_9\text{SO}_3\text{H}$	Xylene sulfonic acid
$\text{C}_9\text{H}_{11}\text{SO}_3\text{H}$	Mesitylene sulfonic acid

In order to determine the course of hydration, an isothermal heat flow calorimeter designed by KUZEL [2][3] was applied. The instrument consists of 4 measuring cells sited in an aluminum block. One cell is occupied by the reference, in this case a copper vessel and cover closely sealed and filled with 1 ml H_2O . The other cells are used to determine the hydration of cement pastes. Due to the exothermal heat evolution of the cement hydration, the evolved heat is measured in difference ($\text{Heat}_{\text{Sample}} - \text{Heat}_{\text{Reference}}$). This construction allows the determination of corrected heats per time as voltage (mV) without background heat effects. The heat is detected by BiTe semiconductors and registered by a digital multimeter from PREMA. The measured mV-values are stored on the hard disk of a computer and were analysed and interpreted by commercial scientific software. The illustration of the calorimeter files of an OPC (Figure 1) showed a typical heat flow diagram. In order to determine the heat flow quantitatively the heat flow data must be multiplied by the calibration factor K, in order to equalise inhomogeneities of the calorimeter construction.

Figure 1. Typical calorimeter curve of OPC and H₂O (Reference)

In order to determine the effect of admixture addition on the cement paste hydration, the minimum of the period of induction (mpi) and the maximum of the main hydration (mmh) were determined. Additionally, the area under the calorimeter curve was integrated, because the area is directly proportional to the heat flow per time and consequently directly proportional to the phase formation. The partition of the area in different segments gave the ability to determine in which segments the admixtures have had their strongest influences on the hydration of the cement paste. The phase formation as a function of time was firstly determined by Differential Scanning Calorimetry (DSC) and secondly by X-ray diffraction (XRD), because C-S-H is formed as amorphous gel phases [4], [5].

For DSC measurements, cement paste samples of constant mass 10 mg were taken at different hydration times and dried at 35 % r.h. over a saturated CaCl₂ concentration in a desiccator for 4 weeks. The same dried samples were investigated by XRD in order to identify the dehydration reactions of the DSC graphs and to determine changes in the crystal chemistry of Afm- or Aft-phases. For the measurements a Si-single crystal sample carrier for small sample material was used.

3. RESULTS

3.1 The influence of variable chain lengths on the hydration of an OPC

In order to demonstrate the effect of variable chain lengths on the cement paste hydration under the influence of sodium alkane sulfonates C_nH_{2n+1}SO₃Na with n = 1,3,5,6,7,8,9 the properties of 0.25 mole/l will be discussed (Figure 2). In comparison to the reference (OPC and H₂O) the addition of sodium alkane sulfonates shifted the mpi to higher hydration times. Moreover, the time ranges of the induction period of different calorimeter curves were affected. Longer aliphatic chains of the alkanesulfonic acid sodium salt increased the induction periods. Hand in hand with the minimum of the induction period, the maximum of the main hydration compared to the reference were shifted to higher hydration times, too. In relation to these 2 points the bulk heat of hydration during the main hydration was liberated at higher times. The addition of 0.25 molar sodium alkane sulfonic acid solutions to OPC caused the distribution of the heat of hydration over a larger time interval. The evolved heat in the range 0 to 72h showed, that the influence of the admixtures with C_nH_{2n+1}SO₃Na with n = 1,3,5 and 6 is predominantly strong during the end of the induction period up to 36 h (Figure 3). However, for cement pastes mixed with admixtures C_nH_{2n+1}SO₃Na with n = 7,8 and 9

most of the heat was liberated between 36 to 72h. The total heat of hydration was decreased due to the addition of increased chain lengths. Not only retardation effects are visible, in the calorimetric graph of OPC and 0,25 m $\text{CH}_3\text{SO}_3\text{Na}$ accelerates hydration reactions in the range of 0 to 36h, which can be seen due to a higher heat of hydration.

Figure 2. Calorimeter curves: OPC and 0.25 M $\text{C}_n\text{H}_{2n-1}\text{SO}_3\text{Na}$ $n = 1, 3, 5, 7, 8, 9$

Figure 3. Heat of OPC - pastes: OPC and 0.25 M $\text{C}_n\text{H}_{2n-1}\text{SO}_3\text{Na}$ $n = 1, 3, 5, 7, 8$ and 9

3.2 The influence of CH₃-substituents on the cement hydration

The addition of 1M benzenesulfonic acid C₆H₅SO₃H, toluene-p-sulfonic acid C₇H₇SO₃H, xylenesulfonic acid C₈H₉SO₃H and mesitylenesulfonic acid C₉H₁₁SO₃H to an OPC paste diminished the bulk heat evolution in the interval 0 to 72h (Figure 4.) in general.

Figure 4. Calorimeter curves: OPC and 1 M benzene sulfonic acids

The addition of C₆H₅SO₃H produced 32 %, C₇H₇SO₃H 33%, C₈H₉SO₃H 57% and C₉H₁₁SO₃H 75% heat of the reference paste. On the basis of the influence of the admixture addition on the mpi, mmh and the heat flow, the 4 different benzenesulfonic acids must be divided in 2 groups. It can be seen that sulfonic acids without CH₃ substitution (C₆H₅SO₃H) and the sulfonic acid with one CH₃-group, substituted in opposite orientation to the sulfonate group (SO₃H), had a strong retarding effect on the cement hydration. The continuous increase of the CH₃-number at the benzene ring (C₈H₉SO₃H and C₉H₁₁SO₃H), where CH₃ groups are asymmetrically (C₈H₉SO₃H) and symmetrically (C₉H₁₁SO₃H) substituted on the benzene ring, lowered the retarding effect (Figure 5).

Figure 5. Heat evolution: OPC and 1M benzene sulfonic acids

Not only high benzenesulfonic acid concentrations had significant influence on the cement hydration. 10^{-3} to 10^{-6} mole/l additions increased the heat flow of cement pastes, investigated by heat-flow calorimetry. This time sulfonic acids with an asymmetrical and a symmetric distribution of the CH_3 substituents accelerated the cement hydration, whereas admixtures of group 1 with an opposite orientation of CH_3 and SO_3H group ($\text{C}_7\text{H}_7\text{SO}_3\text{H}$) and ($\text{C}_6\text{H}_5\text{SO}_3\text{H}$) did not accelerate as well as group 2 compared to the reference (Figure 6).

Figure 6. Heat evolution: OPC and 10^{-6} M benzene sulfonic acids

3.3 Investigations on sulfonic acid influences on the phase assemblage of a cement paste

3.3.1 Phase formation of OPC pastes investigated by DSC

The measurement of dried cement pastes by DSC made it possible to determine the dehydration reaction of the different main hydration phases indirectly (Figure 7).

Figure 7. DSC graphs of OPC and 1 M $\text{C}_3\text{H}_7\text{SO}_3\text{H}$ w/s=0.5 T = 25°C

In the temperature range 35 to 120°C the dehydration process of the C-S-H phase and the ettringite dehydration reactions progressed. Therefore it was not possible to determine the C-S-H and ettringite concentrations separately. However, the formation of ettringite was followed indirectly on the dehydration of gypsum. If more gypsum was used for the ettringite crystallisation, the peak area of the gypsum dehydration peak became smaller. Furthermore, the endothermic peak in the region

260 to 320°C was identified as the dehydration of the main layer of an Afm-phase. Due to the pyrolysis of the benzene ring or the aliphatic chain of the alkanesulfonic acid most of the DSC graphs showed a big exothermic peak at approximately 250°C. The dehydration of portlandite started at about 430 °C Although, the portlandite formation is a result of the hydration reaction of calciumsilicates, the integration of the area of the endothermic portlandite dehydration peaks did not give sufficient results for quantification of the C-S-H concentrations.

3.3.2 Phase formation of OPC pastes investigated by XRD

Different cement pastes were investigated as a function of the hydration time (Figure 8 and Figure 9). C₃A and the ferrite phase reacted with gypsum to ettringite, which was detected after 15 minutes of cement hydration. The crystal structure of ettringite was not influenced because of the presence of sulfonic acid anions. The 2 Theta values of ettringite were not shifted to higher or lower 2 Theta-values and the refinement of the metric parameters gave the values of the common sulphate ettringite.

Instead of the formation of monosulfate or monocarbonate, new AFm-phases crystallized, because the sulfonic acid ions of the alkanesulfonic acids C_nH_{2n+1}SO₃⁻ with n = 1,2,3,4 and the different benzenesulfonic acid ions were chemically fixed in the interlayer of the AFm-structure instead of sulphate or carbonate ions [6], [7]. The ion exchange is visible due to the 2 Theta shift of the (00l)-base reflections. Most of the time only 3 to 5 (00l) reflections could be detected and used for the refinement of metric parameters due to the low grade of cristallinity. Therefore only the c-dimensions were refined (Table 3).

Figure 8. Phase formation: OPC and 1 M C₃H₇SO₃H

Figure 9. Phase formation: OPC and 0.25 M $C_8H_9SO_3H$

Table 3. Layer distances of in situ formed Afm-phases

Afm-phases	Layer distance c' [nm]
$C_3A \cdot Ca(C_7H_7SO_3)_2 \cdot nH_2O$	1.714
$C_3A \cdot Ca(C_8H_9SO_3)_2 \cdot nH_2O$	1.583
$C_3A \cdot Ca(C_9H_{11}SO_3)_2 \cdot nH_2O$	1.761
$C_3A \cdot Ca(CH_3SO_3)_2 \cdot nH_2O$	1.255
$C_3A \cdot Ca(C_3H_7SO_3)_2 \cdot nH_2O$	1.385

4. DISCUSSION AND CONCLUSIONS

The addition of different benzene sulfonic acids and alkanesulfonic acid sodium salts modified the hydration kinetics of an OPC. Benzene sulfonic acids accelerated or retarded the OPC hydration. Low admixture concentrations (10^{-6} to 10^{-3} mole/l) activated the hydration reactions; the minima of the period of induction of the calorimeter curves were shifted approx. 2h in comparison to the reference to lower hydration times. Higher admixture concentrations (10^{-2} to 1 mole/l) retarded the cement hydration strongly.

The interpretation of the heat flow, determined on the basis of calorimeter curve areas, showed that the time at the end of the induction period to 36h was most influenced by the admixture. Alkane sulfonic acid sodium salts acted as only retarders.

Methane sulfonic acid sodium salt concentrations (10^{-4} to 0.25 mole/l) accelerated the cement hydration. High concentrations of long chained alkane sulfonic acid sodium salts (0.25 and 1 mole/l) showed strong retarding effects. Not only the minimum of the induction period also the maximum of the main hydration were shifted to higher times. The total heat flow of the cement

pastes, measured between 0 to 72 h decreased successively with the addition of long chained sodium alkane sulfonates.

Retardation or acceleration of the OPC hydration kinetics pastes existed due to the orientation and number of CH_3 -substituents at the benzene ring of different benzene sulfonic acids and the variation of the length of alkanesulfonic acid sodium salts $\text{C}_n\text{H}_{2n-1}\text{SO}_3\text{Na}$ $n = 1, 3, 5, 7, 8, 9$. The different molecular structure of benzene sulfonic acids showed that 2 groups one the one side $\text{C}_7\text{H}_7\text{SO}_3\text{H}$ and $\text{C}_6\text{H}_5\text{SO}_3\text{H}$ and on the other side $\text{C}_8\text{H}_9\text{SO}_3\text{H}$ and $\text{C}_9\text{H}_{11}\text{SO}_3\text{H}$ existed. The addition of group 1 admixtures retarded strongly and the addition of admixtures of group 2 retarded too, but not as strong as group 1.

The effects of the acids are based on the number and different orientation of the CH_3 substituents against the sulfonate group. Toluene-p-sulfonic acid has an opposite arrangement of the substituents, the benzene sulfonic acid has no CH_3 substituents. Mesitylene sulfonic acid and xylene sulfonic acid have a symmetric and asymmetric distribution of the CH_3 substituents.

The variation of the chain length of alkanesulfonic acids showed strong retarding effect with longer chain lengths. The comparison of both, alkane- and benzene sulfonic acids gave the result, that strong retarders, as long we talk about these sulfonic acids, are preferably based on an opposite distribution of a sulfonate group and an aliphatic $\text{C}_n\text{H}_{2n-1}$ chain. It is not too important if a benzene ring is put between the $\text{C}_n\text{H}_{2n-1}$ chain and the sulfonate group, the more important is the chain length. The quantitative investigation of the C-S-H phase in the cement pastes by DSC was not possible, because the dehydration reactions of ettringite and the C-S-H phases overlapped during heating in the range 30 to 120 °C. However, the formation of newly formed Calcium aluminate sulfonate hydrates was detected in OPC pastes and 0.25 M $\text{C}_6\text{H}_5\text{SO}_3\text{H}$, $\text{C}_7\text{H}_7\text{SO}_3\text{H}$, $\text{C}_8\text{H}_9\text{SO}_3\text{H}$ or $\text{C}_9\text{H}_{11}\text{SO}_3\text{H}$ and OPC pastes and 1 M $\text{C}_n\text{H}_{2n-1}\text{SO}_3\text{Na}$. The phases were identified and the metric parameters refined.

ABSTRACT

Redispersible powder (RP) and cellulose ether (CE) are two standard additives for ceramic tile adhesives to improve (a) the performance with respect to workability and water retention (mainly given by CE) of the fresh paste, as well as (b) final strength and flexibility properties of the hardened mortar (mainly improved by RP). In addition to established methods for visualisation and quantification of mortar components like pores, fillers and cement minerals, new methods had to be developed for the polymer phases. Based on stained polymers in combination with fluorescence and electron microscopy, digital images can be generated which are processed by image analysis resulting in distribution diagrams of the different polymers in the mortar.

The distributions of all mortar phases can be used to investigate the time dependent changes of processes occurring during preparation, application and hardening of mortars. It becomes evident that individual polymers show specific behaviours during the different stages. During an early stage, CE and latices become locally enriched at the cement matrix/air interfaces due to their high surface activity. In case of CE, the migration of the pore water into the porous substrate induces an enrichment towards the mortar base. In contrast, latices tend to stay in place. Therefore, CE is soluble, whereas latex is not redispersible in the pore water.

The data resulting from the distribution diagrams of different formulations will be compared with their physical properties (e.g. adhesion strength). The quantitative distribution pattern of an additive is one key to understand its performance in the application including the influence on the final mechanical properties of the mortar.

1. INTRODUCTION

Polymer-modified cement mortars, namely, tile adhesives, can be described and classified either by their compositions, working parameters (e.g., application, workability, storage conditions) or final physical properties. All these parameters are closely related to the time-dependent interaction of the individual components (polymers, cement phases, mineral fillers, pores). From initial mixing to the hardened end product (Figure 1) the microfabric evolution in this complex polyphase system links all the different stages and their physicochemical aspects. Therefore, detailed microscopy of polymer-modified mortars is regarded as a key tool for a profound understanding of such composite materials.

Figure 1: a) Reflected light microscope image of a polymer-modified mortar. Fracture surface from tile (top) through highly porous mortar to concrete substrate (bottom); b) environmental scanning electron microscope image of an uncoated fracture surface across a tile (top) mortar interface. Three air voids are separated by a polymer film (vertical) and a cement-polymer composite wall (horizontal).

Common tile adhesives are commercially available as premixed dry compounds. At the construction site only a predefined amount of water must be added and mixed to achieve a ready-to-use fresh mortar. The components of such an instant dry mortar can basically be grouped into binders, fillers and additives. Ordinary Portland cement (OPC) is the most typical binder, which is added in the amount of 20-40 wt%. Other types of cement, hemihydrate, natural and industrial puzzolana can be combined with OPC or even replace it completely. 60-80 wt% are composed of filler materials, typically siliceous and/or carbonate sand and finer grained fractions ($<100\text{ }\mu\text{m}$), but also various light weight fillers can be contained. Typical additives are cellulose ether (CE) and redispersible powder (RP). In order to achieve a good workability and water retention, approx. 0.5 wt% CE is added. RP (0.5-5 wt%) further improves the workability of the fresh mortar and finally provides an increased adhesive strength of the hardened end product.

2. METHODS AND RESULTS

Planar and polished sections of the high-porous mortars (bulk porosity of up to 40 vol%) are required for quantitative microfabric analysis. Unfortunately, conventional impregnation and polishing techniques often affect the polymer phase causing severe artefacts by dissolution and redispersion followed by redistribution and leaching, as well as mechanical damaging of the fragile microstructure (Figure 1). In order to prevent these artefacts various impregnation resins, polishing and cleaning aids were evaluated according to their dissolution effect on the polymer phases (CE, latices and polyvinyl alcohol). Chemical elements (e.g., Cl) occurring exclusively in some polymers or selective staining of the polymers allow their discrimination in the mortar by element mapping (electron microscopy) or fluorescence microscopy.

With these newly developed methods, we can allocate and quantify the polymer phases in addition to the conventionally measured mortar components like pores, fillers and cement minerals (anhydrous clinker and hydrates) [1], [2], [3]. Figure 2, for example, presents a micrograph taken by fluorescence microscopy. Prior to mixing the dry components (35.0 wt% OPC, 42.0 wt% quartz sand, 22.5 wt% carbonate powder, 0.5 wt% CE), CE had been stained by a fluorescence dye, following a similar procedure described by [4]. Under fluorescent light, the occurrence of CE is manifest by very bright yellow colour. Additionally, fillers, air voids and the cement matrix can be distinguished by their different fluorescence behaviour. The segmentation of the phases via image

analysis allows a distribution diagram (Figure 2) to be reconstructed showing the full width of the mortar bed (5 cm). In this way, each horizontal bar of the diagram represents the mortar composition, summarised over the entire image length for a specific depth interval. The diagram shows enrichments of CE and distribution variations of fillers, air voids and the cement matrix through the mortar profile.

Figure 2: left: mortar with tile (top) and concrete substrate (bottom), F: mineral filler, V: air void, CE: cellulose ether stained with fluorescent dye; right: profile across the mortar ranging from the concrete substrate to the ceramic tile. The diagram shows the distribution of CE (including an overshining effect), the cement matrix (cement phases, capillary porosity), filler and air voids in area%. The phases were segmented according to their specific colour range on the micrograph and are not normalised with respect to their initial composition (wt%).

Allocation and quantification of latices is shown by a mortar which has been modified with ethylene/vinyl acetate/vinyl chloride latex (35.0 wt% OPC, 40.0 wt% quartz sand, 22.5% wt carbonate powder, 2.0 wt% latex, 0.5 wt% CE). In order to visualise the spatial distribution of the latex, chlorine mappings were acquired on an electron microprobe by wavelength dispersive spectroscopy. The small chlorine concentration requires long dwell times which leads to a total acquisition time of approx. 8 h for an image with a size of 750x750 pixels, i.e., 1500x1500 μm. Figure 3 shows the chlorine map and the corresponding distribution diagram of the latex. The latter was normalised with respect to the cement matrix to avoid an influence of air void and filler distribution on the latex distribution.

Figure 3: left: mortar with tile (top) and concrete substrate (bottom), mortar with mineral fillers and air voids (black, F/V) and the chlorine distribution (latex) in the cement matrix; right: profile across the mortar ranging from the concrete substrate to the ceramic tile. The diagram shows the distribution of latex in the cement matrix in vol%, normalised with respect to its initial composition.

3. DISCUSSION

Fluorescence light microscopy of FITC-stained CE revealed a strong enrichment of CE towards the porous concrete substrate in mortars without latex-modification. This strong segregation, which causes large concentration gradients (Figure 2), must be related to the migration of free pore water in the first minutes to hours after application. Hence, CE must be dissolved in the pore water rather than being adsorbed to mineralic surfaces of filler and cement grains. On the other hand, the air entraining ability indicates that CE partly occupies the air/slurry interface to stabilise air bubbles. CE trapped at air/slurry interfaces is regarded as stationary whereas CE dissolved in the pore water can be transported together with the migrating capillary water. The accumulation of CE in the lowermost part of the mortar bed creates a CE-rich contact layer with increased water retention. Interestingly, only a limited amount of CE is able to enter the porous concrete substrate over short distances. This penetration is in particular concentrated along microcracks in the concrete substrate. It is as yet unknown, the extent to which the CE enrichment affects cement hydration in the lowermost part of the mortar and the consequences for the final adhesion properties of the substrate.

In mortars containing CE and latex, the CE distribution pattern is different from mortars without latex. The strong enrichment towards the substrate is less evident, but there is an additional enrichment towards the uppermost 30 μm of the mortar layer, directly underneath the mortar/tile interface. We believe, therefore, that latices stop the large-scale migration of CE and/or reduce the migration of the free pore water, but allow small-scale migration due to the high surfaces activity of CE which enhances a CE accumulation at the mortar air interface.

Latices seem to be homogeneously distributed throughout the cement matrix. As the latex particles have a defined particle size of about 1 μm , they cannot pass the capillary pores, and are, therefore, restricted to very local migration. However, some latices tend to be enriched at the mortar-tile interfaces, which significantly increases adhesion strength. These enrichments result from a local fractionation mechanism, which must be attributed to an early stage of mortar evolution, i.e., to the time interval between mortar application on the substrate and the inlaying of the tile.

Our new microstructure analysis techniques have also been applied to water stored samples. The distribution pattern of the ethylene/vinyl acetate/vinyl chloride latex did not change. However, the CE is remobilised and now enriched towards the concrete substrate. This is in agreement with conclusions drawn from wetting experiments on in-situ polymer films [5], which showed that latices cannot be remobilised, but CE is redissolved in water. For that reason, the remobilisation and migration of CE in the hardened mortar during wet storage is not hindered by latex films.

In addition, distribution patterns of the non-polymeric phases can also be used to detect processes occurring during preparation, application and hardening of mortars. For example, the enrichment of air voids towards the tile interface (Figure 2) is related to additional air entrapment between the pre-applied mortar with its uneven surface and the tile. The amount of entrapped air is supposed to increase with both longer open time and the tendency of the mortar to form a skin. The mechanism of air entrapment generates a mechanically weak zone and might induce decreased adhesion strength at the mortar-tile interface.

4. CONCLUSIONS

This study demonstrates that even in a highly viscous mortar, phases strongly fractionate and can produce large concentration gradients across the mortar bed. The quantitative distribution pattern of an additive is a major key to understand its performance in the application.

Each quantitative microscopic technique is dedicated to a certain additive chemistry requiring specific staining methods. Therefore, different staining and scanning microscopy techniques must be combined to generate a global picture of the whole mortar microstructure, which is valid over the entire range of thickness and composition.

In the future, these newly developed methods will be applied to a wider range of mortar types subjected to different storage types (dry vs. wet storage). The resulting data will be compared with the physical properties (e.g. adhesion strength) of the different samples.

In order to understand the physical properties, and to develop new products with specific performance profiles, the quantitative microscopy of polymer structures is regarded as an important step in the study of the entire evolution of the microfabric of such composite materials.

ABSTRACT

This paper reviews the hydration and hydration products of alkali-activated slag cements, interactions between alkali ions and calcium silicate hydrate (C-S-H), and leachability of alkalis from C-S-H. The presence of alkali ions of the activator ensures a high alkaline environment for vitreous slag to initiate and to continue hydration. C-S-H, with a low C/S ratio and a significant amount of alkalis, is the major hydration product of alkali-activated slag cements although some minor hydration products may vary with the nature of the slag and activator used. The amount of alkalis in C-S-H increases with the increase of alkali concentration in the solution and with the decrease of C/S ratio. Alkalis incorporate into C-S-H in three different mechanisms. One or another mechanism may dominate depending on the C/S ratio of C-S-H. However, the three mechanisms co-exist. The incorporation of alkalis into C-S-H changes its solubility curve. Alkalis in C-S-H can leach out easily. The solubility curve of C-S-H changes to its original shape when alkalis leach out. Thus, alkalis provide a high pH environment and act as catalysts rather than reactants during the hydration of alkali-activated slag cements.

1. INTRODUCTION

Alkali-activated slag cements are drawing more and more attention because of their high performance and utilization of by-product materials in their manufacture. The principle of alkaline activation of slag has been known since the 1940's [1]. Although many attempts have been made to explain the hydration process of alkali-activated slag cement, the roles of activators are still not well understood.

It is generally agreed that the performance and microstructure of alkali-activated slag cements are determined by the chemical and mineralogical compositions of the slag and the dosage and nature of the activator(s) used. Thus, it is not surprising that different results are obtained in different laboratories since the raw materials used in various laboratories could be very different. Different mechanisms have been proposed to explain the roles of activators. For example, Kondo regarded NaOH as a catalyst during the activation of slag [2]. However, Narang and Chopra [3] believed that NaOH took part in the reactions in much the same way as lime and gypsum but, due to strong cationic influence, acts relatively strongly.

In this paper, the author reviews the hydration and hydration products of alkali-activated slag cements, interactions between alkalis and C-S-H, leachability of alkalis in C-S-H, and tries to clarify the status and role of alkalis in alkali-activated slag cements.

2. LIHYDRATION BEHAVIOUR OF ALKALI-ACTIVATED SLAG CEMENTS

Many researchers have tried different means to investigate the early hydration of alkali-activated slag cements. Shi and Day [4, 5] conducted a systematic study on the early hydration behaviour of alkali-activated slag cements containing different activators using a calorimeter.

The hydration behaviour of alkali-activated slag cements can be classified into three types as shown in Figure 1. For type I, one peak occurs during the first few minutes and no peaks appear thereafter. Hydration of the slag in water or in Na_2HPO_4 solution at both 25 and 50°C is an example. In this case, the slag usually does not set and harden during the testing period. For Type II, only one initial peak appears before the induction period and one accelerated hydration peak appears after the induction period. The hydration of slag activated by alkali hydroxides belongs to this type. For Type III, two peaks, one initial and one additional, appear before the induction period and one accelerated hydration peak appears after the induction period. The initial peak could be lower or higher than the additional initial peak depending on the nature of activators and hydration temperature. This type of hydration includes the cements activated by alkali weak acid salts including silicates, carbonates, phosphates and fluorides.

Although alkali fluoride has a low pH, it can still activate the potential hydraulic reactivity very obviously. The hydration behaviours of slag are in agreement with the statement that any alkaline compound, whose anion or anion group can react with Ca^{2+} to form a less soluble or hardly soluble Ca-compound, can act as an activator for a slag [6]. The initial pH has an effect on the initial dissolution and hydration of the slag. However, the further hydration of the slag is determined by the formation of a hardly soluble Ca-compound.

When an alkali weak acid salt is used, it has a low initial pH, so that the initial dissolution and hydration of the slag will be slow. However, the formation of the hardly soluble Ca-compound will leave free alkalis in the solution and increases the alkalinity of the solution, which then accelerates the hydration of the slag. If an alkali salt solution has a low pH, and no hardly soluble Ca-compound can form, the alkali salt cannot be used as an activator. It has been noted that the Ca-Compound has a great effect on the structure formation and properties of hardened cement pastes [4]. The anion or anion group plays a critical role the hydration of alkali-activated slag cements in two aspects: initial pH and the formation of hardly soluble Ca-compound.

If an alkali salt solution has a low pH, and no hardly soluble Ca-compound can form, the alkali salt cannot be used as an activator. It has been noted that the Ca-Compound has a great effect on the structure formation and properties of hardened cement pastes [4]. The anion or anion group plays a critical role the hydration of alkali-activated slag cements in two aspects: initial pH and the formation of hardly soluble Ca-compound.

3. HYDRATION PRODUCTS OF ALKALI-ACTIVATED SLAG CEMENT

Many researchers have investigated the hydration products of alkali-activated slag cements and it is generally agreed that the major hydration product of alkali-activated slag cements is calcium silicate hydrate (C-S-H) with a low C/S ratio [7-10]. However, a variety of minor hydration products such as

Figure 1. Hydration Models for Alkali-Activated Slag Cements [4]

C_2ASH_8 , $C_3AS_xH_{6-2x}$, C_4AH_{13} , M_4AH_{13} , $C_3A.CaCO_3.12H_2O$, etc, have been reported. There is no doubt that the minor hydration products vary with the composition of both slag and activator.

3.1 Effect Of Chemical Composition Of Slag On Hydration Products

The chemical compositions of a slag vary among ore bodies and furnace operations. Osborne et al. [11] conducted a large-scale test of practical furnace operation and determined the composition of blast furnace slag for optimum furnace operation in CaO - MgO - Al_2O_3 - SiO_2 system (Table 1).

Table 1 Optimum Chemical Composition of Blast Furnace Slag for Furnace Operation (% by mass) [11]

No.	Al_2O_3	SiO_2	CaO	MgO
1	5.0	36.0	43.0	16.0
2	10.0	32.0	44.0	14.0
3	15.0	28.5	44.0	12.5
4	20.0	24.0	45.0	11.0
5	25.0	19.0	48.0	8.0
6	25.0	12.0	57.0	6.0
7	30.0	9.0	56.0	5.0
8	35.0	7.0	54.0	4.0

Experimental results have indicated that the chemical composition of blast furnace slag has a significant effect on its hydration process due to the formation of different hydration products [12]. In many cases the MgO content of blast furnace slag is low and the slag can be described by the CaO - SiO_2 - Al_2O_3 system. The phase diagram of CaO - Al_2O_3 - SiO_2 - H_2O system, as shown in Figure 2 indicates that five different products such as C - S - H , $Ca(OH)_2$, C_4AH_{13} , C_2ASH_8 and CS_2H_3 could appear in this system, while calcium hydroxide and gehlenite hydrate cannot co-exist at equilibrium [13]. In reality, equilibrium is attained only locally on a scale of microns or less due to difficulty of ionic transport within the pastes [14]. It must also be recognized that some calcium hydroxide may be made essentially non-reactive by the formation of an impermeable coating of C - S - H [15]. Thus, it is not surprising that calcium hydroxide and gehlenite hydrate have been detected at the same time [16].

Figure 2. Phase Diagram in CaO - Al_2O_3 - SiO_2 - H_2O system [13]

It can also be expected that hydration products vary with the chemical composition of the slag in the presence of an activator. Granulated phosphorus slag consists mainly of CaO and SiO_2 , and its Al_2O_3

and MgO content is usually very low. X-ray diffraction analysis and scanning electron microscopic observations have indicated that C-S-H is the only hydration product of activated ground granulated phosphorus slag when NaOH is used as an activator [17, 18]. However, C_2ASH_8 and C_4AH_{13} have also been detected in NaOH activated blast-furnace slag in addition to C-S-H [19]. C_2ASH_8 or gehlenite hydrate is an AFm phase which has an interlayer aluminosilicate anion [20]. M_4AH_{13} , instead of C_4AH_{13} , occurs if the MgO content of the slag is high. Since strength depends on initial porosity, the degree of reaction and space filling, and the intrinsic strength of the reaction products [21], the chemical composition of slag will have a direct influence on strength development of alkali-activated slag cement.

3.2 Effect Of Chemical Activators On Hydration Products

The nature of the chemical activator influences the hydration products. It was found that C-S-H, C_4AH_{13} and C_2ASH_8 are products of NaOH and lime-activated slag, and ettringite forms when sulphates are present [19]. X-ray diffraction patterns of alkali-activated slag and ASTM Type III Portland cement pastes hydrated for 540 days at 23°C are shown in Figure 3. Hydration products of alkali-activated slag are different from those of Portland cement pastes. The main hydration product of the three alkali-slag cement pastes is C-S-H, but minor hydration products vary with the nature of activators. C_4AH_{13} appears in $Na_2O \cdot SiO_2$ -activated slag, $C_3A \cdot CaCO_3 \cdot 12H_2O$ in Na_2CO_3 activated slag and C_4AH_{13} and C_2ASH_8 in NaOH-activated slag [22]. Other research found that the addition of different activators changes hydration products of lime-natural pozzolan, lime-fly ash and lime-slag blends [23]. Change in hydration products due to the presence of different activators will change the hydration process and microstructure formation, which affect the strength development of the cement in turn.

Wang and Scrivener [8, 24] examined NaOH- and waterglass-activated slag cement pastes using XRD. As hydration time increases, the diffuse peak attributed to the $CaO \cdot SiO_2 \cdot Al_2O_3$ vitreous structure decreases, but a peak belonging to C-S-H intensifies. The crystallinity of C-S-H in NaOH-activated slag cement is obviously higher than that in waterglass-activated slag cement. A crystalline compound $Mg_6Al_2CO_3(OH)_{16} \cdot 4H_2O$ also appears in NaOH-activated slag cement.

Figure 3. XRD Patterns of Alkali-Slag Cement Pastes Hydrated for 540 Days at 23°C [22]

Glukhovskiy et al [7] reported a series of crystalline compounds such as hydrogarnet, zeolitic phases, mica phases including nepheline, natrolite, analcite, paragonite and gismondite, from the hydration of alkali-activated slag cements based on XRD analyses. However, many researchers [17, 25, 26, 8] could not identify those crystalline phases in hardened alkali-activated slag cement pastes cured at room temperatures, even after 15 years of curing [10]. Crystalline compounds such as xonotlite, tobermorite, sodium-zeolite, such as NAS_2H_3 could be identified in hydrothermal treated alkali-activated slag cement pastes [10, 27].

4. INTERACTIONS BETWEEN ALKALIS AND C-S-H

Stade [28] suggested that the incorporation of alkalis into C-S-H, from room to elevated temperatures, follow the following three mechanisms:

- (1) Neutralization of acidic Si-OH groups by Na^+ or K^+ :

- (2) Ion exchange of Na/K for Ca. This process would increase with increasing C/S ratio.

- (3) cleavage of Si-O-Si bonds by Na^+ or K^+ , with the attachment of Na^+ or K^+ to Si, represented by:

The first mechanism happens mainly to C-S-H with a low C/S ratio because it contains a high concentration of acidic Si-OH group. The second mechanism is applied mainly to C-S-H with a high C/S ratio. The third mechanism depends on the surface area of C-S-H. Due to the complexity of the system, it is also suggested that multiple mechanisms at any one time may be operating to uptake alkaline ions.

It is agreed that the incorporation of alkalis into C-S-H increases as the C/S ratio of C-S-H decreases. It was found [29] that there is almost a linear relationship between the log scale of the Na/Ca and the C/S ratios of the C-S-H, ranging from 0.85 to 1.8, as shown in Figure 4. This means that the incorporation of alkalis into C-S-H decreases swiftly as the C/S ratio of C-S-H increases. The alkali incorporated into C-S-H is almost linearly proportional to the initial concentration of the alkali in the solution. Kalousek [30] found that the limited composition for N-C-S-H system is $0.25\text{Na}_2\text{O} \cdot \text{CaO} \cdot \text{SiO}_2 \cdot x\text{H}_2\text{O}$. Taylor [31] found that the Na/Ca atom ratio is about 0.01 in hydrated Portland cement pastes, since the C/S ratio of C-S-H in hydrated Portland cement paste usually ranges from 1.2 to 2.3 depending on the cement composition, water to cement ratio, hydration temperature, age, etc. [32]. The incorporation of impurities into a crystalline structure is usually governed by crystallochemical restraints that limit the number of possible replacement mechanisms and their stoichiometry, while C-S-H is a poorly crystallized version of the mineral tobermorite and the main restriction for the incorporation of alkali into the structure of C-S-H is probably the condition of electroneutrality [33].

Figure 4. Effect of C/S Ratio and Initial Alkali Concentrations on Na/Si Ratio in C-S-H Phase [29]

Curing temperature can have a significant effect on the alkali retention capacity of C-S-H. For a given C/S ratio, C-S-H formed at elevated temperatures has a higher crystallinity and lower surface area, and will bind smaller amounts of alkalis than that formed at lower temperatures. ^{29}Si NMR spectroscopy indicated that there is little difference between Na-free and Na-contained C-S-H gel with a high C/S ratio, however, some differences were found in C-S-H gels with a low C/S ratio. Q_2/Q_1 ratio decreases as the Na content increases [34]. This indicates that the presence of Na decreases the Si chain lengths in C-S-H.

Taylor concluded from his analysis of pore solution data that sodium was significantly better bound into hydrated cement paste than potassium [31]. Experimental results obtained by Stadel [28], and Hong and Glasser [29] indicated that there is no significant difference in uptake of Na and K by C-S-H.

C-S-H in NaOH activated-slag cement pastes has a similar C/S ratio, but waterglass-activated slag cement paste has a C/S ratio lower than that of the slag due to the addition of SiO_2 from the waterglass [8]. The initial alkali concentration in alkali-activated slag pastes can be as high as several moles. It can be expected that the alkalis bound by C-S-H are higher than that by Portland cement.

Hong et al [26] monitored the concentration of Na_2O in the liquid phase of 0.3 N NaOH and Na_2SiO_3 activated-slag cements with a water to slag ratio of 20 from 3 hours to 28 days. It was found that the Na_2O concentration in the liquid did not change with time in Na_2SiO_3 -activated slag cements, but decreased slightly with time in the NaOH activated-slag cement. In another study, it was found that 80 to 90% of initial alkali could be detected in the liquid phase of the hardened alkali activated slag cement (Figure 5). The author proposed that the alkaline cation acts as a destruction catalyst, based on the wave character of the change of Na_2O concentration in the liquid phase of hardened alkali-activated slag cement, during the destruction of the glassy slag structure and the formation of hydrates [35].

Figure 5. Wave character of the change of Na_2O concentration in the liquid phase of hardened alkali-activated slag cement [35]

5. SOLUBILITY OF C-S-H AND LEACHABILITY OF ALKALIS FROM C-S-H

The presence of alkalis significantly increases the solubility of Si and decreases the solubility of Ca due to common ion effect. However, it does not change the K_{sp} of C-S-H. The solubility curve of N-C-S-H is very different from that of C-S-H (Figure 6), but is closer to that of C-S-H after the leaching test. Analysis of liquid and solid phases indicated that the Na/Ca molar ratio in leachates is much higher than that in the solid phase, which means that Na is preferably leached from the solid phase. The Na/Ca molar ratio in the leachate consistently increases with decreasing C/S ratio of N-C-S-H gel. This is attributed to the fact that lower C/S ratio gels are relatively enriched in Na.

Several studies have been conducted on the leachable alkalis in alkali-activated slag cement pastes in order to understand the activation mechanism of slag cements. Belitsky et al [36] measured the non-

leachable amount of Na_2O by immersing 2 grams of 1 - 2 mm size crushed hardened $\text{Na}_2\text{O} \cdot n\text{SiO}_2$ activated slag cement pastes in 100 ml of distilled water for 7 days. The total alkali content was determined by dissolving the pastes in 1 N HCl solution. Experimental results indicated that the non-leachable Na_2O varied only from 0.17 to 0.37% by mass of slag, depending on the age, molar ratio n and dosage of $\text{Na}_2\text{O} \cdot n\text{SiO}_2$.

Eight batches of hardened alkali-activated slag cement pastes were prepared using four types of slag - gelhlenite, akermanite, diopside and melilite, and two types of activators – NaOH and Na_2CO_3 and cured at 80, 200 and 250°C for 28, 90, 360 and 720 days [10]. The cement pastes were ground in a agate mill and the ground samples washed with distilled water until it showed $\text{pH}=7$. The measured soluble alkali content varied from about 16% to 46% and changed slightly with the type of activator and the composition of slag, but decreased significantly as the curing temperature increased.

6. SUMMARY

The hydration of alkali-activated slag cements falls into three categories: For type I, one peak occurs during the first few minutes and no peaks appear thereafter. In this case, the slag usually does not set and harden during the testing period. For Type II, only one initial peak appears before the induction period and one accelerated hydration peak appears after the induction period. For Type III, two peaks, one initial and one additional initial peaks, appear before the induction period and one accelerated hydration peak appears after the induction period.

C-S-H with a low C/S ratio is the major hydration product of alkali-activated slag cements although other minor hydration products may vary with the nature of the slag and activator used. Solubility Curves of C-S-H and N-C-S-H [34] incorporate into C-S-H in three different mechanisms: (1) neutralization of acidic Si-OH groups by Na^+ or K^+ , (2) ion exchange of Na/K for Ca, and (3) cleavage of Si-O-Si bonds by Na^+ or K^+ , with attachment of Na^+ or K^+ to Si. Depending on the C/S ratio of C-S-H, one or another mechanism may dominate, however, the three mechanisms co-exist.

The incorporation of alkalis into C-S-H increases as the alkali concentration in the solution increases and as the C/S ratio of the C-S-H decreases. The main restriction for the incorporation of alkali into the structure of C-S-H is probably the condition of electroneutrality. The incorporation of alkalis affects the solubility curve of C-S-H. However, alkalis in C-S-H can be leached out easily. The leaching out of alkali from C-S-H moves its solubility curve toward its original curves.

Figure 6. Solubility Curves of C-S-H and N-C-S-H [34]

The presence of alkalis keeps a high pH value in the solution, which is important to initiate and to continue the hydration of the slag. However, the alkalis are not really involved in the hydration process and hydration products. Alkalis can be simply regarded as catalysts rather than reactants. However, the anion or anion groups of activators have a great effect on the hydration, structure formation and properties of hardened alkali-activated slag cements.

ABSTRACT

In previous studies (1-4) the authors have discussed the identification of suitable chemical and mechanical activation systems for low calcium fly ash activation, and the role of mineralogical and chemical compositions of the fly ash on the chemical and mechanical activation. The goal of the present study is to characterize the performance of chemically and mechanically activated fly ash - cement materials when exposed to a simulated steam curing environment. The effect of simulated steam curing conditions on the compressive strength was evaluated up to 350°C with and without the chemical and mechanical activation system. Heat of hydration, BET surface area measurement, and x-ray diffraction studies were used as the other characterization techniques. The studies clearly show that the steam curing increases the compressive strength development of fly ash - cement materials during the early hydration period. No acceleration of compressive strength development was observed at 28-day hydration. The steam cured fly ash-cement materials exhibit the same order of influence of chemical and mechanical activation as observed for room temperature curing.

1. INTRODUCTION

Fly ashes are fine powders formed from pulverized coal combustion process. Fly ashes pose a major solid waste disposal problem all over the world. Fly ashes are widely used in blended cements or with Portland cement. Properties of fly ashes vary significantly with coal composition and plant operating conditions. Alkali activation of cementitious materials has been the subject of research for the last few decades (1- 6). In the previous studies of low calcium fly ash activation studies by the authors (7,8), combined effects of chemical and mechanical activation of the fly ash at 20 wt % replacements level were identified using various chemical activators. It has been demonstrated that the addition of NaOH in small concentrations (0.5-1wt % of fly ash) produced equal or higher compressive strengths than the 100% OPC control mixture. The mechanically activated fine ash produced higher strengths than the respective non-activated ash. A low concentration of sodium hydroxide was an effective chemical activator for all the fly ashes studied. The chemical and the mineralogical composition of the low calcium fly ashes did not influence the alkali activation. The treatment of the fly ash particles with NaOH prior to paste formation with OPC is necessary for early strength development. Morphological and heat evolution studies revealed that the possible surface renewal effect of the fly ash particles may be key to the effective chemical activation. The optimization studies showed that the sodium hydroxide concentration between 0.05 N and 0.1N produces the best alkali activation effect for the low calcium fly ash.

Among the most important factors to be considered on concreting are curing temperature and humidity. Temperature and humidity can have a major effect on the mechanical properties of concrete.

Temperature can accelerate or decrease the rate of strength development of concrete at early stages (9-11). It has long been known that elevated curing temperatures, while accelerating the early strength gain of concrete, reduce the ultimate strength (12). In this study, the effect of simulated steam curing conditions on the mechanical properties was evaluated on low calcium fly ash with and without the chemical activation system identified in the previous study. The study also discusses the procedures and conditions used for the simulated steam curing and the results obtained therein.

2. MATERIALS

The materials and methods used for the alkali activation of low calcium fly ash are described elsewhere (7,8). The various inorganic salts used in this study were either AR/GR or Reagent Grade chemicals. The superplasticizer used was a sulfonated naphthalene formaldehyde condensate supplied by Boremco, trade name Mighty 150. X-ray diffraction and hydration calorimetric evaluations were carried out on the cured and uncured samples.

2.1 Milling

Milling of the coarse fly ash was carried out in an attrition mill using zirconia balls in an isopropanol medium. Milling of the fly ash was carried out at room temperature and 90°C.

2.1.1 Room Temperature Milling

Forty grams of the ash was dispersed in 60 grams of de-ionized water and transferred into the grinding pot containing zirconia balls. Appropriate concentrations of sodium hydroxide were added wherever applicable. The slurry were milled for 15 minutes and transferred quantitatively into the beaker. The slurries were allowed to stand for 12 hours before mixing with OPC.

2.1.2 Milling at 90°C

Forty grams of the ash was dispersed in 60 grams of hot deionized water (90°C) and transferred into the grinding pot containing zirconia balls. Appropriate concentrations of sodium hydroxide were added wherever applicable. The slurries were milled for 15 minutes and transferred quantitatively into the beaker. The slurry was allowed to stand for 12 hours before mixing with OPC.

2.2 Reactive fly ash preparation

A novel method was used for the preparation of chemically activated fly ash suspension. A forty-gram portion of the as received or milled ash was dispersed in 60 grams of de-ionized water in a 500 ml glass beaker. The various activators (inorganic salts) were added to the slurry in different concentrations. The contents were covered with a watch glass and digested with magnetic stirring for 2 hours at 90°C using a hot plate. The contents were cooled and the water lost during the digestion was replaced. The treated ashes were blended with OPC in the slurry form to make cement paste.

2.3 Cement - Fly Ash Paste Preparation

Ordinary Portland Cement (OPC), and OPC and untreated and treated coarse and fine fly ashes were mixed in the ratio of 80:20. The water content was maintained at the ratio of W/S= 0.30 for all the studies. When used in the slurry form, the liquid phase was the same solution as used during the chemical treatment of the ashes. The slurry was allowed to stand for 12 hours before mixing with OPC. The cement (OPC-1) and the various treated fly ashes were mixed in the ratio of 80:20 (by

weight of solids), with the W/S=0.30. The batch compositions of the formulations used in the steam curing treatment are given in Table 1.

Table 1. Batch Composition of different Formulations used in Steam Curing Treatment

Sample Code	OPC (g)	Fly ash (g)	Water (g)	NaOH (g)	Mighty 150
S1	160	40	60	Nil	Nil
S2	160	40	60	Nil	Nil
S3	160	40	60	Nil	Nil
T1	160	40	60	0.2	1
T2	160	40	60	0.2	Nil
T3	160	40	60	0.2	Nil
T4	160	40	60	0.2	Nil
T5	160	40	60	0.4	Nil
T6	160	40	60	0.6	Nil

S 1 = 100% OPC; S 2 = OPC + Coarse fly ash; S 3 = OPC + Coarse fly ash milled at 90°C in water; T 1 = OPC + Coarse fly ash + 0.5 wt% NaOH of fly ash (digested at 90°C); T 2 = OPC + Coarse fly ash 0.5 wt % NaOH of fly ash + 0.5% superplasticizer (digested at 90°C); T 3 = OPC + Coarse fly ash milled at room temperature in water with 0.5 Wt% NaOH of fly ash; T 4 = OPC + Coarse fly ash milled at 90°C in water with 0.5 Wt% NaOH of fly ash; T 5 = OPC + Coarse fly ash milled at 90°C in water with 1.0 wt% NaOH of fly ash; T 6 = OPC + Australian coarse milled at 90°C in water with 1.5 wt% NaOH of fly ash

The compositions S1 to S3 were used as control mixtures against which the performances of test mixtures (T1 to T6) were compared.

2.4 Curing Schedule

Simulated steam curing experiments were conducted at 65± 5°C. Initially the temperature rise in the cube with respect to curing chamber temperature was optimized using a model cube prepared from OPC: Coarse ash (80: 20). It has been noted that the cube temperature reaches the curing chamber temperature of 65°C within two hours and thereafter stays constantly within 2°C of the chamber temperature till the end of 350°C - hours (65 °C x 5.4 hours) curing. Delay between mixing and application of steam was maintained at 30 minutes for all samples. Paste temperature during mixing was 20+ 5°C and cube temperature at the stripping time was less than 40°C. The humidity of the curing chamber was maintained above 95% R.H. throughout the curing cycle. The curing conditions used in this study are given in Table 2.

Table 2. Curing Conditions used in the Study

Curing Cycle	Time for each Cycle*	Total Cubes for each Curing Cycle
100°C curing hours	92.3 minutes	4
200°C curing hours	184.6 minutes	4
300°C curing hours	276.9 minutes	4
400°C curing hours	323.0 minutes	4

*: One Curing hour is equivalent to 65°C-hour.

3. RESULTS AND DISCUSSION

3.1 Compressive Strength

The compressive strengths of steam-cured cubes were measured after the respective curing cycles up to 350°C-hours curing. After 350°C-hours, the samples for 28-day strength were removed from the curing chamber and stored at 25°C + 5°C for 27 days. Results of compressive strength development after accelerated curing of different OPC: ash formulations are given in Figure 1. In agreement with the general trend, steam curing accelerates the early strength (12).

The comparison of 1-day strength obtained for room temperature curing as reported earlier (7,8) and the results of 350°C-hours shows that, by steam curing, 1-day strength can be obtained within 5 to 6 hours. Likewise, the influence of alkali activation by NaOH and mechanical activation by grinding on compressive strength has been observed in the same order as in the case of room temperature curing. However, the comparison between ambient curing (7,8) and steam curing shows that steam curing did not have a positive effect on compressive strength at 28-day hydration. This observation is in agreement with the earlier reported studies on high temperature curing of concrete (9-12). Sample code T4, T5, and T6 represents the results for OPC: ash activated by three different NaOH concentrations. The result shows that overdose of NaOH has a negative effect at all curing ages, and the optimum seems to be around 0.5 Wt% (0.0833 N) NaOH. This observation also in agreement with the earlier data obtained with different NaOH concentrations (7,8).

Figure 1. Development of Compressive Strength as a Function of Curing Temperature for the Various Activated OPC: Ash Paste Mixtures.

3.2 X-Ray Phase Analysis

XRD phase analysis has been done on 350°C-hour steam cured and 28-day hydrated samples. The major phases present in the samples and their respective intensities are given Table 3. Portlandite and calcium silicate are the major crystalline phases observed in all the samples. Minor amount of ettringite also observed in most of the hydrated samples. The 350°C-hour steam cured pastes and 28-day hydrated samples show no difference in phase formation but provide a slight variation in their quantity. X-ray diffraction powder patterns for 28-day cured samples are more amorphous in nature. There is no appreciable difference in intensities of the phases formed between 100% OPC, and non-activated OPC: ash mixture and activated OPC: ash mixture (S1 to T6).

Table 3. Cement Hydration Phases and their Respective Intensities Present in 350°C-hour Steam Cured and 28-day Hydrated Samples

Sample Code	C ₃ S		Portlandite		Ettringite	
	350°C-hour	28-Day	350°C-hour	28-Day	350°C-hour	28-Day
S1	Very Strong	Strong	Medium	Strong	Very Weak	Weak
S2	Very Strong	Strong	Medium	Strong	Very Weak	Weak
S3	Very Strong	Strong	Medium	Strong	Very Weak	Very Weak
T1	Strong	Strong	Medium	Strong	-	N.D
T2	Strong	N.D	Strong	N.D	Very Weak	Very Weak
T3	Very Strong	Strong	-	Weak	Very Weak	Very Weak
T4	Strong	Very Strong	Weak	Strong	Very Weak	Very Weak
T5	Strong	Strong	Strong	Strong	Very Weak	Very Weak
T6	Strong	Strong	Strong	Strong	Very Weak	Very Weak

3.3 Hydration Calorimetry

A series of hydration calorimetric studies were conducted to investigate the reason for the high early compressive strength gains of the elevated-temperature-cured OPC: fly ash mixtures. In the first series the effect of alkali concentration on the fly ash activation was evaluated using isothermal calorimetry. The results of this study are given in Figure 2. The heat evolution profiles did not clearly distinguish the effect of various sodium hydroxide concentrations on the fly ash activation. In the second series of isothermal calorimetric studies, the effect of elevated temperature on the fly ash activation was performed for the paste samples containing non activated fly ash: OPC mixture (Figure 3) and 0.5% NaOH activated (Figure 4) fly ash: OPC. The heat evolution profiles were obtained at 25, 35, 45, and 55°C for both the as received and 0.5% NaOH activated OPC: ash pastes. High early heat evolution profiles clearly confirm in both the cases (Figure 3 and 4) the high temperature curing has a positive effect on the activation and hydration of fly ash cement paste.

Figure 2. Isothermal Heat Evolution Profiles

Figure 3. Isothermal Heat Evolution Profiles for as Received OPC: Fly Ash Mixture Cured at Various Temperatures.

Figure 4. Isothermal Heat Evolution Profiles for 0.5 Wt% NaOH Activated OPC: Fly Ash Mixture Cured at Various Temperatures.

4. SUMMARY

This study describes the effects of steam curing at elevated temperatures on chemical and mechanical activation of a low calcium fly ash. It has been clearly shown that the steam curing increases the strength development during early hydration period. The study also stresses the importance of using the optimum dosage of NaOH concentration for alkali activation. The results of the steam curing at elevated temperatures show the influence of chemical and mechanical activation in the same order as observed for room temperature curing. The acceleration of strength by steam curing is not observed for 28-day hydration. Hydration calorimetric studies confirm the positive effect of elevated temperature on the 0.5% NaOH activated fly ash. X-ray powder diffraction studies on 350°C-hour curing and 28-day hydration samples indicate that the formation of calcium silicate and portlandite as the major crystalline phases and ettringite as the major crystalline phase is completed at 350°C-hour curing itself.

ABSTRACT

Among the mechanisms of degradation of concrete from the presence of excess sulfate identified in recent years has been the phenomenon of delayed ettringite formation (DEF). This phenomenon is a degradation process that sometimes is identified in concrete that has been exposed to curing at temperatures above 70 °C. The process, however, is complex and is still not thoroughly understood, even with intense research interest in the past decade that focused on understanding the process. According to the latest interpretation, any ettringite formed prior to curing at above 70 °C is destroyed during the initial heat treatment, and the damage in the concrete structure is associated with the formation or reformation of ettringite during the subsequent service at ambient temperatures. To explore the influence of variation in cement composition upon possible damage, twenty-one Type I and Type II portland cements from North America were investigated, that represented a statistical variation in range of sulfate, equivalent alkali, C3A and fineness. These were evaluated for DEF following a modification of the J. Stark procedure. The results and evaluations will be discussed in detail.

1. BACKGROUND

Cement manufacture has changed significantly in the past two decades, mainly because of environmental and energy concerns (1). As a consequence, rising concerns have raised questions in various scientific forums as to how far these changes in cement compositions have affected the performance of modern concretes. According to Mehta (2), while many 50-90 year old concrete structures are still in good condition, there are numerous cases of deterioration in recently built structures. Skalny (3) indicated that "*... that there are some 253,000 bridge decks ...in varying states of deterioration and approximately 35,000 are being added to this list every year in the United States alone.*" The condition in Europe and other parts of the world is no better (4,5).

An NCHRP study has been conducted on the composition of Portland cement, the important physical characteristics of Portland cement and the role played by these various chemical and physical properties of Portland cement on performance of concrete and their influence on the durability of concrete. In this paper, we focus on one aspect of durability, i.e. the relation of cement composition to secondary ettringite formation/delayed ettringite formation, SEF/DEF.

2. INTRODUCTION

Delayed ettringite formation is a complex process, not wholly understood (6,7,8,9). In recent years, a number of failures have been reported for concrete products precast at elevated temperatures. They have been characterized by cracking after some years of service in environments exposed to

the weather. This cracking is related to the presence of abundant ettringite at paste-aggregate boundaries and elsewhere. Kennerly(10), was one of the first to report possible problems with delayed ettringite formation. However, the more detailed and pioneering work of Ludwig and co-workers (11,12,13) has confirmed the damage caused by ettringite formation in heat-treated concrete structures. According to these studies, any ettringite formed prior to curing at temperatures of above about 70° C is destroyed during the heat treatment, and that the damage is associated with the formation or reformation of this phase during the subsequent service at ambient temperature. The term ‘delayed ettringite formation’, or DEF is widely taken to denote this phenomenon, but some investigators include the late formation of ettringite in material that has been cured at ordinary temperatures

The most comprehensive and extensive literature review of DEF was done by Day (14). According to Day, the term “delayed ettringite formation” is not accurate and “secondary ettringite formation” is more correct. Delayed formation of ettringite may cause expansion of the concrete, loss of strength, and ultimately deterioration. As described above, it has been observed that a number of conditions must be present for delayed ettringite formation to occur (6,8,11,15,16). The temperature of the concrete at early ages must be at least 65-70° C, and during its lifetime, the concrete must be either completely or nearly saturated intermittently or continuously. An excess of SO₄ also facilitates the reaction (15)

The phenomena of alkali-silica reactivity (ASR) and DEF have often been shown to be linked (8,17,18,19,20). These results are in accord with the observations on field concretes and also with those of (19), who found that a limestone mortar did not expand significantly after curing at 95°C. However, if reactive silica was added to the mix, marked expansion occurred, initially from ASR, and was later exacerbated by the effect of DEF. Diamond (7) reports that damage from DEF can occur in normally cured concrete. He attributes this effect to high contents of SO₃ (4-5 %) in the cement and more specifically in the clinker and indicates that ASR almost always precedes DEF. Brown and Bothe [20] have suggested that the ettringite formation cannot occur in pore solutions with high alkalinity. Influence of cement composition on the delayed ettringite formation was studied recently by many authors among the these are studies by (21,22,23). The Glasser (23) study approaches the DEF mainly in terms of thermodynamic modeling and pore fluid analysis.

Odler and Chen (24) reported that significant expansion occurred only with cement that was high in both SO₃ (4.9%) and C₃A. Famy et al. (25) emphasize the effect of the microstructural characteristics. Contrary to the findings of Taylor (15), Klemm and Miller (6) claims that high SO₃ content in clinker and silicate phases of cement paste are innocuous in the formation of secondary ettringite. C₃A was also targeted as a parameter influencing DEF, but research by (26). shows no clear correlation between the amount of potentially damaging monosulfate crystals and the original C₃A content of the cement. Kelham (22) also contends that sulfate-resisting cements with low C₃A contents are not susceptible to DEF, and that the addition of KOH or K₂SO₄ accelerates expansions at elevated temperatures.

Other researchers have focused their efforts on how characteristics other than SO₃ and C₃A such as increased fineness, Na₂O, MgO, C₃A, and C₃S can be correlated with increased expansion. Stark [26] points out, however, that the combined action of frost and deicing salt can also aggravate the problem. Therefore, in view of the controversies concerning causes and mechanisms of SEF/DEF deterioration, the investigations described below were undertaken, in an attempt to relate cement composition from a wide variety of sources in the U.S. to the potential for concrete deterioration.

3. EXPERIMENTAL

Twenty-one cements that represent the compositional extremes for all 114 Type I and Type II Portland cements manufactured in the United States were employed in this study (27). Bogue

mineralogies for each are detailed in Table 1. For this study both air-entrained and non-air-entrained mortar specimens were prepared according to ASTM C 305 as detailed in Table 2.

Table 1. Bulk Mineralogical Composition of Type I and Type II Cements

3.1 Studies of Delayed Ettringite Formation

In order to evaluate delayed/secondary ettringite formation for each of the 21 cements, a testing regime involving both air-entrained and non-air-entrained mortar bars and both 60°C and 80°C elevated temperatures was generated, as can be seen in Table 3.

The variation in temperatures provides microcracking, and the elevated temperatures and varying humidity levels provide conditions that encourage crystal formation.

Previous work done by (27) was used to develop a cycle of alternating temperature and moisture conditions. Samples were initially allowed to cure for 28 days at room temperature in saturated lime water in order to provide adequate strength. Samples were then transferred to drying ovens at either 60°C or 80°C for two weeks and then returned to room temperature lime water for eight weeks, in the hope of allowing crystals to form. After eight weeks in room temperature lime water, bars were transferred to a freeze-thaw tester, where they underwent a ramped freeze-thaw protocol

that varied temperature between 20°C and -20°C over a period of 24 hours. This testing cycle was repeated three times, and can be seen in Table 3. The testing protocol for delayed ettringite formation outlined above was followed, and length and mass measurements at each stage in the cycling were recorded.

4. RESULTS

4.1 Secondary/Delayed Ettringite Formation

Modified Stark method (26) was used to evaluate the expansion produced by SEF/DEF. The mortar bar samples were treated in three different exposure conditions. After initial curing at room temperature in saturated lime water, 1) air-entrained mortar bar samples cured at 60°C (A60), 2) air-entrained mortar bar samples cured at 80°C (A80), 3) and non-air-entrained mortar bar samples cured at 60°C (NA60). Each drying period was followed by room temperature saturation and then freezing and thawing. The time for the total 3 cycles of curing/exposure was 242 days.

The data obtained for the total dimensional change in the SEF/DEF mortar bar by modified Stark test for 21 cements after 3 cycles of the different exposure conditions are given in Table 5. It is first noted that only very limited net expansions were generally observed; and then in only a few of the 21 cements (including the three cements shown in Figures 1, 2 and 3).

5. DISCUSSION

Indeed, after an analysis of the final averaged expansion data for three test specimens for each of the 21 cements, only five of the twenty-one cements used in this program showed a positive expansion and then only in the non-air-entrained sample series. One cement expanded nearly an order of magnitude larger than the remaining four. This single cement, #11, represented a star point for both SO₃ and alkali and content with among the highest Blaine fineness. As such, it represents a unique extreme outlier in all Type I and II cements manufactured in the United States.

Table 3. Modified Stark SEF/DEF test

<u>Cycle #</u>	<u>Days</u>	<u>Action</u>
Initial	1 to 28 29 to 43	curing in RT saturated limewater drying at 60 °C or 80 °C
1	43 to 99 100 101 to 114	curing at RT in saturated limewater 24 hour freeze-thaw cycling drying at 60 °C or 80 °C
2	115 to 170 171 172 to 185	curing at RT in saturated limewater 24 hour freeze-thaw cycling drying at 60 °C or 80 °C
3	186 to 241 242	curing at RT in saturated limewater 24 hour freeze-thaw cycling

The majority of the cements, seventeen in all, exhibited a net shrinkage, as a result of the 172-185 day thermal cycle in the testing sequence, that was larger than any expansion caused by ettringite formation. Statistical modeling with all twenty seven of the chemical and mineralogical variables examined in this program resulted in a positive single variable correlation between expansion and sulfate of 70% for the air-entrained samples cured at 80 °C of the form:

$$\text{Exp} = 1.27 \times 10^{-2} - 5.66 \times 10^{-2} \times \text{SO}_3 + 1.19 \times 10^{-2} \times (\text{SO}_3)^2$$

and 67% for the non-air-entrained samples cured at 60°C, with the form:

$$\text{Exp} = -7.9 \times 10^{-2} + 3.24 \times 10^{-3} \times \text{SO}_3 + 4.74 \times 10^{-3} \times (\text{SO}_3)^2.$$

A weak negative trend with CaO, R^2 -42%, is represented in the non-air-entrained data as

$$\text{Exp} = -21.6870 + 0.70058 \times \text{CaO} - 5.66 \times 10^{-3} \times (\text{CaO})^2$$

Among the major oxides of the Portland cement compositions, SO_3 content showed a significant positive correlation and CaO exhibited a negative correlation with the 242 day DEF expansion for all of the test specimens. Correlations were observed for C_3S , P_2O_5 and Blaine fineness but did not necessarily apply to all of the test specimens studied. The best correlation was observed between DEF expansion and the ratio of $\text{SO}_3/\text{Al}_2\text{O}_3$ for all three sets of test specimens even though Al_2O_3 alone does not correlate with the observed expansions. This relationship took the form:

$$\text{Exp} = 1.9 \times 10^{-1} + 0.363346 \times \text{SO}_3/\text{Al}_2\text{O}_3 - 0.153024 \times (\text{SO}_3/\text{Al}_2\text{O}_3)^2$$

Additionally, the ratio between SO_3/CaO also exhibited a significant correlation to all after 242 days at 80°C which took the form:

$$\text{Exp} = 5.28 \times 10^{-3} - 3.32353 \times \text{SO}_3/\text{CaO} + 45.478 \times (\text{SO}_3/\text{CaO})^2$$

In addition to evaluating the final averaged expansion data, if the individual samples are tracked through each cycle of the testing protocol, a more detailed pattern emerges. Figures 1, 2 and 3 are normalized expansion data for three of the five cements [#1, #11 and #12] that demonstrated expansive behavior at the end of the full 3 cycle testing. Supporting data for each of these figures are presented in tables 3, 4 and 5, respectively.

Very little happens through the end of the first cycle; however by the time that the second cycle is completed the non-air-entrained samples can be differentiated from the air-entrained samples. By the termination of the testing cycle at 242 days, a clear separation between the two classes of cements can be seen. In all cases, the non-air-entrained specimens are exhibiting greater expansion than the air-entrained specimens. In contrast, figure 4 is a typical example of comparable data for a cement [#19] that did not exhibit expansion. Clearly no differentiation between air-entrained vs. non-air-entrained specimens can be seen.

Examination of the data presented in figures 1 to 3 also points out the lack of impact that the ultimate temperature of the heating cycle had upon the observed shrinkage/expansion behavior of the test cements. The air-entrained specimens heated to 60°C are virtually indistinguishable from those heated to 80°C. The heating cycles manifest changes in the masses of the test specimens as detailed in figure 5 for cement #12.

Figure 1. Normalized expansion data for Cement #1 after 3 cycles of DEF testing. *[data for sample 1-A-60-A are the result of experimental difficulties during the testing protocol and are not valid].*

Figure 2. Normalized expansion data for Cement #11 for 3 cycles of DEF testing.

Figure 3. Normalized expansion data for Cement #12 for 3 cycles of DEF testing.

The influence of the air-entraining agent separates the specimens into two sets with the air-entrained specimens generally being about 7% lighter than the non-air-entrained specimens. The heating cycle results in a loss of mass for the specimens of approximately 7 to 8% of the original mass. Upon rehydrating, the cements test specimens take up only about 5 to 6% of the mass lost relative to the initial weight.

Scanning electron microscopic [SEM] characterization coupled with energy dispersive x-ray [EDX] analyses of the non-air-entrained specimens identified massive ettringite formation in extrinsic porosity formed in the specimens. The chemistry of the pore filling was determined by EDX to be consistent with ettringite. In these studies, only massive formation was observed in open porosity (cements #11 and #13). Note the extensively developed micro-cracking adjacent to the ettringite from cement #11 and cement #13. (see figures 6 and 7)

Figure 4. Normalized expansion data for cement #19 for 3 cycles of DEF testing.

Figure 5. Change in mass of cement #12 as a result of thermal cycling in the DEF testing protocol.

An example of an air void filling in the non-expanding cement [#19] which showed extensive development of monocalciumsulfoaluminate phase in the large voids.

Figure 7. Low magnification [450x] of the surface of cement #13 showing distribution of extrinsic pores filled with massive ettringite. Note predominant cross-cutting micro-cracks.

6. CONCLUSIONS

The experimental design for the DEF studies was structured to limit the extremes of environmental conditions that were/are known to contribute to ettringite formation by restricting the use of reactive aggregates, emphasizing air-entrained specimens and limiting the non-air-entrained samples to the lowest of the test temperatures. The purpose of this action was to address only the extremes of the DEF reactions from the chemistry of the cement. Based on the current observations, DEF should not be a concern if the concrete is manufactured from cements with typical chemical and mineralogical characteristics for Type I or Type II Portland cements. Only if extremes in properties, notably equivalent alkali and sulfate or in Blaine fineness, are approached should concern be warranted. For samples cured at elevated temperatures [80°C] as a means of exacerbating the DEF formation, only a weak correlation was noted with single chemical factor sulfate for the air-entrained samples at 80°C. A slightly better correlation with the ratio of sulfate to calcium oxide for the same sample sets was noted. For the non-air-entrained specimens cured at 60°C single factor correlations were noted for sulfate and a negative correlation with calcium oxide; both of which were weak correlations at best. Finally, the second best fit to the data occurred with a ratio of sulfate to alumina for these non-air-entrained specimens.

ABSTRACT

The study was conducted as part of a comprehensive effort directed at examining the effects of cement composition on concrete durability. Detailed characterization was performed on 21 statistically diverse Type I and II Portland cements manufactured in North America. The cements were studied and derivative properties were determined including heats of hydration. In addition, physical characteristics such as compressive strength were also determined. Analyses of the relationships between 72 measured cement characteristics and various properties were performed. Multi-variant and response surface modeling were conducted on this data set. Combination of four variables (C_3A , Blaine surface area, potential CH and equivalent alkali) showed the greatest correlation with 1-day isothermal heat of hydration. The highest correlation with single variable correlated with C_3S , as expected. The strongest single variable correlation of compressive strength with any of the cement characteristics was with equivalent alkalis at both 28 and 90 days of curing. This was a negative correlation. A multi-variant, center-weighted response surface modeling approach showed a significant relationship between compressive strength measured at 28 days and 180 days to equivalent alkali and Fe_2O_3 . Similarly, a significant correlation was found between the ratio of 28/7 day heats of hydration, equivalent alkali and 180 day compressive strength.

1. INTRODUCTION

Cement manufacture has changed significantly in the past two decades, mainly as a result of environmental and energy concerns (1). Environmental concerns have resulted in the use of alternative fuels and fuels with reduced sulfur; in addition, kiln dust, which is rich in alkalis, is routinely collected and returned to the kiln as raw feed, resulting in cements with a higher alkali contents. It has being reported that modern cements are not as durable as older cements (2).

The important question is being raised in various scientific forums as to how far changes in cement compositions have affected the performance of modern concrete versus how changes in loadings, maintenance practices and environmental conditions have affected the performance of concrete structures. This paper investigates the correlation of chemical composition and heat of hydration on compressive strength. Other concrete properties are addressed in separate papers.

2. COMPRESSIVE STRENGTH OF CONCRETE

The compressive strength of concrete is related to a wide variety of factors, including: w/cm ratio, cement type and content, aggregate type and gradation, air content, compaction, and curing. However, at a more fundamental level, the strength of concrete is related to the chemical and physical properties of the Portland cement used. Tricalcium silicate and dicalcium silicate play the most decisive roles in compressive strength development. The tricalcium silicate is the more soluble form and contributes to the early age strength development and dicalcium silicate increases the compressive strength of concrete at later ages. The strength development of the four major Portland cement compounds as reported for pure components is illustrated in Figure 1 (3). Past research has primarily been conducted on the effects of isolated variables (4). However, the compounding effects have not been analyzed because of the limited nature of computational hardware. A complete discussion of past studies on cement hydration and reactions is available in another reference (5). The past work has emphasized the importance of particle fineness, SO_3 content, alkalis, heat of hydration, along with C_3S and C_2S content in the development of compressive strength. This past work lays the ground work for the study undertaken by the authors for the National Cooperative Highway Research Program. Strength development is not just a function of four chemical compounds.

Many researchers have investigated the dependence of compressive strength of cement pastes or concrete on fineness of cement. Helmuth (6) stressed the importance of minimum and maximum particle sizes as well as particle size distributions in determining the strength development of cements. According to Valenta (7), and Alexander (8), fineness is important for high compressive strength, but the actual particle size distributions of the cements are of even more importance. Kumar and Roy (9) found that the fineness of Portland cement plays an important role on strength development up to 28 days of hydration, but the fineness of normal Portland cements produced no pronounced effect on strength at later ages.

Figure 1. Development of Compressive Strength of Pure Phases of Portland Cement (3)

The chemical reactions that occur during the early stages of hydration of the phases in Portland cement concrete are responsible for the setting and hardening of mortar and concrete. The heat generated by the exothermic reactions play a role in the rate of hydration of the remaining Portland cement. The liberation of heat occurs most rapidly during the first hours and days after mixing. Heat of hydration of hydraulic cement measures the difference in heat of solution of anhydrous cement to that which has been hydrated for different ages between 7 and 28 days. The heat of hydration provides a convenient way to monitor hydration using either isothermal or adiabatic calorimetry (10). As hydration progresses the

compressive strength of concrete increases. However the amount of increase of compressive strength is not strictly a function of heat evolution, since some hydration reactions generate a lot of heat and very little strength. With this in mind, the maturity of a particular concrete must include both the heat generated and chemical composition of a particular Portland cement. The advantage of using an isothermal method is that information would be obtained concerning other aspects of hydration such as initial and final setting time. Jawed et al. (11) reported the contribution of

individual hydration reactions to the heats of hydration of Portland cement. The heats of hydration of individual reactions for complete hydration are given Table 1.

Lerch (12) established the important influence of SO_3 content of cement on the strength and drying shrinkage. Since then the relationship between optimum SO_3 content for strength and fineness, C_3A content and equivalent alkalis were studied by many other researchers. Lerch (12) reported that the optimum requirement of SO_3 for properly retarded cement increased with an increase in both C_3A and alkali contents. Meissner (13), Equation 1, and Haskell (14), Equation 2, generated linear regression equations for optimum SO_3 contents and strength of cement.

Table 1. Heats of Individual Hydration Reactions of Cement Compounds (11)

Reactions	- ΔH (J/g) for complete hydration		
	Pure compounds	Clinker measured	Cement measured
$\text{C}_3\text{S} \rightarrow \text{C-S-H} + \text{CH}$	~ 500	570	490
$\text{C}_2\text{S} \rightarrow \text{C-S-H} + \text{CH}$	~250	260	225
$\text{C}_3\text{A} \rightarrow \text{C}_4\text{AH}_{13} + \text{C}_2\text{AH}_8$	-	-	-
$\text{C}_3\text{A} \rightarrow \text{C}_3\text{AH}_6 + \text{CH}$	880	840	-
$\text{C}_3\text{A} + \text{Gyp.} \rightarrow \text{monosulfoaluminate hydrate}$	-	-	~1160
$\text{C}_4\text{AF} \rightarrow \text{C}_3(\text{A,F})\text{H}_6$	420	335	-

$$\text{SO}_3 (\%) = 0.789 + 0.1149 (\text{C}_3\text{A} \%) + 1.872 (\text{Na}_2\text{O}_{\text{eq.}} \%) \quad (1)$$

$$\text{SO}_3 (\%) = 1.841 + 0.0950 (\text{C}_3\text{A} \%) + 1.6364 (\text{Na}_2\text{O}_{\text{eq.}} \%) \quad (2)$$

Later, Ost (15), extended Haskell's treatment to include cement fineness. He obtained the Equation 3 in which fineness, Na_2O , and Fe_2O_3 content were the factors determining the optimum SO_3 content with respect to compressive strength.

$$\text{SO}_3(\%) = 0.556 (\text{Na}_2\text{O}_{\text{eq.}} \%) + 0.0017659(\text{Blaine, cm}^2/\text{g}) - 0.1072(\text{Fe}_2\text{O}_3 \%) - 3.6004 \quad (3)$$

Alkali compounds, in general, accelerate the rate of early hydration of Portland cement and give high early compressive strength, although the final strengths are lower than those of the low alkali cements. Alkalis seem to act as catalysts in forming calcium silicate hydrate from lime and silica. This is due to the formation of sodium silicate which reacts with $\text{Ca}(\text{OH})_2$ to form calcium silicate hydrate (C-S-H). On mixing the cement with water, alkali ions readily pass into solution and influence the early hydration reactions of cement, particularly of C_3A .

3. EXPERIMENTAL PROGRAM

A multi-variant, center-weighted response surface modeling approach was used to evaluate statistical correlations between the 32 Portland cement variables, as well as ratios of related properties in order to explain the dependence of compressive strength upon these variables. The data obtained used 21 statistically diverse Type I and II Portland cements manufactured in North America. The cements were selected using a center cube model using and containing a full range of four variables, SO_3 , C_3A , fineness and equivalent alkalis. The statistical variations in compressive strength of concrete made with the 21 Portland cement concretes for different curing periods are given in Table 2. This table provides the minimum, maximum, and mean of compressive strength calculated for all cements at various curing periods. The highest increase in compressive strength was reported for all cements between the 3 and 28 days of curing. This increase was similar for

most of the cements. Similarly, uniform increase was observed for most of the cements at 90 and 180 days of curing. However, the rate increase decreased as the curing period increased.

Multi-variant and single-regression analysis was conducted on combinations of Portland cement properties and the dependency of compressive strength. R^2 and p values were documented to isolate potential statistical correlations. While many of the more than a million computer correlations showed no reliable relationship, there are certain variables that act in concert to contribute to the strength development of concrete. Some of the multi-variant analysis data for the dependency of compressive strength on the combination of 9 trace and minor elements are given in Table 3. Multi-variant combinations were run on more than 300,000 combinations including all nine elements simultaneously, any eight of the nine, through single variable evaluations. Combined trace and minor elements show a strong correlation to 3 and 28 day compressive strengths. This correlation generally increased as the curing period increased. While some of these models would appear to be quality prediction tools, the number of data points is insufficient to make 9 or 8 variable equations valid, especially since the chemical ranges of trace elements were not used in the selection of the cements for the study. The center point model used in this study provides for valid models with 4 or less chemical or physical factors. The individual trace element oxides showed very poor correlation to the compressive strength except for that of chlorine. Since the percentage of chlorine was very low and similar for all the cements, the high R^2 for chlorine alone does not represent a reliable correlation. The value of looking at this set of data for a relationship between trace elements and compressive strength is to validate the concept that they play a role in the development of compressive strength in Portland cement. Additional work must be conducted to verify the significance of this role.

The similar increase in compressive strength among the cements shows that the greater variations in SO_3 , equivalent Na_2O , C_3A , and Blaine fineness observed in these cements have relatively little influence on the compressive strength. However, there was a reasonable (negative) correlation between equivalent Na_2O and the compressive strength at 28, 90, and 180 days.

Table 2. Compressive Strengths of Concrete Specimens Derived from all Cements at 3, 28, 90, and 180 Days of Curing.

Property	3-day (MPa)	28-day (MPa)	90-day (MPa)	180-day (MPa)
Minimum	22.68	41.43	48.29	50.48
Maximum	33.93	51.72	61.36	65.2
Mean	27.67	46.37	53.28	57.11
Std Deviation	3.45	3.01	3.65	4.28

Multi-regression and single-regression analysis data for the dependency of compressive strength on the combination of SO_3 + equivalent Na_2O + C_3A + Blaine fineness + C_3S/C_2S ratio are given in Table 4. Combined SO_3 + equivalent Na_2O + C_3A + Blaine fineness showed increasing correlation to 28 to 90 to 180 day compressive strengths. Further analysis of this combination suggests that this correlation (negative) was dominantly due to equivalent Na_2O content of the Portland cement.

Multi-regression and single-regression analysis data for the dependency of compressive strength on the combination of C_3S/C_2S and the calcium hydroxide associated with C_3S and C_2S , showed no reasonable correlation between the compressive strength and the combination of C_3S/C_2S ratio + CH from C_3S and C_2S . Similarly, there was no correlation observed between the individual or combination of cement phases and the compressive strength of the Portland cement, including C_3S , as shown in Figure 2.

Figure 2. Compressive Strength vs. C_3S %.

All cements showed an increase in compressive strength as the equivalent Na_2O decreases; however, this correlation was less strong as the curing period increased. This correlation decreased from about 60 percent at 28 and 90 days curing to 51 percent at 180 days curing (Table 4). As 90 percent of the compressive strength development of the Portland cement is completed at 90 days curing, the influence of alkalis at 28 and 90 days on the compressive strength is very significant on the compressive strength. Analysis of the data shows that total equivalent Na_2O above 0.60 percent or K_2O content above 0.70 percent adversely affected the compressive strength. Distributions of 28, 90, and 180 days compressive strength as a function of total equivalent Na_2O content of the Portland cement are plotted in Figure 3. R^2 values for K_2O and Na_2O suggest that the compressive strength was mainly influenced by the K_2O content of Portland cement.

Figure 3. Distribution of compressive strength as a function of total equivalent alkali content of Portland cement

As was noted in the linear and quadratic statistical analyses, alkali demonstrated a strong negative correlation with strength. The negative correlation with alkali content is apparent, and when coupled with Fe_2O_3 , which also agrees with the work done by Ost (17). In the response surface modeling, this observation carried through, and it was determined that the best correlation to the observed unconfined compressive strengths was achieved with equivalent alkali and Fe_2O_3 at 28 days of hydration. Figure 4 is a plot of the actual surface calculated for these data.

Figure 4. Surface for 28-Day Compressive Strength vs. Equivalent Alkali (Na_2O) and Iron (III) Oxide.

The response surface can be simplified as modeled, shown in Figure 5 according to Equation 4. At 180 days, a similar relationship with $\text{Na}_2\text{O}_{\text{eq}}$ and Fe_2O_3 was observed. This is provided in Equation 5 and Figure 6.

Figure 5. Response Surface Model for 28-Day Compressive Strength vs. Equivalent Alkali and Iron (III) Oxide.

$$28 \text{ d } F_c = 31.325 + 4.29 \text{ Na}_2\text{O}_{\text{eq}} + 15.09\text{Fe}_2\text{O}_3 - 2.37(\text{Fe}_2\text{O}_3)^2 - 6.28(\text{Na}_2\text{O}_{\text{eq}} \times \text{Fe}_2\text{O}_3) \quad (4)$$

$$180 \text{ d } F_c = 32.75 - 10.65 \text{ Na}_2\text{O}_{\text{eq}} + 21.67\text{Fe}_2\text{O}_3 - 3.63(\text{Fe}_2\text{O}_3)^2 \quad (5)$$

The correlation with iron oxide Fe_2O_3 was observed to also be functionally correlated with C_4AF in a related manner. This suggests that, indeed, iron oxide is not the variable directly responsible for the observed correlation, but rather C_4AF .

Figure 6. Response Surface Model for 180-Day Compressive Strength vs. Equivalent Alkali and Fe_2O_3 .

Table 3. Dependence of Compressive Strength (AASHTO T 22) of Concrete on the Combination of Minor and Trace Elements of Cement

Independent Variables									3-day	28-day	90-day	180-day
P_2O_5	ZnO	Mn_2O_3	B_2O_3	BaO	Cr_2O_3	NiO	SrO	Cl	R^2	R^2	R^2	R^2
x	x	x	x	x	x	x	x	x	0.65	0.79	0.62	0.71
x	x	x	x	x	x	x	x	-	0.49	0.58	0.41	0.49
x	x	x	x	x	x	x	-	x	0.65	0.74	0.45	0.66
x	x	x	x	x	x	-	x	x	0.46	0.74	0.62	0.70
x	x	x	x	x	-	x	x	x	0.51	0.77	0.6	0.66
x	x	x	x	-	x	x	x	x	0.5	0.74	0.61	0.68
x	x	x	-	x	x	x	x	x	0.5	0.53	0.58	0.57
x	x	-	x	x	x	x	x	x	0.5	0.75	0.62	0.71
x	-	x	x	x	x	x	x	x	0.65	0.79	0.61	0.73
-	x	x	x	x	x	x	x	x	0.38	0.71	0.55	0.7

In the linear and quadratic analyses, the heat of hydration, which reflects the degree to which the chemical reaction has proceeded, was never correlated to strength. In the response surface modeling, this correlation was identified as being statistically significant. Unlike the correlation with iron oxide, there appears to be a pessimum where modest levels of alkali are important. The correlation with the ratio of 28-day to 7-day heats of hydration suggests that as this value increases at moderate alkali content, the 180 days compressive strength increases. The ratio of heats of hydrations between 28 and 7 day would suggest the relative importance of the contribution of C_2S hydration, relative to C_3S although neither of these two phases individually was significantly correlated, but are known to be the most significant cementing compounds. Figure 7 is the model response surface for this data, and Equation 6 is the mathematical surface.

$$180\text{d strength} = 47.87 + 18.63\text{Na}_2\text{O}_{\text{eq}} + 5.95 [28/7 \text{ day heat of hydration}] - 23.78[\text{Na}_2\text{O}_{\text{eq}}]^2 \quad (6)$$

Figure 7. Relation Of 180-Day Compressive Strength vs. Alkali and Ratios of the Heat of Hydration at 28 and 7 Days.

4. SUMMARY

The strongest single variable correlation of compressive strength with any of the cement characteristics was with equivalent alkalis at both 28 and 90 days of curing. This was a negative correlation. A multi-variant, center-weighted response surface modeling approach showed a significant relationship between compressive strength measured at 28 days and 180 days to equivalent alkali and Fe_2O_3 . Similarly, a significant correlation was found between the ratio of 28/7 day heats of hydration, equivalent alkali and 180 day compressive strength. Isothermal calorimetry measurements were used to determine the kinetics of hydration reactions taking place within the first 24 hours of hydration. Isothermal calorimetry data for 24 hours provide a general trend of early hydration behavior regarding setting time, but not a correlation to compressive strength development.

Table 4. Dependence of Compressive Strength (AASHTO T 22) of Concretes on the Combination of Physical and Chemical Characteristics of Cement.

Independent Variables					3-day	28-day	90-day	180-day
SO_3	Eq. Na_2O	C_3A	Blaine	$\text{C}_3\text{S}/\text{C}_2\text{S}$	R^2	R^2	R^2	R^2
x	x	x	x	x	0.14	0.54	0.46	0.31
x	x	x	x	-	<0.10	0.54	0.46	0.31
x	x	x	-	x	0.14	0.54	0.64	0.31
x	x	-	x	x	0.14	0.52	0.62	0.31
x	-	x	x	x	<0.10	<0.10	<0.10	<0.10
-	x	x	x	x	0.11	0.54	0.62	0.29
x	-	-	-	-	<0.10	<0.10	0.45	0.11
-	x	-	-	-	<0.10	0.57	0.60	0.51
-	-	x	-	-	0.17	<0.10	0.24	0.13
-	-	-	x	-	<0.10	<0.10	<0.10	<0.10
-	-	-	-	x	<0.10	<0.10	<0.10	<0.10

Heat of solution calorimetry (adiabatic) was used to determine the longer-term heat of hydration of partially hydrated cement samples at 7, 14 and 28-day hydration periods. R^2 values for the four

major cement phases suggested that 7-day hydration was negatively correlated to C_2S or C_4AF content.

As the C_2S or C_4AF content increased, the 7-day heat of hydration decreased. C_3S content by itself showed no significant correlation to compressive strength.

1. INTRODUCTION

Phases in Portland cement can be quantified by conventional approaches such as Bogue, optical microscopy, or X-ray diffraction (XRD) methods (1). The Bogue method is a normative calculation reconstructed from the chemical analysis, while the optical microscopy point counting method is tedious and time consuming. In Bogue calculation, the phases calculated may be in either crystalline or partially crystalline form. The most direct way to quantify the cement phases would appear to be XRD. QXRD quantifies the cement phases that are crystalline. Good agreement between the Bogue and XRD methods will provide the extent of crystallinity and completion of the phase formation during clinker processing. In addition, QXRD can identify the presence of minor and impurity phases other than the four major cement phases. Because the cement phases exist in various polymorphic forms, quantification of these polymorphic forms would be useful in studying the influence of cement phases on the concrete durability. Computer controlled scanning electron microscopy (CCSEM) with quantitative energy dispersive X-rayspectroscopy (EDS) was also utilized. The automated CCSEM point counting approach can truly identify all particles including minor or trace phases by using chemical compositions. The CCSEM approach also allows for discrete elemental discrimination of variations within a specific phase within a clinker as well as other parameters such as porosity.

The present study has combined selective dissolution techniques, MATCHDB, GMQUANT, and Rietveld methods to identify and quantify the cement phases; GMQUANT results were compared with Rietveld method results. Identification of phases by MATCHDB uses the whole-pattern database (2), wherein the basic procedure is to compare each pattern in the database with the pattern of the unknown. GMQUANT employs the full diffraction pattern collected over a specified 2θ range pre-selected to cover all of the major peaks of all of the phases to be studied (3).

2. MATERIALS AND METHODS

A total of 21 Type I and Type II Portland cements, which represent a statistical selection of cements based on the full range of four variables, sulfate, tri-calcium aluminate, fineness and equivalent alkali, were used for phase analysis.

2.1 Qualitative X-Ray Diffraction

The samples were ground and sieved to pass 325 mesh and then slurry mounted on a zero background quartz plate using ethanol. A Scintag PDS, automated X-ray diffractometer, was used for all of the X-ray measurements. The X-ray generator was operated with a copper target X-ray tube (wavelength of 1.5406 Å) at 45 kV and 40 mA. The powder patterns were measured over the range of 5° to 60° 2 θ at a scanning rate of 2° 2 θ per minute. The data were processed using an automated graphics workstation.

2.2 Quantitative XRD of Cement Samples

Quantitative determinations of four major cement phases, C₃S, C₂S, C₃A, and C₄AF, were carried out for all of the 21 cement samples. Analysis of the cement phases was done using the full pattern fitting method, which was performed using GMQUANT method (3) and Rietveld QXRD method (4) using the Young's software system (DBWS –9411). The following sections describe the various steps involved in the sample preparation and raw data collection and quantitative determination of cement phases.

2.2.1 Sample Preparation

Each as-received cement sample was mixed with pure aluminum oxide (corundum, as an internal standard) in the ratio of 1:1 and ground very finely to pass through 325-mesh sieve. The dry powder was then introduced into a glass jar, wrapping the jar with paper towels, and the jar was placed into a small paint can, which was then rolled for 3 minutes. The samples were loaded in the sample holders pressed against filter paper (Whatman, #50). The filter paper had a textured surface that helped to reduce preferred orientation (3).

2.2.2 Data Processing

MATCHDB software was first used to identify the component phases of the cement. A database of “full spectrum” cement and hydration product phases is maintained with the search/match program. The user is given the opportunity to evaluate the “goodness” of fit for each identified phase and is also allowed to compensate for line broadening induced by particle size effects. Once identification of all of the phases in the cement has been completed, GMQUANT software is used to determine the percentage of each phase identified. For processing the unknown samples with the Young Rietveld analyses program, four major cement phases (C₃S, C₂S, C₃A, and C₄AF) and the reference were used, Table 1. Table 2 summarizes the most frequently encountered phases.

Table 1. Crystal structure data for Rietveld Analyses

Phase	Space group	a ₀	b ₀	c ₀	reference
C ₃ S	R _{3mh}	7.078	7.078	24.94	(7)
C ₂ S	P2 _{1/n}	5.51	6.758	9.314	(8)
C ₃ A	P _{A3}	15.26	15.26	15.26	(9)
C ₄ AF	I _{BM3}	5.588	14.61	5.38	(10)

2.3 Selective Dissolution

Selective dissolution techniques were used to improve precision in the phase identification and quantification using QXRD methods. GMQUANT tends to overestimate/underestimate cement phases with poorly resolved XRD patterns having overlapping by the adjacent peaks. For example, the results of the aluminates and ferrite phases that are present in small amounts in comparison to silicate phases may be overestimated by the influence of silicate phases. Similarly, the closeness of XRD patterns of various forms of dicalcium silicate phases-alpha, beta, and alpha prime and tricalcium aluminate phases-makes it difficult to resolve by QXRD. To resolve these difficulties, two types of selective procedures were used. The first technique (5) dissolves the silicate phases preferentially, leaving interstitial phases in the sample.

Table 2. Phases Identified Using MATCHDB Program
for All the Cements after the Peak Shift Correction

PSU Sample Code	C ₃ S		C ₂ S			C ₃ A		C ₄ AF
	42-0551	31-0301	24-0234	33-0303	33-0302	38-1429	32-0150	30-0226
	Monoclinic	Triclinic	α'	α	β	Cubic	Ortho	Brownmillerite
1	x	x			x	x		x
2	x				x	x		
3	x				x	x		
4	x		x		x	x	x	
5	x				x	x		
6	x				x	x		
7	x	x			x	x		x
8	x			x	x	x		
9	x		x		x	x		
10	x				x	x	x	
11	x				x	x		x
12	x				x	x		
13	x				x	x		
14	x	x			x	x		x
15	x				x	x		x
16	x				x	x		
17	x				x	x		
18	x				x	x		
19	x				x	x		
20	x	x			x	x		x
21	x				x	x	x	

The second technique (6) dissolves the interstitial phases preferentially and leaves the silicate phases in the samples.

2.4 SEM quantification methods

The SEM is an analytical tool that uses a focused beam of electrons to form magnified images. Under ideal conditions, the SEM is capable of producing images with a feature resolution at the nanometer (10^{-9} m) level. In addition to detailed image capabilities, the SEM can provide information on the elemental composition of microscopic features. Information on the image and elemental characteristics of a sample is obtained through the interaction of the electron beam with the sample, which produces various effects that can be monitored with suitable detectors. The resulting signals, which include secondary and backscattered electrons along with characteristic X-rays, can be collected in synchronization with the position of the electron beam to provide highly detailed spatial and compositional information. Simply stated, secondary and backscattered electron signals provide image information, while characteristic X-rays are used to determine elemental composition.

Point counting is commonly used on non-homogeneous solids, such as geological cores and concrete sections. It is extremely useful for determining the volume fractions of the constituents of the sample, without regard for the size and shape of individual features. During the CCSEM analysis, fields on the samples were analyzed “in order”. Grid points were detected on the polished clinker by moving the electron beam in discrete increments (“x, y” pattern) across the sample. At each point, the computer directed the electron beam to pause and a chemistry of each point was collected. This point-by-point approach permitted the CCSEM analysis to be performed in an automated mode. Therefore, a grid of equally spaced points is superimposed upon each field-of-view; the beam is placed at each point in turn, and EDS characterization proceeds in the normal way, using vectors and classification rules. In this way, each point can be assigned to a particular

mineral or other classification. Stereological principles are then applied to relate the proportion of points of each particular classification (relative to the total points) to the volume fraction of that classification in the sample. Depending upon the application, a threshold may be used to discriminate points to be analyzed. When a threshold is used, points at which the grayscale (brightness) is out of threshold will be discarded, i.e., not analyzed, and not counted in the total number of points used for volume fraction calculations.

3. RESULTS AND DISCUSSION

The X-ray powder pattern of an original cement sample is shown in Figure 1. The exact identification of all of the phases is very difficult in the sample due to the close proximity and overlap of peaks of cement phases. Two types of selective dissolution techniques were used to solve this problem. In the first method, the cement samples were subjected to a selective dissolution technique using the salicylic acid-methanol-acetone mixture to concentrate the aluminates and ferrite portions; here, the calcium silicate phases (C_3S and C_2S) were dissolved preferentially (5). The X-ray powder pattern of the sample after the salicylic acid-methanol-acetone mixture selective dissolution is compared with the untreated powder pattern in Figure 1. The pattern shows the peaks in the 2θ range 30 to 35 degrees. Usually, this is the region in which all four major cement phases show their strongest peaks. The pattern clearly shows that the salicylic acid-methanol mixture removes the silicate phases by preferential dissolution. This process retains the interstitial phases in the sample, making them easy to identify. By this dissolution method, it is possible to quantify the interstitial phases from the residue obtained after the removal of silicates. Total silicates can also be quantified by mass balance calculation.

Figure 1. XRD Patterns before and after Selective Dissolution of Phases

In the second method, the cement samples were subjected to a selective dissolution using a solution containing 30 g of potassium hydroxide and 30 g of sucrose in 300 ml water to remove the interstitial phases. The X-ray powder pattern of the sample after the potassium hydroxide and sucrose solution treatment is shown in Figure 1. The KOH-sucrose method is useful in resolving the silicate and aluminate peaks present in the 2θ range 32 to 34 degrees. For example, the resolution of the peak at 2θ 33.17 is in question in the untreated powder pattern because this peak belongs to 100 percent intensity peaks of both cubic C_3A and α' C_2S . The absence of a peak at $33.17^\circ 2\theta$ in the XRD powder pattern after the potassium hydroxide and sucrose solution treatment confirms that there is no α' C_2S present in the sample.

3.1 MATCHDB Program

The MATCHDB identification program complemented the results of the selective dissolution techniques; identification of phases by MATCHDB uses the whole-pattern database (2). Before the MATCHDB routine, any shift in the peak during the data collection was corrected using the automatic peak correction routine. MATCHDB results obtained for all the cement samples are given in Table 2, although only the phases that show the figure of merit (FOM) above 0.500 are given. Apart from these major phases, small amounts of the MgO (periclase), calcite, and gypsum were also found in the samples; however, since the figure of merit was below 0.500 for these minor phases, they are not included in Table 2.

3.2. Quantification of C_3A and C_4AF by Salicylic Acid-Methanol Dissolution Method

After removing the silicate phases by the salicylic acid-methanol mixture, the residue left in the process was dried and quantified as the interstitial phases (aluminate and ferrite) in two ways. First, C_3A and

C_4AF contents were calculated as the total interstitial phases from the weight of residue obtained after the salicylic acid-methanol dissolution. From the mass balance calculation, C_3S and C_2S were reported as the total silicates. Second, the residue obtained from the dissolution technique was used to quantify the aluminate and ferrite phases by GMQUANT method. The X-ray diffraction data were collected for the residue after mixing the residue with corundum in the ratio of 1:1. The data treatment and quantification procedures were the same as the original cement samples. The results of the above calculations are given in Table 3.

Table 3. Results of Major Cement Phases Determined by GMQUANT Method after Preferential Dissolution of Silicates

PSU Sample Code	Percentage				
	C_3A	C_4AF	Total Interstitial Phases	Total Silicates from Mass Balance	Total Silicates ($C_3S + C_2S$) from Bogue

3.3 Results of X-Ray Phase Analysis

The results of phase analysis of cement samples by X-ray methods are given in Table 4. The Rietveld program normalized the values to 100% based on the phases specified in the calculated reference program. Therefore, a correction for minor phases not specified in the program was applied before computing the exact amount of the four major phases. Bogue values were taken as the base value for this calculation.

3.4 Discussion of Phase Analysis

The data presented in Table 4 are graphically summarized in Figure 2 for C_3S , Figure 3 for C_2S and Figure 4 for a combination of $C_3A + C_4AF$. The averages and standard deviations for C_3S presented in Figure 2 show that within the experimental error of the determinations, all five quantification methods overlapped. The Bogue determination most nearly approximates the results determined by the Rietveld method and of the point counting method but this latter method and the CCSEM both experience large standard deviations. GMQUANT underestimated the C_3S value by approximately 13%.

Figure 2. Comparison of the average and standard deviation for C_3S for each quantification method

For C_2S determination, again the experimental errors for all five methods overlapped. Point counting and CCSEM methods again both have large standard deviations with average values that closely approximate each other and are only slightly lower than the Rietveld determination. GMQUANT and Bogue methods very closely agree but are about 20% smaller than the other methods.

Figure 4 summarizes the combined data for C_3A and C_4AF . As in the tri- and di-calcium silicates, the point counting and CCSEM methods tend to provide a high value with relatively close agreement between the two methods. GMQUANT, Rietveld and the Bogue methods more closely agree for the interstitial phases.

Figure 4. Comparison of the average and standard deviations for $C_3A + C_4AF$ for each quantification method

Each quantification approach has strong points and weaknesses associated with the method. GMQUANT and Rietveld X-ray methods are “full pattern” fitting routines. In the case of GMQUANT, the approach is interactive and relies upon the operator to fit the particle size broadening and crystal chemically induced peak shifts to the data. To be effective, reference full spectra data sets need to be contained in the database that is used to identify the contents. This approach is effective in fitting overlapping peaks and in general is easy to use. The Rietveld’s program is a theoretical modeling program, which relies upon a precise knowledge of the clinker mineralogy. Its drawbacks are that it requires an intimate familiarity with the program to generate quality data and will only include in the analyses those phases that you program into the calculation.

The CCSEM point count method is very useful for the determination of the concentration of the various clinker phases. A larger standard deviation between samples was noted by the CCSEM technique due to the small area of analysis. Light microscopy studies have shown that error from counting statistics depends on the number of points, the size of the grid, and the grain sizes of the phases. In general, 4000 points has shown to give reasonable precision (11). Although the grain sizes of each phase do not cause a significant error in the analysis by SEM, the grid spacing is of great importance. Future analyses using CCSEM point counting should include a larger grid spacing than utilized within this study. The CCSEM approach also allows for discrete elemental discrimination of variations within a specific phase within a clinker as well as other parameters such as porosity. The SEM-based method has the potential to be the most accurate approach to quantification because they are based on non-biased analyses. Additionally, new technology allows for chemical acquisition to be collected in fractions of a second, which allows for short analysis times. The approach, however, will not differentiate polymorphs and is restricted by rather limited availability.

4. SUMMARY

The present study has combined selective dissolution techniques, QXRD methods - MATCHDB, GMQUANT, Rietveld, SEM based point counting and CCSEM methods to identify and quantify the cement phases. Selective dissolution techniques were used to improve precision in the phase identification and quantification using QXRD methods. QXRD analysis show that except for the C_2S content, the phase contents determined by QXRD were lower than the potential phases calculated by the Bogue method. A relatively close match is observed for C_4AF content from the Bogue and QXRD calculations. The values for interstitial phases determined by the dissolution technique, Bogue, GMQUANT, and Rietveld value compare within the precision range of the methods. The accuracy of the QXRD methods highly depended on the better resolution of C_3S and C_2S peaks. In general, GMQUANT and Bogue more nearly agreed. This agreement is in contrast to the SEM-based method which tended to produce higher values than did the other methods. Overall though, when the results were normalized to 100%, as the reported by the SEM method, the results were very similar.

Normalized Compositions of the 21 clinkers by each Technique

	<u>C3S</u>	<u>C2S</u>	<u>C3A/C4AF</u>
<u>Bogue</u>	64.1	17.5	18.4
<u>GMQuant</u>	60.6	19.8	19.6
<u>Rietveld</u>	61.1	23	15.9
<u>CCSEM</u>	60.1	20.1	19.8

ACKNOWLEDGEMENTS

The authors wish to thank Dr. J. Johnson and the late Dr. D. K. Smith of Pennsylvania State University for their advice and help in QXRD analysis. The authors also gratefully acknowledge the financial support provided by the Transportation Research Board through the project NCHRP 18-5.

ABSTRACT

An aqueous dispersion of chemically precipitated C-S-H has been used as an addition to Portland cement concrete as a means of increasing durability and service life. The C-S-H, when used in this application, has been determined to act as seeds which template the nucleation and growth of the hydration products of di- and tri-valent calcium silicate in the Portland cement concrete. The C-S-H seeds have been determined to be x-ray amorphous, similar to conventional C-S-H, with particles measuring ~5nm in size. The dosage of these seeds is typically 400 parts per million by mass of concrete. The mechanism by which they function has been interpreted as a modification to the pore structure of the hydrating concrete resulting in an increase in its tortuosity. This increased tortuosity increases service life by controlling the ingress of water. Microstructural evidence on laboratory concretes and 25-year-old in-service concretes support the proposed theory.

1. BACKGROUND

The admixture that will be the focus of the discussion in this paper is a commercial product that is marketed under the trade name IPANEX. This product has been marketed in the United States for 30 years by IPA Systems. IPANEX is a chemically precipitated C-S-H that is sold in the form of a redispersable solid/liquid suspension which can be added to concrete in the final mixing just before placing. The presented performance behavior of concretes containing IPANEX has been based on field observations. Anecdotal evidence exists that supports the following observations: extremely low flow rate of water, the reduction in alkali induced expansion in ASTM C 441 testing [Figure 1], the reduction or elimination of bleed water, the reduction in autogenous cracking [Figure 2], depth of penetration of chloride ions, air flow, and reduced water absorption.

Figure 1. Comparison of ASTM C 441 expansion data for cements of varying alkali content contrasting the expansion in specimens with (filled squares) and without (filled triangles) IPANEX. Data representative of all 114 Type I and II United States manufactured cements are presented for comparison.

Figure 2. Comparison of two pre-stressed double “Tees” prepared by the same manufacturer with the same concrete formulation and cured under identical condition for the same period of time. The Tee on the left was prepared with the admixture and the Tee on the right was prepared without the admixture.

2. DISCUSSION

2.1 Characterization of admixture

Characterization of the IPANEX suspension showed that it is a hydrous calcium silicate with a calcium to silicon ratio of just slightly less than 1:1. Phase identification based on X-ray diffraction characterization does not indicate any crystalline component to the IPANEX. This observation is supported by TEM studies showing individual particles of the admixture measuring approximately 5 nanometers in length [Figure 3], well below the minimum 200-nanometer size necessary to diffract x-rays.

Figure 3. Transmission electron microscopic image of IPANEX seeds.
The white bar on the left [see arrow] represents 10 nm scale.

2.2 Characterization of hardened concrete

Field inspections of fourteen box culverts on the Pennsylvania Turnpike between mile marker 133 through 137 was conducted by Miss Jenny Elstner in 1993 [1] revealed severe degradation of the roof members of the culverts in thirteen of the fourteen culverts. Figure 4 clearly reveals the contrast between the one durable culvert and a typical example of the remaining thirteen compromised structures. The WJE study quantified the degradation into area spalled, cracks and area delaminated. These individual measurements were merely summed to reflect a degradation factor presented in Figure 5.

(a)

(b)

Figure 4. Panel a (-top) is a photograph of the box culvert at milepost 133.4 of the PA Turnpike that was prepared by Pennsylvania Turnpike personnel using IPANEX. Panel b (bottom) from milepost 135.3 is typical of the remaining box culverts that were commercially prepared. The concrete formulations and curing were for all practical purposes identical.

Figure 5. WJE quantification of the deterioration of the box culverts.

The initial characterization studies by Garvey [2] of the microstructures of Portland cement concrete from the PA Turnpike bridges with and without IPANEX were striking [Figure 6]. In the control specimen (B), individual cement particles with hydration products can readily be seen. The hydration products contacted adjacent particles and formed an interconnecting tangle of C-S-H fibrils which is hydrated Portland cement concrete. These specimens also contained discernable pores between the cement particles. By contrast, the bridge sample containing IPANEX (A) similarly contained discernable cement particles also with hydration products but in these specimens, the microstructure did not contain large discernable pores.

(a)

(b)

Figure 6. Contrast of scanning electron microscopic images of (a) 25-year-old concrete containing IPANEX and (b) similar concrete exposed under identical conditions but without IPANEX.

It can more graphically be described as a homogeneous microstructure in which the C-S-H particles are uniformly distributed minimizing the appearance of large open pores. This same appearance has been confirmed on all examples of field placed concrete that have subsequently been characterized.

3. Mechanism for the performance of IPANEX

To achieve this degree of homogeneity in the microstructure, the formation of the C-S-H particles in the hydrating concrete would need to be “controlled” to grow evenly throughout the body of the concrete. Control over microstructure is routinely engineered into ceramics by “seeding” the green body. The development of the microstructure of the ceramic occurs during processing where the nucleation and growth of the ceramic phase is carefully controlled by the thermal history of the object [Kholkin, A.L (2001) [3], Tartaj, J (2001) [4], Huling, J.C. (1992) [5]]. Seeded, controlled nucleation and growth of the microstructure of structural Portland cement concretes in field applications has never been suggested nor demonstrated in the context of structural concrete.

At first blush, it is not obvious that a material that is admixed at 400 ppm by mass of concrete will have any effect on the properties of the concrete. However, preliminary modeling on the “micrometer” scale at NIST suggests that significant improvement in the properties of concrete are achievable from this approach. Preliminary modeling [NIST, 2002] [6] suggests that the seeding of concrete with C-S-H can increase the degree of hydration [Figure 7], which is consistent with our interpretation of the hydration mechanism, where the supersaturation of the pore fluid relative to the hydration products is eliminated [or restricted] by direct growth on the pre-existing seeds. The model also suggests that a modest increase in strength would be anticipated [Figure 7]. The increase is seldom seen in practice.

Figure 7. Predicted increase in hydration and compressive strength due to "seeding" microstructure with 1 μm C-S-H particle.

Taking into consideration that the average particle size of the IPANEX seed is just 5 unit cells of the crystalline counter part of C-S-H, tobermorite [approximately 10 molecules], 400 ppm corresponds to approximately 5×10^{23} seeds per hundred weight of concrete. On the “nanometer” scale, the sheer number of IPANEX particles interacting with the hydrating cement particles in the concrete can readily be visualized as controlling the microstructural development. Since the total mass of additional C-S-H added to the concrete is very small, no great influence in mechanical properties should ensue.

The research reported by Garrault-Gauffinet and Nonat (1999) [6] on the determination of the nucleation mechanisms of C-S-H support the observations that were used in this model. Their findings determined that critical radii for nucleation of C-S-H ranged from 2 to as many as 50 molecules or 1 to 25 unit cells and that the process for both tri- and di-calcium silicate is a heterogeneous process. Their

study quantified the degree to which the pore fluids must become supersaturated with respect to C-S-H before the sufficient nuclei were formed and the process of growth would occur. They defined a relationship for the supersaturation as:

$$\beta = K_{\text{super}}/K_{\text{solubility}}$$

in which:

K_{super} is the activity product in the supersaturated solution,
 $K_{\text{solubility}}$ is the solubility product.

They reported spontaneous nucleation from tri-calcium silicate hydration at a degree of supersaturation in which $\beta = 15$. The primary influence of the addition of C-S-H seed is to eliminate the supersaturation and provide a lower free energy surface to initiate the growth as soon as the solution concentration reached the saturation concentrations for C-S-H.

In the proposed model for the seeding of the microstructure, there is insufficient material added to the concrete to influence the mechanical properties. The impact of the seeding is manifested in a homogenizing of the C-S-H development. It does not necessarily influence the pore size distribution but does have a direct impact on the connectivity of the pore structure. Concretes fail by the ingress of deleterious components, usually contained in water, into the interior of the concrete via the accessible pore structure. Porosity in concrete can be described in terms of composite models as being a 3-3 composite. That is to say, there are two intertwining three-dimensional structures; one the porosity and the other is the matrix of the concrete. As a first approximation, ingress to the interior of the concrete specimen can be easily visualized as water entering and moving through the pores. If the pathway that the water must take is not convoluted and connected directly to the depth of the specimen, deleterious agents can be deposited deep within the specimen. However, if the pathway that the water must take is highly convoluted, movement of water, over the same period of time as the previously described “control” specimen, would only allow a minimal depth of penetration into the interior of the specimen.

The length of the pore pathway can be described as:

$$D_{\text{eff}} = \theta \gamma D_{\text{intrinsic}}$$

where:

D_{eff} is the effective diffusivity
 θ is porosity
 γ is tortuosity
 $D_{\text{intrinsic}}$ is the intrinsic diffusivity of the concrete

The degree to which the flow pathway is lengthened by the seed nucleation and growth of the microstructure is tortuosity, the proportionality constant that along with the porosity of the concrete equates intrinsic diffusivity to effective diffusivity. The concept of tortuosity is depicted in Figure 8.

Figure 8. Tortuosity will effect the ease or difficulty for fluids/ions to flow through the concrete structure. The top image shows a flow path through the concrete showing low resistance and hence a lower overall tortuosity. The bottom image indicates a more difficult flow path and therefore a higher tortuosity.

Field observations as in Figure 2, suggest that for exposed concrete surfaces, the ingress of water on a diurnal basis, does not penetrate as far into the seeded concrete as for the unseeded concrete.

4. CONCLUSIONS

A mechanistic model has been developed that describes the role of IPANEX in structural concrete and adequately addresses 30 years of field observations of the durability of concrete formulated with this additive. The mechanism is based on the presence of C-S-H seeds in the admixture that are dispersed throughout the fresh concrete. The seeds act as nucleation sites for the growth of additional C-S-H from aqueous calcium and silicate species present in the pore solution as a result of the hydration of tri- and di-calcium silicates in the cement. Seeded at only 400ppm by mass of concrete little direct influence on mechanical properties of the concrete occurs. The primary influence of the seeding, which contains in excess of 10^{23} seeds per hundred eight of cement, is on the development of a homogenous microstructure in the concrete and is manifested in the inter-conductivity of the pore structure. This inter-conductivity is defined as tortuosity and in practice limits ingress of water and hence deleterious agents into the interior of concrete structures extending the service life and durability.

ABSTRACT

Twenty-one diverse clinkers were selected from 114 commercially available type I & II North American cements. Microscopic characterization of the clinkers was conducted without the knowledge of the manufacturing process, and the equipment or the manufacturer nor the source of raw materials. The results illustrate clinker differences and their effect on differences in cement performance in mortars and concrete. The clinkers were examined by an assemblage of analytical microscopic techniques including polarized light microscopy, reflected light microscopy, and scanning electron microscopy provided with back-scattered electron imaging. The samples were chemically etched in order to impart variation in color and textures among and within the various crystal phases. Several general observations can be made that pertain to the suite of clinkers examined and used to augment the information derived from strictly chemical data. It can be inferred from the microscopic analysis that a variety of different processing environments were represented in the data set. This included microstructures that are interpreted to be indicative of well-processed "normal" Portland cement. Additionally, large clusters of belite crystals are observed in many of the clinkers, which suggest inhomogeneity in the raw feed mix. Some of the clinkers exhibited what could be interpreted as reducing kiln atmosphere conditions. The observed size of the alite crystals suggested that the clinkers that give rise to cement with average properties possess predominantly smaller crystals. In contrast, clinkers that give rise to cements with poor properties possessed average and large size alites.

1. EXPERIMENTAL

Twenty-one North American clinkers were obtained from commercially available Type I and II Portland cements. The set of specimens included in this study was statistically chosen to span the range of characteristics that were identified as most significantly impacting the long-term durability of concretes manufactured from them (Table I). An experimental study was conducted to better understand the breadth of variation in manufacturing Portland cement. Statistically based samples of Portland cement clinker with a wide variety in properties were selected in the experimental design. The experimental design of this study is based on a center weighted response surface model in which the concentrations of equivalent alkali, C_3A , SO_3 and fineness were taken to represent four properties in the cement that could most differentiate one cement from another in terms of field performance. The "Center" cements represent a statistical average over all of the 114 available cements of the four characteristics in question. The "Corner" cements represent examples in which the four properties varied by one standard deviation high and low. Finally, the "Star" points represent extreme compositional variation of the four properties. Specimens from each of the clinker samples were examined with multiple-microscopic techniques including polarized light microscopy, reflected light microscopy, Nomarski differential interference microscopy (which is utilized for

examining subtle variations in surface), scanning electron microscopy, and back-scattered electron imaging. A minimum of five samples of each clinker was randomly selected, epoxy impregnated and polished to a 0.3-micron diamond paste finish. The final polish was achieved by stepwise reduction in corundum grit to 1 micron and with diamond paste to 0.3 microns. The samples were chemically etched in order to impart variation in color and textures among and within the various crystal phases. The polished sections were etched using dilute solution of potassium hydroxide (0.1 molar aqueous KOH) followed by Nital solution (mixture of 1.0 ml nitric acid and 99 ml isopropyl alcohol) for 20 and 10 seconds, respectively. This combination will turn alite crystals to light blue to green and belite to brown to green. Both silicates will show details of internal structures. The tricalcium aluminate phase will turn to light brown.

2. RESULTS AND DISCUSSION

2.1 Center Points Clinkers

Some of the center point clinkers show nests of belite surrounded by ill-defined and rough-surfaced alite crystals (Figure 1a). This microstructure represents a heterogeneous distribution of phases with large belite nests. The belite nests are an indication of ash shortage, excessive quartz grain size, or presence of feldspar and blast furnace slag [1]. It also indicates an inadequately mixed raw material, which may lead to a decline of mortar strength [2]. The development of belite in the form of a ring around a central pore shown in the optical micrograph is probably formed by silica mobilization during sintering of coarse quartz in the feed [3]. The large number of belite clusters with rough textures may also be an indication of overheating or overburning [4]. The large, irregularly shaped belite crystals are attributed to: prolonged heating below liquid-formation temperature [5]; coarse quartz or quartzite in feed; or very slow cooling [6]. The observed multidirectional lamellar structure of belite is due to its formation and coarsening during alpha to alpha-prime transition during cooling [7]; or alternatively is due to clinker burned at greater than 1420°C [8].

Some alite crystals are elongated and show broad twin green and brown zones. The interstices are composed of brown aluminate phase and the brighter brown to tan ferrite phase. Some other specimens show large clusters of belite associated with relatively high contents of free lime, as indicated from the chemical analysis, which may indicate a high lime saturation factor [9]. The simple twinning in alite crystals has been reported as a result of the rhombohedral to monoclinic transition at approximately 1050°C [7].

The back-scattered electron micrograph (Figure 1b) shows the euhedral alite of average size of 40 μm with inclusions. The interstitial phase is composed of distinct aluminate and aluminoferrite phases. The EDX analysis of the ferrite phases demonstrates a higher percentage of Al relative to Fe due to its distribution between two phases. The back-scattered electron micrographs much more clearly reveal the microstructure showing belite grains with crossed-striated lamellae. Most of the belite grains are "ragged" and some can be seen to be dismembered, that is, the belite grain is broken into much smaller grains along the lamellae boundaries (Figure 1c). The microstructure represents a suite of homogeneously distributed phases of idiomorphic alite, rounded belite, and a finely differentiated matrix with rare small free-lime crystals. This microstructure is indicative of optimized manufacturing conditions: a "correct" chemical composition of well mixed raw feed, with no coarse particles, and satisfactory maintenance of sintering and cooling temperatures, *i.e.* good production conditions [9].

The increase in amount of small alite, decrease in large alite may represent a rapid burning at high temperature [6], resulting in growth rate of crystals slower than formation of nuclei [10]. The matrix is composed of aluminate and ferrite phases. The fine structure of aluminate and ferrite phases shown in the SEM micrographs is indicative of a rapid cooling from high temperature [7, 11]. The rough belite surface, prominent lamellae, segmented finger-like sections shown in the SEM

micrographs may indicate a reducing condition [4] in the kiln atmosphere. The ragged belite microstructure is indicative of a slow cooling [1, 12, 13, and 14].

(b)

(c)

Figure 1. Optical and SEM micrographs representative of microstructures of the Center clinkers

2.2 Corner Points Clinkers

Reflected light microscopy of the Nital over KOH etched polished section shows coarsely crystalline blue-green alite of an average size 70 μm . Belite appears to be intergrown with alite and some very small belite crystals are growing from alite edges. The interstices are composed of brown aluminate phase, and the brighter brown to tan ferrite phase with also tiny tan-brown blebs (belite) in interstitial phase (Figure 2a).

Some clinkers in this category show coarsely crystalline euhedral relatively clear blue-green alite of an average size 60 μm . Belite is present as rounded twinned crystals. The interstices are composed of brown aluminate phase, and the brighter brown to tan ferrite phase. The black spots distributed over all of the micrograph are probably free lime (Figure 2b).

The Nomarski interference microscopy shows cross striations and the presence of islands or blotches within the boundaries of the belite grain. In addition, dark cores are observed in the center of the belite grains [can not distinguish lime by its dark appearance with this technique]. Also, some belite grains with "ragged" edges are readily observed (Figure 2c). This microstructure represents a homogeneous distribution of silicate phases which indicates an optimized manufacturing condition. The large alite is due to a number of factors including: longer burning time, higher temperature, lime-poor environment in the vicinity of belite; coarse raw mix; and high-viscosity liquid due to alkali or sulfate [4]; or extreme hard burning and porous shell on clinker nodule [15]. Larger alite crystal size, however, may have a greater effect in accelerating the very early strength development of cement [16, 17].

The presence of free lime is attributed to large pieces of raw mix, indicating insufficient fineness of grinding and uniformity of raw mix [18], insufficient homogenization of raw mix [19], local concentration of limestone [2], or pure calcite particles [9]. The observed multidirectional lamellar structure of belite is formed and coarsened during alpha to alpha-prime transition during cooling [7] of clinker burned at greater than 1420°C [8]. The large belite with rough exterior is ascribed to the overheating or overburning [4]. The outgrowth on the surface of belite crystals observed in the Nomarski interference micrographs can be ascribed to high alkali (K-feldspar) in raw mix [1]; Low primary air volume or pressure, excessive burning-zone temperature, slow cooling rate [4].

The ragged dismembered belite structure, which appears in the Nomarski micrographs, may originate during the alpha to alpha prime-inversion in with melt and slow cooling [20]. The large aluminate (C_3A) crystals are indicative of an extremely slow cooling and exsolution of lime from silicates [21]. Some coarsely crystalline euhedral blue-green alite, some with cores, and sizes ranging from 40 to 60 μm . Alite crystals exhibit mottled, rough surfaces, reflecting inclusions. Some of the large alite grains exhibit striations. The interstices are composed of brown aluminate phase and the brighter brown to tan ferrite phase. The back-scattered electron micrograph shows large alite crystals with rough surfaces and the average size is 50 μm (Figure 2d).

Some with cross-striated lamella belite grains with ragged edge reacting protrusions appear as typical morphology of reacting belite. The coarsely crystalline alite is typical of longer burning time, higher temperature, lime-poor environment in the vicinity of belite; coarse raw mix; and high-viscosity liquid due to alkali or sulfate [4]; or extreme hard burning and porous shell on clinker nodule [11]. Larger alite crystal size, however, may have a greater effect in accelerating the very early strength development of cement [16, 17]. The fine inclusions are probably due to pseudomorphic resorption of alite from lime-poor melt; slow cooling [1, 2], or perhaps excess solid solution [22].

The ragged belite microstructure is indicative of slow cooling [1, 12, 13, and 14]. The rough texture of the belite contains prominent lamellae, segmented finger-like sections shown in the SEM

micrographs is indicative of reducing conditions [4] in the kiln during processing. Nomarski interference microscopy shows details of the interstitial phases and it contrasts the darker tricalcium aluminate from the lighter ferrite phases. The tricalcium aluminate appears to dominate the ferrite phase. Two patterns are observed, one in which the ferrite phase forms rims around the outer surface of the tricalcium aluminate phase and one in which it appears as alternate banding between the two phases. The ferrite is never observed as being totally encapsulated within the calcium aluminate phase. The large aluminate (C_3A) crystals observed in the Nomarski interference micrographs is indicative of an extremely slow cooling and exsolution of lime from silicates [21].

(c)

(d)

Figure 2. Optical, SEM, and Nomarski micrographs representative of microstructures of the Corner clinkers

Some sections show crystalline euhedral green alite of average size 40 μm but isolated alite crystals can be quite large approaching 70 to 100 μm . Belite exists as rounded brownish twinned grains as well as small rounded, dark grains of CaO. The interstices are composed of brown aluminate phase, and brighter brown to tan ferrite phase, and contain blebs of belite. The back-scattered electron micrograph shows the belite much more clearly as rounded grains with parallel- to crossed-striated lamellae.

This microstructure represents a homogeneous distribution of silicate phases; medium sized alite and rounded belite; finely differentiated matrix; scarce, small free-lime crystals. It may represent optimized manufacturing conditions: “correct” chemical composition of raw feed, well mixed and satisfactory maintenance of sintering and cooling temperatures [7], which generally represents good production conditions [9]. The variation in alite size indicates a non-homogeneous raw mix as well as locally high lime saturation factor [9]. Simple twinning in alite crystals forms as a result of rhombohedral to monoclinic transition at approximately 1050°C during cooling [7]. The multidirectional lamellar structure of belite forms and coarsens during alpha to alpha-prime transition during cooling [7] of clinker burned at greater than 1420°C [8]. The matrix is composed of dark aluminate phase and yellow ferrite, which may represent a normal clinker [1]. The dendritic intergrowth of the matrix phases is probably due to the relatively rapidly cooled clinker [1].

2.3 Star Points Clinkers

Reflected light microscopy of the Nital over KOH etched polished section shows coarsely euhedral blue-green alite of an average size 60 μm (Figure 3). Alite crystals are largely in contact with each other. At the point marked (a), belite is present in conjunction with a large crystal of alite, which has been interpreted as an incomplete conversion of the belite to alite. Alite contains some inclusions. Throughout the figure, belite is rounded or irregular in appearance and always associated with alite crystals. The interstices are composed of brown aluminate phase, and the brighter brown to tan ferrite phase. This microstructure represents a suite of homogeneously distributed phases of idiomorphic alite, rounded belite, and a finely differentiated matrix with rare small free-lime crystals. This texture is indicative of optimized manufacturing conditions: “correct” chemical sintering and cooling temperatures, *i.e.* good production conditions [9].

The large alite develops due to longer burning time, higher temperature, lime-poor environment in the vicinity of belite; coarse raw mix; and high-viscosity liquid due to alkali or sulfate [4]; or extreme hard burning and porous shell on clinker nodule [15]. It is estimated that this alite crystal size represents the optimal size for greatest effect on cement properties [16]. The small-scale inclusions are probably due to pseudomorphic resorption of alite from lime-poor melt; slow cooling [1,2], or excess solid solution [22]. The belite inclusion in alite is attributed to residual original belite [18]. The matrix is composed of very small brown aluminate phase and yellow ferrite which may represent a low aluminate matrix [1]. Few clinkers in this category possess belite nests which is an indication of ash shortage, excessive quartz grain size, or presence of feldspar and blast furnace slag in the raw feed. Some ragged belite structure was also observed which may originate during the alpha to alpha-prime which suggests inhomogeneity in the raw feed mix.

Figure 3. Optical micrograph representative of microstructures of the Star clinkers

3. GENERAL OBSERVATIONS

Several general observations can be made that pertain to the suite of clinkers examined. It can be inferred from the microscopic analysis that a variety of different processing environments were represented in the data set. This included microstructures that are interpreted to be indicative of well-processed "normal" Portland cement, [14%]. Additionally, large clusters of belite crystals are observed in many of the clinkers [28%]. Ten percent of the clinkers exhibited what could be interpreted as reducing kiln atmosphere conditions. This non-standard processing condition was not characteristic of any one of the individual statistical types of cements [center, corner or star] but, in fact, distributed evenly amongst the types. The observed size of the alite crystals suggested that the "average clinkers", the so-called center cements, possess predominantly smaller crystals. In contrast, the corner and star cements possessed average and large size alites.

In an attempt to relate the different clinker fabric to the bulk chemistry and properties of mortars and concrete made from them, the following observations can be made:

- **Alkali content:** For clinkers with low alkali content ($<0.60\%$), 80% of the clinkers contain large to average sized alite crystals and all of them possess belite grains that are twinned, hard to see, associated with alite or having ragged edges. For clinkers with high alkali content ($>0.60\%$), 90% of the clinkers contain small to average sized alite crystals and 55% of possess nested belite.
- **Mortar strength:** 60% of the mortars showing above average compressive strength (at 8 days) are made from clinkers with average sized alite crystals, whereas 85% of the mortars showing below average compressive strength (at 8 days) are made from clinkers with large to average sized alite crystals. On the other hand, 85% of the mortars showing above average compressive strength (at 121 days) are made from clinkers with large to average sized alite crystals, and 85% of those showing below average compressive strength (at 121 days) are made from clinkers with small to average sized alite crystals.
- **Concrete strength:** 50% of concretes that show below average compressive strength (at 180 days) are made from clinkers with nested belite.
- **Heats of hydration:** 40% of cements giving higher than average heat of hydration are made from clinkers with nested belite.

ABSTRACT

This article reports on the investigation of the relation between the activated blast-furnace slag cement hydration and unrestrained autogenous shrinkage development on mortar specimens. The chemical and microstructure changes due to hydration were determined on pastes by conduction calorimetry, mercury porosimetry and thermogravimetric analysis. Samples were prepared with ground blast furnace slag activated with sodium hydroxide (5% of Na₂O) and sodium silicate (silica modulus of 1,7) with 2.5, 3.5 and 4.5% of Na₂O, all them by slag mass. The high early strength Portland cement was used for comparison. Autogenous shrinkage for all activated slag mixes was higher than HESC; early hydration makes an important contribution to the total result that increases with the silica content of the mix. The calorimetry results show that as Na₂O content increases induction period decreases. The degree of reaction increases with the silica content as does autogenous shrinkage and the percentage of non-evaporable water measured by thermogravimetry.

1. INTRODUCTION

Activated slag cement (ASC) is a blend of blast furnace slag and activators, which are chemical species capable of enhancing the slag reactivity during hydration. In addition to the benefit of the use of an industrial residue, ASC based materials show, in many other aspects, advantages over the normally employed Portland cement. It is possible to develop ASC compositions that show extremely fast development of mechanical properties [1, 2] that, for instance, could be advantageous for diminishing operation downtimes during repair of roads or industrial structures. The nature of its hydrates confers to ASC a high resistance to chemical attack, especially under acidic conditions [3, 4]. ASC could be the main component of protection overlays. Adding to the technical advantages, the ASC material cost can be as low as a half of that of Portland cement.

Shrinkage of activated slag cement is reported to be greater than that of Portland cement, and it may represent the most serious limitation for the use of this material [5, 8]. During hydration, changes in chemical composition and microstructure take place, and shrinkage relates to both chemical and physical aspects [9, 10,]. Different studies have identified the main parameters involved with ASC shrinkage, namely the activator chemical species and dosage [11]; the ASC fineness [12]; and the curing conditions [13]. In general, shrinkage increases with higher activator dosages and ASC fineness, and it is greater for sodium silicate (waterglass) based activators compared with sodium hydroxide and sodium carbonate based materials.

The shrinkage mechanism of this cement is not yet very well understood. Published results on ASC do not relate shrinkage and hydration evolution. The majority of the reported earlier shrinkage measurements refer to seven days of hydration and an important period of the phenomenon is missed, as pointed out by Collins; Sanjayan [14].

The results of an ongoing investigation at University of São Paulo show that autogenous shrinkage is significant in ASC, and can represent 50% of the shrinkage measured by the drying shrinkage method. Because autogenous shrinkage happens mainly at very early ages, it can be responsible for the reported early age cracking of ASC based elements. The understanding of autogenous shrinkage development and its relation to hydration evolution is essential for the development of casting procedures and admixtures intended to reduce or compensate the shrinkage of ASC. This article reports on the relationship between autogenous shrinkage and hydration evolution for different types and amounts of activators.

2. EXPERIMENTAL

2.1 Materials and mix proportion of mortars and pastes

The granulated blast furnace slag was supplied by Companhia Siderúrgica de Tubarão, with a basicity coefficient $K_b = (CaO + MgO)/(SiO_2 + Al_2O_3) = 1,06$. The slag consisted of 99,5 % of glass and some crystalline components such as gehlenite and merwinite. It was ground to a Blaine fineness of 500 m²/kg. The mass percentage composition was: SiO₂ - 33,78; Al₂O₃ - 13,11; Fe₂O₃ - 0,51; CaO - 42,47; MgO - 7,46; K₂O - 0,32; Na₂O - 0,16; SO₃ - 0,15; S²⁻ 1,14; free lime - 0,1; loss on ignition - 1,67; insoluble residue - 0,53. For comparison, samples were also tested with a high early age strength Portland cement – HESC whose mass percent composition was SiO₂ - 19,45; Al₂O₃ - 4,86; Fe₂O₃ - 3,12; CaO - 64,44; MgO - 0,62; SO₃ - 2,94; K₂O - 0,70; LOI - 2,92; CO₂ - 2,45. The Blaine fineness was 461,8 m²/kg, not too much lower than the slag. Other characteristics were: initial set: 138 min; final set: 200 min.; compressive strength (MPa): 1 day – 29,2; 3 days – 42,6; 7 days – 46,9; 28 days – 56,1. The sand used was a Brazilian standard sand composed of four equal proportions of the fractions sieved: 2.4-1.2 mm, 1.2-0.6 mm, 0.6-0.3 and 0.3-0.15 mm.

Mortar samples were prepared with a mass proportion of HESC or cementitious binder:sand:water of 1:2:0.48, while the paste samples were prepared with mass proportion of 1:0.48. The cementitious binder corresponds to the total mass of slag and the solid fraction of the activator combined; the water contained in the activators was deducted of the total amount of water. The ground blast furnace slag was activated with sodium silicate having a silica modulus of 1.7, with 2.5, 3.5 and 4.5 % of Na₂O, and sodium hydroxide (5% of Na₂O), by slag mass. The different alkali activators and their composition are summarized in Table 1. Mortars and paste samples are named according to the activator's name.

Table 1. Composition of activators

Name	Type	Composition	Silica Modulus
2NS	Sodium silicate	2,5%Na ₂ O+4,25%SiO ₂	1,7
3NS		3,5%Na ₂ O+5,95%SiO ₂	1,7
4NS		4,5%Na ₂ O+7,65%SiO ₂	1,7
5N	Sodium hydroxide	5% Na ₂ O	-

2.2 Testing methods

2.2.1 Autogenous shrinkage

Nine mortar prisms (25x25x285 mm) were cast for each binder and the measuring of length change was according to ASTM C490 after 6, 8, 10, 12 hours and 1, 2, 3, 4, 5, 6, 7, 9, 11, 14, 21, 28 days. Because hardening is faster for the mortars 3NS and 4NS, the first shrinkage measurement happened 2 hours after mixing. To avoid moisture evaporating from the mortar, the prisms were wrapped with an inner layer of plastic sheet and an outer layer of aluminium foil. Aluminium foil should not be in contact with the highly alkaline mortar, since air bubbles are formed and this can

affect the shrinkage measurements. The protective wrapping sheets were applied over the moulding before casting.

Each prism was tightly sealed with an aluminum tape, guaranteeing a maximum moisture loss of 0.2% after 56 days. After demoulding, the prisms were stored in the dry room at a constant temperature of 24°C and 50% RH. The first length reading was taken just after demoulding, and the results were expressed as $\text{mm/mm} \times 10^{-6}$. The maximum temperature rise due to the heat of hydration was 3°C and the calculated thermal expansion coefficient was $15 \times 10^{-6}/^\circ\text{C}$. Because the temperature variation was too small, autogenous shrinkage results were not corrected for temperature effects.

2.2.2 Hydration evolution tests

Conduction calorimetry, thermogravimetric analyses, mercury porosimetry and X-Ray diffraction were performed for the investigation of the hydration evolution on paste samples prepared with water/binder ratio of 0.48. After each period corresponding to autogenous measurements, the hydration of the pastes was stopped by freezing in liquid nitrogen and then freeze dried. All mixes were tested after 6, 8, 10, 12 hours and 1, 2, 3, 7, 14, 28 days. For the calorimetry tests, samples of paste were prepared by mixing 20g of slag and water+activator in a plastic bag and immediately transferred to a JAF Wexham conduction calorimeter at 20°C. The heat output was recorded after 30 minutes, time needed for the system to reach equilibrium. The heat of hydration was determined up to 72 hours after mixing. For thermogravimetric analyses, the tests were made with ground samples of paste using only the 75 μm to 150 μm fraction sieved. Tests were performed in a NETSZCH TG 209-C thermobalance, with a heating ratio of 10°C/min and under a nitrogen atmosphere with a gas flux of 30 ml/min. The pore size distribution was determined using a Micromeritics Autopore III 9410 porosimeter under pressures ranging from 0 to 414 MPa. The assumed surface tension of the mercury was 0.485 N/m at 25°C (ASTM D 4404-84). The density of the mercury was 13.5413 g/ml and the assumed contact angle was 130°. The X-Ray diffraction was performed on ground samples of paste using a Philips powder diffractometer with Cu K α radiation, in sample holder with zero background.

3. RESULTS AND DISCUSSION

3.1 Autogenous shrinkage

The plotted results in Figure 1 confirm that the cumulative autogenous shrinkage for all activated slag mixes is higher than HESC and that it increases with the silica content of the mix. It can also be seen that most of the total autogenous shrinkage takes place during the early hydration stages after hardening.

Figure 1. Comparative and cumulative autogenous shrinkage of activated slag and HESC.

The average results of the autogenous shrinkage of the silicate mixes increase with the SiO_2 content, but the difference between the 3NS and 2NS mixes are only statistically significant until 21 days. The 4NS mix shrinkage is 4.5 times greater than the one presented by HESC.

3.2 Conduction calorimetry

Figure 2(a) shows the profile of the heat liberation during 72 hours. The 5N mix shows the fastest heat evolution, with a maximum at 6 hours and no induction period. The HESC has also no induction period, and the highest rate of heat evolution, being the maximum around 18 hours. The induction period of all slag activated mixes correlates well with the Na_2O content, increasing as its content decreases, showing the effect of the alkaline media on the solubility of the slag and hydration evolution.

Figure 2. Cumulative heat of hydration (a) and heat evolution rate (b) of activated slag and HESC.

After the induction period, diffusion is the mechanism that controls hydration [15-17]. The slag solubility also influences the reaction sequence, and the total cumulative heat diminishes as Na_2O content decreases, as shown in Figure 2(b). Because the silica modulus is constant, it can be said that the degree of reaction increases with silica content. The influence of the activators on heat evolution rates is clear: a) for the soda mix, the induction period was not observed, but an acceleration period peak; b) for sodium silicate mixes it can be seen that as the Na_2O content decreases, the induction period increases and the magnitude of the peak corresponding to the main product formation decreases.

3.3 Thermogravimetry and X R D analyses

X Ray diffraction patterns of 4NS and 5N are shown in figure 3. The more evident differences between them are (a) the cristallinity of the hydrated products of the 5N mix and the amorphous structure of the silicate mixes and (b) the more evident presence of aluminate phases in the 5N mix, here illustrated by the diffractogram of the 4NS and 5N mixes.

Figure 4 shows the DTGA curves. The hydration reactions start on the first day, and continue to occur during the period studied of 28 days. Silicate activated mixes show only one peak observed between 30°C and 220°C attributed to C-S-H (I) and aluminates; and a smooth loss of mass observed between 275°C and 425°C due to hydrotalcite formation, better defined for the soda activated mix. The main difference observed between silicate and soda activators is the shoulder of the main peak between 125°C and 185°C , due to aluminates formed on soda mix. The HESC presents peaks for C-S-H, AFm species, Portlandite and calcium carbonate.

Figure 3. X Ray diffractogram of 4NS and 5N 28 days-old.

Figure 4. DTGA curves of activated slag and HESC.

3.4 Porosity

In Figure 5(a) the cumulative curves of pore size distribution show the different profile of HESC and soda activated and silicate activated slag. The total volume of pores at 28 days follows the order: 2NS > HESC \cong 5N > 3NS > 4NS. The incremental pore size curves show the quantitative distribution frequency of the pore sizes in the range of mesopores and macropores (Figure 5(b)). The 4NS and 3NS is practically unimodal as the 2NS and HESC are bimodal and 5N three modal. It can be seen that silica plays an important role in the gel densification, being the maximum pore sizes of 25 nm for the 3N mix and of 15 nm for the 4N mix. The activated slag systems have a typical microstructure, which differs from that of hydrated OPC. In the case of alkali-activated slag, the volume of pores in the micropore size range tends to be bigger than that of HESC. The volume of pores within the capillary range is smaller than that of HESC. Under normal application conditions shrinkage depends on loss of water from macropores and mainly from mesopores [18, 19]. The volume of smaller pores is larger for the silicate mixes than for HESC and 5N. The threshold limit for silicate mixes are in the region of mesopores, whose value diminishes as the silica content increases. From the total pore volume the percentage of mesopores is 90-95% for the silicate mixes while for 5N and HESC are 58% and 54%, respectively. The results obtained are in good agreement with other studies on ASC porosity [15, 20, 21].

Figure 5. Cumulative (a) and incremental (b) pore size distribution of 4NS, 3NS, 2NS, 5N and HESC pastes at 28 days, with autogenous curing.

4. ANALYSIS OF RESULTS

Figure 6 shows results up to 28 days of autogenous shrinkage; cumulative heat of hydration (H); the total weight loss between 30 and 230 °C, the range in which the most part of C-S-H and AFm formed dehydrates; and the total volume of mesopores, assumed to have diameters between 3nm and 50 nm, expressed as a percentage of the sample bulk volume. Autogenous shrinkage is significant, and values as high as 2400 $\mu\text{ε}$ were measured for the mortar samples 28 days after casting. In general, at all ages up to 28 days, autogenous shrinkage increases according to the following: HESC < 5N < 2NS < 3NS < 4NS. The larger the amount of silicates in the silicate activators, the bigger the autogenous shrinkage, and the sooner it takes place. Soda activated ASC did not show significant autogenous shrinkage up to 28 days, and compared well with the HESC mortar mix.

Figure 6. Comparative curves of autogenous shrinkage, cumulative heat (H), loss weight (TGA) and mesopores (P) for 4NS(a), 3NS(b), 2NS(c), 5N(d) and HESC(e) mixes.(Cont.)

When autogenous shrinkage and heat of hydration evolution curves of ASC activated with silicate are compared, it is possible to see that the beginning of the acceleration period of hydration and the initiation of autogenous shrinkage practically coincides. This shows that during the induction period, hydration is very slow and so too is the formation of a more rigid microstructure and the consumption of water capable of causing autogenous shrinkage due to self-desiccation or chemical contraction. Once the hydration becomes more intense, autogenous shrinkage increases rapidly and it is more evident.

The evolution of mesopores also coincides with the beginning of the acceleration period of the hydration. A linear correlation between the evolution of autogenous shrinkage and mesopore volume was found only for the 4NS mix (coefficient of correlation of 0.92). It is more evident in this mix that autogenous shrinkage results from the synergic effect of chemical shrinkage and the physical phenomenon of self-desiccation, mainly occurring at mesopores size pores.

The relation between autogenous shrinkage evolution and the volume of formed mesopores becomes less evident as the amount of silicate diminishes in the activators. It is possible to observe that the volume of mesopores also does not agree well with the heat of hydration and the weight loss evolution associated with the degree of hydration for the pastes prepared with less silicate. One should expect that the larger the heat of hydration, the larger would be the volume of formed mesopores and the weight loss associated with C-S-H content. All of these parameters should relate to the amount of autogenous shrinkage. This apparent discrepancy is probably due to the fact that although hydration evolves through the 28 days tested, part of the hydrated products does not cause the refinement of the pores, but the formation of inner particle hydrated products. Autogenous shrinkage still increases even after the formation of mesopores diminishes. The most likely cause is the consumption of water, or self-desiccation, promoted by the inner particles' hydration. This effect is more evident for the mixes prepared with activators with smaller amounts of silicate. It can be also said that the volume of outer product diminishes with the silicate activator content. As the hydration evolves, the inner products are formed, with migration out of Ca, Al and Si of the slag into the outer product and densifying it [20]. For the 2NS mix, after the acceleration period, the hydration does not contribute to the increase in mesopores' volume.

The 5N mix has a high heat of hydration just after mixing followed by a low ratio of reaction. The shrinkage is very low, increasing after 24 hours. If the total percentage of non-evaporable water for all mixes is compared, it can be observed that the result for mix 5N is equal to or higher than that for silicate mixes, although no correspondence to the autogenous shrinkage was observed.

On the other hand, there was a good correlation with the increase of mesopores. As it was concluded the contribution of silicate on the shrinkage, this can explain the lower result observed for this mix.

The HESC has a high porosity at early hydration that diminishes as the new hydrated products fill in the pores. However, from the total volume, the mesopore evolution practically stabilizes. The autogenous shrinkage on the contrary increases but very slowly and there is no correlation between these properties. A very high correlation exists with heat of hydration and non-evaporable weight loss, considered until 220°C. The 5N and HESC have both, similar products identified by XRD, and also similar volumes of mesopores (57% for 5N and 54% for HESC), and lower shrinkage if compared to silicate mixes.

5. CONCLUSIONS

The conclusions of this study are:

- Determinations indicated that autogenous shrinkage is a significant part of the total dimensional changes observed for these cements. This can explain the fact that the amount of water loss by evaporation does not account for the total measured shrinkage values.
- The silicate content in the activators has an important role on autogenous shrinkage. At 28 days, shrinkage of the mortar prepared with ASC activated with higher silicate content (4NS) was 4.5 times greater than that of HESC; the 3NS mix was 3,9 times greater and the 2NS mix 3,6 times greater.

- Given that autogenous shrinkage is the macroscopic effect of both chemical shrinkage and self-desiccation, the volume of mesopores has an important effect on autogenous shrinkage development. The total volume of mesopores increases as the non-evaporable water loss weight and the activator silicate content increase. The volume of mesopores is much bigger for the silicate activated than the soda activated ASC. Mesopores are approximately 95% of the total volume of the high dosage silicate activated ASC, and only approximately 54% of the Portland cement porosity, both at 28 days.
- Autogenous shrinkage of ASC does not always agree with hydration heat evolution, mesopore formation and degree of hydration. The degree of correlation among these parameters depends not only on the activator's chemical species, but also on the number of active elements that compose the activators.
- Autogenous shrinkage in ASC is a complex phenomenon that results from the synergic effect of chemical and physical parameters. From the comparisons of porosimetry, TGA and XRD results, it can be said that there is some evidence of the effect of microstructure on shrinkage results between silicate activated mixes and soda mix or HESC

ABSTRACT

The phase rule has been applied to model the binding of chlorides in hydrated Portland cements. The model predicts the solid solution of at least two AFm phases. It was tested in the laboratory on cement pastes prepared from white Portland cements containing 4 and 12% C₃A, and a grey Portland cement containing 7% C₃A. 1% calcite was added to all cements. The pastes were stored in solutions of different Cl (from CaCl₂) and Na (from NaOH) concentrations. When equilibrium was reached the mineralogy of the pastes was investigated by XRD and EDS analysis on the SEM. The solution was also analysed for Cl in addition to all other major components. The distribution of chloride between the solution and the solid phases was found to be controlled by an AFm solid solution phase consisting of monocarbonate and Friedel's salt. Higher contents of Friedel's salt in this solid solution phase corresponded to higher concentrations of Cl in the aqueous solution. Chloride was also bound by the C-S-H phase, but this too was governed by the content of Friedel's salt in the solid solution phase. All of the results obtained can be predicted by applying the phase rule and assuming equilibrium conditions.

1. INTRODUCTION

The harshest conditions that concrete can be subjected to usually involve some form of attack by chlorides. These include marine environments, roads and bridges exposed to de-icing salt, etc. In the case of reinforced concrete, the time it takes for the chlorides to migrate to the reinforcement is the main parameter used to predict the service life of the concrete.

It is generally agreed that when chlorides migrate into concrete they become partially fixed by the hydrate phases through one or more processes collectively referred to as binding. The binding capacity of the cement paste system has a significant effect on the service life of reinforced concrete, where only chlorides in solution can be transported towards the reinforcement where at some critical concentration they initiate corrosion.

The mechanisms that result in binding of chloride ions are still not entirely clear [1], but it is assumed that it is mainly the aluminium-bearing hydration products that react chemically with the chloride ions to form Friedel's salt, or solid solutions which include Friedel's salt [3]. Competition for the aluminates by the sulfate and carbonate ions will affect the capacity of the system to bind chlorides. The very high specific surface area of the C-S-H phase is often believed to substantially contribute to binding through physical adsorption [7], although evidence that it plays little or no role is also convincing [4].

The binding process is normally examined by determining the contents of chlorides bound in cement paste as a function of the concentration of chlorides in an external solution over a wide range of total chloride contents. The results are then expressed by means of the so-called Langmuir or Freundlich isotherms [5], depending on which of these provides the best fit over the range of concentrations examined. In this paper we describe a thermodynamic model based on the phase rule for predicting the stable or metastable equilibrium phase assemblages in cement paste. The model is specifically applied to binding of chloride ions in presence of carbonates at constant alkali contents. The model is then tested experimentally in the laboratory.

2. THERMODYNAMIC MODEL BASED ON THE PHASE RULE

Although the 'Phase Rule' is valid for all chemical systems in equilibrium, only a handful of workers have used it to describe hydrated cement [2,8,9]. The rule states that the number of *phases* (P) plus the *degrees of freedom* (F) in a system is equal to the number of *components* (C) plus n . In the standard form n is equal to 2, but at constant temperature and pressure n can be reduced to 0, so that the phase rule becomes $P + F = C$.

The main components in hydrated Portland cement are CaO , SiO_2 , Al_2O_3 , Fe_2O_3 , SO_3 and H_2O .

The maximum number of phases that can form in the fully hydrated system (for the invariant assemblage where $F=0$) is, therefore, six. For a typical Portland cement these phases would be the C-S-H phase, portlandite, monosulfate, ettringite, an iron oxide phase (possibly FH_3) and the pore solution. From the chemical composition of the system, and standard chemical compositions of the individual hydrate phases, the contents of phases in wt. % within any invariant system can be calculated by solving 'n' equations for 'n' unknowns, where 'n' is the number of components and phases. As a first approximation the composition of the pore solution is set to that of pure H_2O . This is valid as long as the weight fraction of components dissolved is negligible compared to the weight fraction that has reacted to form solid phases.

The introduction of chloride and carbonate adds two extra components to the system allowing up to eight phases at constant temperature and pressure. At small additions of these components the two additional phases would normally be the AFm phases, monocarbonate, and Friedel's salt. For convenience, CaCl_2 , CaCO_3 , CaSO_4 and C_3A are chosen as components in this paper rather than Cl , CO_2 , SO_3 , and Al_2O_3 . This is valid as long as these components occur as stoichiometric units in all hydrate phases. The presence of sodium (or potassium) introduces a degree of freedom rather than an extra phase, except at very high concentrations, but this can be disregarded when the alkali content is held constant. When CaCO_3 and CaCl_2 (and additional CaSO_4) are introduced to the 6-component system for hydrated Portland cement, all of the changes in phase assemblages (except at very high contents) take place within the subsystem for C_3A - CaSO_4 - CaCl_2 - CaCO_3 . The other phases (i.e. C-S-H, $\text{Ca}(\text{OH})_2$, FH_3 , pore solution) occur as excess phases which participate in all phase assemblages, and as long as invariant conditions prevail remain constant in composition within any given assemblage. The 4-component sub-system C_3A - CaSO_4 - CaCl_2 - CaCO_3 is illustrated in Figure 1 by means of the two 3-component sub-systems for chloride attack (Figure 1a), and carbonate addition (Figure 1b).

Figure 1a. Sub-system for C_3A - $CaSO_4$ - $CaCl_2$ Figure 1b. Sub-system for C_3A - $CaSO_4$ - $CaCO_3$. Arrow schematises the change in phase contents with increased $CaCl_2$. Filled circles indicate initial composition for all three pastes examined (see table 2) before chloride addition.

The addition of $CaCl_2$ to an under-sulfated Portland cement consisting of hydroxy AFm and monosulfate shown in Figure 1a for the sub-system C_3A - $CaSO_4$ - $CaCl_2$ would initially form Friedel's salt. Further addition results in a depletion in the hydroxy AFm phase until it is eventually exhausted. Ettringite can only form at this point and continues to form alongside Friedel's salt with further addition of $CaCl_2$. In all, four different 3-phase assemblages are possible with increasing $CaCl_2$ contents. Four 3-phase assemblages are also possible in the C_3A - $CaSO_4$ - $CaCO_3$ shown in Figure 1b. By combining the two diagrams, addition of $CaCl_2$ to a system starting out with a mixture of monosulfate, hydroxy AFm and monocarbonate, should result in the sequence of five 4-phase assemblages shown in table 1.

Table 1. Predicted sequence of phase assemblages resulting from $CaCl_2$ addition to hydrated Portland cement with relative high $C_3A/CaSO_4$ ratio.

1.	Hydroxy-AFm, Monosulfate, Monocarbonate and Friedel's salt	Phases in excess: C-S-H, Calcium hydroxide, Goethite and Pore solution
2.	Monosulfate, Ettringite, Monocarbonate and Friedel's salt	
3.	Ettringite, Calcite, Monocarbonate and Friedel's salt	
4.	Ettringite, Calcite, Gypsum and Friedel's salt	
5.	Calcite, Gypsum, Friedel's salt, + degree of freedom (i.e. \uparrow of Cl in PS)	

According to the phase rule, no degrees of freedom are possible in assemblages 1 to 4 since each assemblage consists of eight components and the maximum number of phases (i.e. eight). An important constraint imposed by this invariance is that the composition of all phases must remain constant within each assemblage. However, once the total binding capacity is exhausted, i.e. when all the ettringite has reacted to form gypsum and Friedel's salt (assemblage no.5), only seven phases exist giving one degree of freedom. This degree of freedom would allow the $CaCl_2$ concentration to increase in the pore solution upon further addition, until it eventually becomes saturated with respect to $CaCl_2 \cdot 2H_2O$.

A CaCl_2 -binding isotherm for the sequence of reactions described above, at a constant level of alkalis, would be expected to develop as illustrated in Figure 2. The small increases in concentration of free chloride ions are the result of probable differences in the composition of the pore solution between assemblages.

Figure 2. Schematised development of a CaCl_2 binding isotherm in an invariant system.

Significantly, this hypothetical isotherm for CaCl_2 has not been reported in the literature. Instead, the relationship between bound and free chlorides is invariably described as a continuous curve best described by the Langmuir or Freundlich models [2,6]. This implies either non-equilibrium conditions, which in our view is unlikely, or solid solution between two or more phases. The latter would reduce the number of phases and, therefore, provide one or more degrees of freedom, which would allow the chloride concentration to increase in the pore solution as a function of the total chloride content in the system. In the absence of sulfate and carbonate, a likely candidate for this solid solution would be the hydroxy-AFm - Friedel's salt solid solution phase reported in [3]. In the presence of carbonate, a solid solution between monocarbonate and Friedel's salt has also been reported [10,11], and this, in our view, would be the most likely phase to occur in realistic systems which must always contain some carbonate. The possible solid solution of monocarbonate and Friedel's salt forms the basis of the model which is tested in this study.

3. EXPERIMENTAL

Three Portland cement pastes were examined: two white Portland cements with Bogue- C_3A contents of approx. 4 and 12%, and a grey ASTM type II Portland cement. All the pastes were prepared at a w/s ratio of 0.70 after replacement of the cement by 1.0 wt. % calcite (note that all of the cements already contain some CO_2 , present of course as carbonate). Compositions of the cements (determined by XRF) are shown in table 2.

Table 2. Composition of the Portland cements tested

Cement id.	SiO_2	Al_2O_3	Fe_2O_3	CaO	SO_3	MgO	Na_2O	K_2O	CO_2^*
WPC(4)	24.8	1.87	0.33	68.9	2.20	0.52	0.16	0.11	0.14
WPC(12)	23.6	4.49	0.21	65.9	2.38	0.97	0.03	0.20	0.72
OPC	21.0	4.90	3.64	65.1	3.00	0.89	0.30	0.41	0.08

* Determined by DTG.

Cement id.	C_3S	C_2S	C_3A	C_4AF
WPC(4)	72.2	16.8	4.4	1.0
WPC(12)	51.7	28.6	11.5	0.6
OPC	59.1	15.6	6.8	11.1

The cement pastes were cast in 2 cm³ centrifuge tubes, sealed and kept at a constant temperature of 20°C for one month. The samples were then de-moulded and crushed to between 2-4 mm in size. The crushed paste of approximately 8.25 g was then weighed before being placed in 12.5 ml. solution for 5 months at 20°C. For each type of cement paste, the specimens were exposed to solutions of increasing CaCl₂ concentration, allowing progressively higher degrees of reaction, but at a constant alkali content. WPC(4) was stored at a sodium concentration (by addition of NaOH) of either 250 or 550 mM, whilst the OPC specimens were stored at 550mM and the WPC(12) specimens at 250mM.

After six months when the pastes had fully reacted with the solutions to equilibrium, the phase equilibria was examined by a combination of EDS (Energy Dispersive Scanning, at 15keV, 25μA and measuring time of 40 s.) and XRD (X-Ray Diffraction) analysis. As well as analysis of the solutions by titration (chloride and pH), ICP (Inductively Coupled Plasma Atomic Emission Spectrometry), and AA (Atomic Absorption), for all major components after removal of the solid phases by filtration.

4. RESULTS AND DISCUSSION

The Al/Ca and S/Ca ratios were found by EDS analysis to be fairly constant in the C-S-H at approximately 0.40 and 0.30, respectively.

A combination of XRD and EDS analysis verified the sequence of phase assemblages 1, 2 and 3, listed in table 1, except that Friedel's salt and monocarbonate occurred in solid solution, instead of as two separate phases. As predicted, the initial assemblage to form at low contents of CaCl₂ in the paste prepared from the low C₃A white cement (WPC(4)), was ettringite + calcite + monocarbonate + Friedel's salt (assemblage no. 3 in table 1), or more correctly ettringite + calcite + AFm_{ss}, where the solid solution phase is a mixture of monocarbonate and Friedel's salt. The initial assemblage formed from the high C₃A white PC, (WPC(12)) corresponds to assemblage no. 2 in table 1. Assemblage no. 3 formed at higher concentrations. The initial assemblage formed at small contents of CaCl₂ in the paste prepared from the grey Portland cement (OPC) corresponds to assemblage no. 1 in table 1. Assemblage no. 2 followed by assemblage no. 3 formed at higher CaCl₂ contents for this cement. In no case was the content of CaCl₂ high enough to form assemblage nos. 4 and 5, although preliminary results not included here indicate that these assemblages form as well.

Solid solution was found between Friedel's salt and monocarbonate for all of the specimens examined. This is illustrated by plotting the Cl/Ca vs. Al/Ca ratios determined from EDS analysis shown in Figure 3. Only two data sets are plotted here, i.e. for the low C₃A white PC (WPC(4)) with Na = 550mM, at two different Cl contents. Figure 4 shows the same data, but plotted as S/Ca vs. Al/Ca. Since assemblage no 3 persisted at all chloride contents investigated for this cement, neither monosulfate nor Kuzel's salt were identified. Monosulfate was identified in assemblages 1 and 2 for the two other cements, where it invariably occurred as a pure phase without forming a solid solution with any of the other AFm phases.

XRD-patterns for the pastes examined confirmed the assemblages described above (not shown). For the AFm_{ss} phase, the same type of ordered stacking of layers of monocarbonate and Friedel's salt described in [11] was observed.

Figure 3. EDS-data illustrating the development of Cl/Ca in the AFm_{ss} phase between monocarbonate (MĈ) and Friedel's salt (FS) and in C-S-H, at increasing Cl additions.

Figure 4. S/Ca vs. Al/Ca from EDS analyses. Actual plots are the same as the presented in Figure 3.

The solid solution of Friedel's salt and monocarbonate introduces a degree of freedom to the system. This permits the relative content of Friedel's salt to increase in the AFm solid solution, along with a concomitant increase in the concentration of chloride ions in both the pore solution and in the C-S-H phase. The phase rule is satisfied as long as a single relationship exists for the distribution of Cl between all three phases regardless of C₃A and C-S-H contents. That such a relationship exists at constant alkali content for the two white cements can be seen in Figures 5 and 6 where, despite a marked difference in C₃A contents (as well as C-S-H contents due to the significant difference in C₃S contents in the clinker), almost exactly the same distribution is found between all three phases at the constant alkali content of 250 mM Na. Lower concentrations are found in the C-S-H phase and AFm_{ss} phase at the higher concentration of 550mM Na in the solution. The slight difference in binding in the AFm_{ss} and C-S-H phase between the white and grey cements is possibly due to the presence of iron in the grey cement which adds an extra degree of freedom to the system. The relationship between the concentration of Cl in the C-S-H phase and the AFm_{ss} phase (Figure 6), appears to be independent of the alkali content.

Figure 5. Cl/Ca ratio in the C-S-H and AFm_{ss} phases versus the concentration of chlorides in solution.

Figure 6. Cl/C ratio in the C-S-H versus the Cl/Ca ratio in the AFm_{ss} phase for all cements and alkali contents.

The above relationships apply to the distribution of chloride between the individual phases, but not to the ratio of total bound and free chlorides, since this will of course vary depending on cement composition (i.e. C₃A content etc.). This is clear from the traditional Cl isotherm shown in Figure 7 (for the same data used in Figures 5 and 6), where different isotherms clearly exist for the two white cements.

Figure 7. Chloride binding isotherms for the same data shown in Figures 5 and 6.

The above relationship can be understood more readily from the ternary subsystem shown in Figure 8 which is constructed from Figures 5 and 6. This diagram should apply to any Portland cement in which the concentration of Na in the pore solution is fixed at 250 mM. At higher alkali contents, concentrations of Cl (or Friedel's salt) in the AFm_{ss} phase and C-S-H phase will be lower for the same concentration of Cl in the pore solution. The same relationship should apply regardless of the relative content of C₃A, C-S-H, sulfate, carbonate and pore solution. The relationship can be used to calculate the overall binding capacity, i.e. the relationship between the free and bound chlorides, from the overall hydrate phase assemblage (which can in turn be calculated quantitatively from the chemical composition of the cement and water cement ratio as described above for the thermodynamic model).

Figure 8. Pseudo ternary system for 'C-S-H'-Friedel's salt-Monocarbonate at a constant Na concentration in solution of 250 mM. Solid tie lines and corresponding chloride concentrations were determined in this study. The dashed lines are extrapolated from this.

The above relationship predicts that for a given aluminate content, low sulfate contents and high carbonate contents should be beneficial to binding since both would effectively increase the content of monocarbonate and therefore lower the mole fraction of Friedel's salt in the AFm_{ss} phase. Lower contents of Friedel's salt in the AFm_{ss} phase are beneficial because they lower the concentration of Cl in the pore solution (and C-S-H phase). Sulfate that invariably accompanies chloride intrusion from sea water, effectively lowers the mole fraction of monocarbonate in the AFm_{ss} phase, increasing the mole fraction of Friedel's salt and the chloride concentration in the pore solution. The reduction in binding capacity caused by sulfate attack, however, can be mitigated by the presence of carbonates which have the opposite effect.

5. CONCLUSIONS

Solid solution between Friedel's salt and monocarbonate reported elsewhere has been confirmed for hydrated Portland cement containing 1% calcite and different contents of C₃A.

The relationship between free and bound chlorides is governed by this solid solution.

Chlorides are also bound by the C-S-H phase, with a well defined distribution of chloride between all three phases (i.e. the AFm solid solution phase, the pore solution and the C-S-H phase) at any given alkali content.

Higher alkali and sulfate contents reduce the binding capacity of hydrated Portland cement. Carbonates increase the binding capacity.

All these results can be predicted by applying the phase rule.

THE EFFECT OF 4 ALKANOLAMINES ON PORE WATER COMPOSITION AND STRENGTH DEVELOPMENT OF MORTAR

Paul J. Sandberg¹

¹ Grace Construction Products, Cambridge, MA, USA. E-mail: paul.j.sandberg@grace.com

ABSTRACT

The combined effect on cement hydration of adding 4 alkanolamines and soluble alkali and/or sulfate was studied for an undersulfated Portland cement, by means of pore solution analysis and compressive strength development at 1, 7 and 28 days. The results indicated some correlation between 7 and 28 day strength enhancement and iron solubilization, although 2 alkanolamines were able to enhance strength without any strong iron solubilization. 1 day strength enhancement did not correlate with soluble iron for any alkanolamine. A synergistic strength enhancing effect was found when the alkanolamines were combined with soluble alkali and sulfate. The results indicate that while iron solubilization seems important for strength enhancement after several days of hydration, other mechanisms may be important to explain the strength enhancing effect of the alkanolamines studied.

1. INTRODUCTION

The effect of 2 proprietary alkanolamines, referred to as CB 200 and CB 300, on EN 196 mortar strength development and iron solubilization, were studied and compared to the effects of Triethanolamine (TEA) and Triisopropanolamine (TIPA). TEA is the most basic alkanolamine, commonly used in grinding aids. TIPA is a proprietary alkanolamine used in the CBA® series of strength enhancing cement additives.

It has previously been shown that the alkanolamine TIPA, and to some extent TEA, has the ability to enhance the strength of hydrating cement [1]. The strength enhancing effect of TIPA has been linked to its ability to solubilize iron, and thus enhance the dissolution and hydration of anhydrous ferrite and hydrated iron compounds, which otherwise tend to block the strength-giving hydration of the silicate phases [2].

The purpose of this study was to conduct parallel studies of the pore solution chemistry on cement paste and strength development on mortar, both with and without the addition of soluble alkali hydroxide and alkali sulfate. The Portland cement used was ground to a Blaine surface area of 300 m²/kg in a laboratory ball mill, with added hemihydrate to a cement SO₃ of 1.65%. This represents the unusually low SO₃ in the commercial low alkali cement, which was known to be very responsive to TIPA.

The clinker chemistry is shown in Table 1, which includes XRF analysis of the clinker sample used and a QRDA analysis using Rietveld refinement on a sister clinker, produced at the same plant but at a different date.

Table 1. Clinker chemistry

2. EXPERIMENTAL

2.1 Preparation of mix water compositions

High dosages of alkanolamine, 200 ppm, were chosen to ensure that any changes in porewater chemistry were readily detectable. Note that 200 ppm alkanolamine is a 2-4 times higher dosage than usually required to achieve strength gains in industrial cement additive applications.

Additives were dissolved in mix water for EN 196 mortar and cement paste at water - cement ratio 0.50 using the following mix water solutions conditioned to + 10 °C, Table 2.

- Deionized water.
- 0.25 mol/l KOH (equivalent to addition of 0.3875 % soluble Na₂O eqv to the cement).
- 0.50 mol/l KOH (equivalent to addition of 0.775% soluble Na₂O eqv to the cement).
- 0.125 mol/l K₂SO₄ (equivalent to addition of 0.50% soluble SO₃ and 0.3875 % soluble Na₂O eqv to the cement).
- 0.25 mol/l K₂SO₄ (equivalent to addition of 1.0 % soluble SO₃ and 0.775 % soluble Na₂O eqv to the cement).

Table 2. Compositions of 25 mix water solutions (% and ppm by weight of cement)

Additive	KOH conc. Mol/l			K ₂ SO ₄ conc. Mol/l	
	None	0.25 mol/l	0.5 mol/l	0.125 mol/l	0.25 mol/l
Soluble Na ₂ Oeqv added	None	0.3875 %	0.775%	0.3875 %	0.775%
Soluble SO ₃ added	None	-	-	0.5 %	1.0 %
NONE					
TEA @ 200 ppm					
CB 200 @ 200 ppm					
CB 300 @ 200 ppm					
TIPA @ 200 ppm					

2.2 Preparation of cement paste for pore solution studies

Mixing was done using 100 g cement and 50 g mix water, using a commercial planetary mixer for 30 seconds initial mixing, followed by 30 seconds mixing using a high speed mixer at 3000 rpm. The cement paste was cured sealed in a container at room temperature until the ages: 30 minutes, 210 minutes, 28 hours, 7 days and 28 days. Pastes were kept rotating until set in order to avoid excess bleeding and segregation.

2.3 Pore solution expression and composition analysis

Pore solutions from cement pastes 30 minutes and 210 minutes old (before set) were collected by means of vacuum filtration. The pore solution expression method [3] was used for extraction of pore solution from hardened cement paste, Figure 1.

Figure 1. Pore solution expression device.

Following the pore solution extraction, 2.0 ml of filtered pore solution was immediately analysed for hydroxide ion concentration by titration with 0.1 mol/l HCl. Remaining filtered pore solution was immediately acidified to $\text{pH} < 4$ with a measured addition of HNO_3 (conc.) to avoid precipitation of the supersaturated pore solution.

ICP was used for the analysis of Fe, Al, Ca, Na, K and S in the expressed pore solution. It was assumed that all S was present as sulfate ions, because of the highly oxidising Portland cement environment. A total charge balance was computed for each pore solution analysed as a control of the validity of the results, using the ions Ca^{2+} , Na^+ , K^+ , SO_4^{2-} and OH^- (from hydroxide ion titration). The concentration of Fe and Al in solution is orders of magnitudes less than the alkali ions, and was therefore omitted from total charge balance computation. A deviation of 10% from the computed charge balance was considered acceptable, based on a pre-study involving triplicate mixes with 200 ppm TIPA and TEA added to plain portland cement. All data reported are from single measurements with less than 10% error in the computed charge balance.

2.4 Preparation and determination of compressive strength of EN 196 mortar

Mortar prisms of w/c 0.50 were manufactured for all mixes according to the European cement standard EN196. The compressive strength of EN196 prisms was determined after 1, 7 and 28 days hydration.

3. RESULTS

3.1 Pore solution analysis

The pore solution compositions for the blank cement are shown in Figure 2, at the hydration times 30 minutes, 210 minutes, 28 hours, 7 days and 28 days.

Figure 2. Pore solution composition of blank cement as a function of hydration time.

An example of the effect of soluble alkali sulfate on the pore solution composition is shown in Figure 3. 0.125 mol/l added potassium sulfate corresponds to 0.3875% soluble Na_2Oeq and 0.5% soluble SO_3 . Note the difference in scale in the y-axis.

The addition of a higher concentration of potassium sulfate or concentrations of potassium hydroxide generated very similar results as shown in Figure 3, and the data are not shown here. The effect of soluble alkali hydroxide and sulfate affected mainly the concentration of calcium, sulfate and hydroxide in the porewater as illustrated in Figure 4.

Figure 3. Pore solution composition of cement with 0.3875% soluble $\text{Na}_2\text{O}_{\text{eqv}}$ and 0.5% soluble SO_3 added as potassium sulfate.

Figure 4. Effect of adding soluble alkali hydroxide or sulfate on the concentration of calcium (left), sulfate (middle) and hydroxide (right) in the porewater.

The effect of alkanolamines on the pore solution composition was small with the exception for iron, as illustrated for of calcium, sulfate and hydroxide in the porewater in Figure 5.

Figure 5. Effect of alkanolamines on the concentration of calcium (left), sulfate (middle) and hydroxide (right) measured in porewater.

3.2 Iron in expressed pore solution

The effect of the alkanolamines on the solubility of iron is shown in Figure 6, for cement with and without addition of soluble alkali sulfate.

Figure 6. Effect of alkanolamines on the concentration of iron in the pore water. Cement with alkanolamine only (left), cement with alkanolamine and 0.3875% soluble Na_2Oeqv and 0.5% soluble SO_3 added as potassium sulfate (right).

3.3 EN196 mortar compressive strength

The EN196 mortar compressive strengths are shown in Table 3.

4. DISCUSSION

4.1 Effect of alkanolamines on soluble iron and strength enhancement

The iron solubilizing effect of the alkanolamines studied was shown in Figure 6. The strength enhancing effect was shown in Table 3. Unfortunately no air content measurements were done on the prisms, but simple aircup measurements on parallel mortar mixes indicated that in no case was more than 1% air entrained in the mortar as an effect of the alkanolamine. It was assumed that 1% air increase in mortar corresponds to 4% loss of strength. As the coefficient of variation was approximately 3%, a strength response of 7% or more can be considered significant.

Individual measurements of iron in porewater had a coefficient of variation in the order of several tens of percent. Nevertheless, the iron solubilization effect of alkanolamines TIPA, CB 200 and CB 300 was found to be far greater than the variability.

Figure 7. Correlation between strength enhancement and iron in porewater for the 4 alkanolamines. Note the differences in X-axis scale. A straight line indicates correlation between soluble iron and strength at 28 days. A dotted line indicates correlation between soluble iron and strength at 7 days. In no case was correlation found between soluble iron and strength at 1 day.

Figure 7 shows the correlation between strength enhancement and iron in porewater at 1, 7 and 28 days. All data for 0.25 mol/l K_2SO_4 added = 0.775 % soluble Na_2O_{eqv} and 1.0 % soluble SO_3 was excluded because of signs of strength loss caused by exceeding optimum SO_3 .

The strong iron solubilizing alkanolamines TIPA and CB 300 showed relatively strong correlation between iron in porewater and strength enhancement at 28 days, as expected. The weaker iron solubilizing alkanolamines TEA and CB 200 showed poor correlation between iron in porewater and strength enhancement. However, CB 200 demonstrated significant strength enhancement also at 7 and 28 days in spite of less iron solubilizing effect as compared to TIPA. Thus it seems probable that iron solubilization, while clearly important, is not the only mechanisms responsible for 7 and 28 days strength enhancement in this study.

It is worth noting that TEA and CB 200 are stronger 1 day strength enhancers but also weak iron solubilizers as compared to TIPA and CB 300. Thus it appears that there is no correlation between the additives' ability to solubilize iron and the early strength enhancement. A possible explanation is that sulfate ions also solubilize iron, thus diminishing the solubilizing effect of the additive until all soluble sulfate has been consumed by the cement hydration.

Addition of soluble alkali or alkali sulfate both resulted in an increased hydroxide concentration in the pore solution, Figure 4. This was expected as sulfate binds into hydrates and release hydroxide. The addition of soluble alkali or sulfate and alkanolamines seem to have synergistic effects on the concentration of iron in expressed pore solution, Figure 6. Furthermore, as seen when comparing Table 3 and Figure 6, the synergistic effect of alkali and iron solubilization also resulted in higher relative strength enhancing effects of the alkanolamines at 28 days. The synergistic effect was predominant for TIPA, CB 200 and CB 300 for all alkali additions except for the highest level of alkali sulfate, which might have been the effect of exceeding the optimum SO_3 .

5. CONCLUSIONS

The combined effect on cement hydration of added 4 alkanolamines, and soluble alkali and/or sulfate was studied, for an undersulfated Portland cement by means of pore solution analysis and compressive strength development at 1, 7 and 28 days. The results indicated some correlation between 7 and 28 day strength enhancement and iron solubilization, although 2 alkanolamines were able to enhance strength without any strong iron solubilization. 1 day strength enhancement did not correlate with soluble iron for any alkanolamine. A synergistic strength enhancing effect was found when the alkanolamines were combined with soluble alkali and sulfate.

The results indicate that while iron solubilization seems important for strength enhancement after several days of hydration, other mechanisms may be important to explain the strength enhancing effect of the alkanolamines studied.

ACKNOWLEDGEMENTS

The clinker used was kindly provided by Lafarge at Lichtenberg, South Africa. The experimental work was carried out in Sweden under a research agreement with Cementa Research, Sweden.

ABSTRACT

China is now the leading manufacturer and user of expansive agents (EA) for concrete. The most extensively used EA in China belongs to the ettringite type, which is manufactured with sulphoaluminate and aluminate clinkers made from high-grade bauxite and burnt at high temperatures. The aim of this research is to explore using low-grade bauxite for EA making, which is calcined at low temperatures. The bauxite expansive agent (BEA) consists of calcined bauxite and calcium sulfate. The physical properties of BEA + Portland Cement (PC) pastes show that the pastes expand sufficiently for shrinkage-compensating purposes. The properties of bauxite, calcined at 950°C can be significantly improved by mixing with alunite or by adding lime. The expansion and compressive strength of BEA expansive pastes are mainly affected by mineral and chemical compositions, the calcining regime of the bauxite as well as the type, content and fineness of the calcium sulfate. The environmental significance of utilising low-grade bauxite not only reduces the cost, but also improves concrete durability by lowering the heat generated by hydrating cement and the amount of calcium hydroxide in hardened cement paste. Results of semi-quantitative XRD and SEM microanalysis confirm that most of the SO₃ from calcium sulfate and Al₂O₃, SiO₂ from calcined bauxite enter the C-S-H gel. It is suggested that the C-S-H with considerable amount of Al₂O₃ and SO₃ is the major hydrate causing expansion.

1. INTRODUCTION

China is the largest producer and user of expansive agents for concrete (EA): more than 300 000 tons of EA are produced and about 8 million cubic meters of shrinkage-compensating concrete is used every year. Shrinkage compensating concrete is made by mixing 8-15% EA (of the PC component) with Portland Cement, sand and gravel and is used to reduce cracks and leakages in buildings and other structures.

Shrinkage compensating concrete^[1] is mainly used in:

- Structural self-waterproofing for base-plates of large structures, basements of high-rise buildings, airports, subways, tunnels, railway stations, etc.
- EA strengthened zones substitute for post-filled joints of extra long structures, continuous placing is carried out so that the construction period is significantly reduced.
- Crack control for structural mass concrete (C40 to C60). The addition of EA compensates for drying shrinkage and contraction shrinkage.
- Roof waterproofing.

More than ten different types of expansive agents, including united expansive agent (UEA), composite expansive agent (CEA) and aluminate expansive agent (AEA) have been developed in China. These EA's consist mainly of expansive clinkers with different mineralogical compositions and CaSO₄. The expansive clinkers containing sulphoaluminate or aluminate are made by burning raw meal mixes with different compositions at about 1350°C. In this research, bauxite, heated to

relatively low temperatures is used to replace expansive clinkers for making EA. The results obtained show that this is feasible. The dehydration of bauxite and its hydration reaction in an expansive cement system are discussed in the paper.

MATERIALS AND EXPERIMENTAL

Bauxite from seven different origins (B1-B7, Table 1) was heated at 800°C for one hour and then ground in a small agate ball mill.

Two modified bauxites were also made:

M1, a mixture of ground burnt B2 and ground alunite (A, Table 2) with B2: A = 2: 1;

M2, a ground mixture of B2 and reagent CaCO₃ (B2: CaCO₃ = 2.3: 1) fired at 950°C for 2.5 hours.

Anhydrite (G1, Table 2) or gypsum (G2) or phosphogypsum (G3) is used as a source of CaSO₄ to make bauxite expansive agent (BEA) with G1 (or G2, G3): calcined bauxite (or modified bauxite) = 1: 1.

The fineness of the BEA's is 8% retained on a 0.08mm sieve. Expansive cements were made of Portland Cement and BEA (PC : BEA = 10 : 1).

Table 1. Chemical and mineral composition of bauxites

Code	Origin	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	TiO ₂	LOI	Minerals*	Appearance
B1	Mixian	27.95	43.83	8.19	0.92	0.81	1.42	15.04	K-ms; Py-mr; D-m; I-l	Black, firm
B2	Mixian	5.79	72.38	1.61	0.50	0.60	3.60	14.58	D-ms; K-mr; P, A-l	Black earth-like, loose
B3	Dengfeng	18.93	61.17	1.55	0.84	0.84	2.56	13.40	D-ms; K-m; P, M, A-l	Gray, firm
B4	Dengfeng	27.73	48.95	1.73	0.50	1.20	2.11	12.24	D-ms; K-mr; M-m; P, A-l	Pale gray with brown, loose
B5	Lincheng	31.90	45.84	4.32	1.80	0.52	1.31	13.39	D-ms; K-mr; P-l	Pale brown
B6	Yangquan	6.81	69.33	2.36	2.01	SO ₃	1.32	15.19	D-ms; K, Q-l	Earth-yellow
B7	Jiyuan	44.16	37.75	1.91	0.45	0.87	1.40	12.42	K-ms; P-m; M, C-l	Pale gray with red-brown, loose
