The reference PC used, was Jidong P·II 525 cement which contains 1.97% SO₃, 1.14% K₂O and 0.18% Na₂O, its strength approximates that of the 42,5 strength class of ENV 197-1:1995. The free expansion magnitude was determined using specimen prisms 7×7×50 mm with steel studs at both ends for measuring). The compressive strength was determined (specimen cubes 20×20×20 mm) using neat paste for the above prepared expansive cements. W:C for neat paste was 0.30.

Specimens were kept in their moulds for one day in a moisture cabinet at 20°C. Immediately after demoulding, the initial length was determined using a 50-75mm outer diameter micrometer, and then the specimens were stored in a water tank at 20°C. The lengths of the prisms were then measured at the pre-determined intervals. Comparison tests of specimens made with materials from different origins, varying quantities and different degrees of fineness of calcium sulphate were also carried out.

The bauxites used were examined by XRD and DTA, using the RIGAKU D/MAX-A diffractometer and the RIGAKU TA 100 DTA/TG thermal analyzer.

To investigate the BEA expansive cement hydration, three series specimens of neat paste (20×20×20 mm cubes) were prepared for each series:

- #0 (9% anhydrite + 91% P·II525 cement);
- #B6 (6% calcined B6 + 9% anhydrite + 85% P·II 525 cement);
- #B7 (6% calcined B7 + 9% anhydrite + 85% P·II 525 cement).

Cubes were removed from the curing water after 1, 3, 7, 14 and 28 days. These were crushed to < 5mm grains, immersed in absolute alcohol to stop hydration, ground to completely pass a 45μm sieve and then dried in a vacuum of 160 mm Hg (absolute pressure). The dried samples then were mixed with 10% of silicon powder (internal standard) for XRD semi-quantitative analysis.

Cubes hydrated for 90days, were fractured and carbon-coated for observation under the KYKY AMRAY 1000B SEM with TN5500 series-II EDXA.

3. RESULTS AND DISCUSSIONS

3.1 Activation of Bauxites

Chinese bauxites contain diaspore, kaolinite, pyrophyllite, muscovite, illite, chlorite, rutile, anatase, iron ores, etc. and have little pozzolanic reactivity. The chemical and mineral compositions for bauxites B1-B7 are given in Table 1 and this shows that diaspore and kaolinite are the most prominent minerals in bauxite. Heating is an effective means to activate bauxite. Figure 1 shows DTA curves up to 1000°C for seven bauxites. The largest endothermic peaks on each curve in the temperature range 508 to 530°C are caused by removing structural water from diaspore and kaolinite:

Figure 1. DTA curves for B1-B7 bauxites

The exothermal peaks in the 940-1050°C range on each curve are due to the phase transformation of metakaolinite to silica-alumina spinel^[2]:

Therefore, for the purpose of activation, the calcination temperature must not exceed 900°C (generally 750°C is used). The approximate amount of kaolinite in the bauxite can be estimated by

examination of the exothermic peak at about 950°C. Thus bauxites B1 and B7 contain more kaolinite. The blunt and small endothermic peak at 520°C in curve B1 is attributable to the exothermic effect of pyrite oxidation. Other than diaspore and kaolinite, paragenetic pyrophyllite, muscovite, illite and goethite will lose crystal water during heating: the 605-680°C endothermic peaks in curves B2, B3 and B5 are due to dehydration of pyrophyllite, and the endothermic peaks at 160°C and 330°C in curve B7 are due to losing water from illite and clinocllore respectively. Dehydrated products metakaolinite, α -Al₂O₃ and other aluminosilicates have pozzolanic reactivity. Another means to activate bauxite is heating bauxite with addition of limestone at 950°C and the XRD confirms the formation of active mineral C₁₂A₇ through reaction of CaO from decarbonation of CaCO₃ with Al₂O₃ and Al₂O₃·2SiO₂ from calcination of bauxite [3].

Table 3. Free expansion magnitude and compressive strength of expansive neat pastes¹

¹ Specimens with moulds cured in a moisture cabinet at 19°C for one day, after demoulding they are stored in water at 13°C;

² B2A consists of 66.7% calcined B2 and 33.3% alunite;

³ B2C made by burning a mixture of B2 and CaCO₃ (B2:CaCO₃ = 2.3:1) at 950°C for 2.5 hours.

3.2 Free Expansion and Compressive Strength of three types of BEA

The neat paste of pure Portland Cement expands marginally (Table 3, 0).

With the addition of 10% BEA of the PC mass, the free expansion of expansive cements 1-5 (Table 3) increases significantly, the compressive strength at 3d decreases, however it increases at 7d and 28days.

With the addition of 16.7% alunite of the PC mass (M1, Table3), the expansion and compressive strengths are increased, because SO₄²⁻ and Al(OH)₄⁻ can dissolve out of alunite KAl₃(SO₄)₂(OH)₆ and react with Ca(OH)₂ to form ettringite.

The expansion and compressive strength for lime-combined expansive cement (M2, Table 3) are also significantly improved, since C₁₂A₇ in B2C reacts with CaSO₄, Ca(OH)₂ forming ettringite.

It is interesting to note that the physical proprieties of expansive cements No.4 and No.5, which were made from low grade bauxites B4 and B5 with the Al₂O₃ content below 50%, are better than those of the No.2 cement which was made from a high grade bauxite with an Al₂O₃ content of 72.4%.

3.3 Effect of Species, Content and Fineness of CaSO₄ as well as Fineness of Calcined Bauxite

3.3.1 Effect of anhydrite, gypsum and phosphogypsum

In Figure 2, G1, G2 and G3 denote the free expansion for BEA expansive pastes with addition of anhydrite, gypsum and phosphogypsum respectively, and S1, S2 and S3 the compressive strength for the pastes with anhydrite, gypsum and phosphogypsum. Figure 2 shows that specimens with addition of phosphogypsum (G3) have the largest expansion and those with gypsum (S2) have the largest compressive strength. The free expansion of anhydrite (G1) exceeds that of gypsum (G2) after 14d. The three types of CaSO₄ are all suitable as a main component for BEA.

Figure 2. Effect of species of CaSO_4

3.3.3 Effect of anhydrite content

The effect of anhydrite content 40 in Figure 3 means that BEA consists of 60% calcined B4 (fineness 10%) and 40% anhydrite (fineness 6%). The 50 and 60 mean 50% and 60% addition of anhydrite to BEA, E represents free expansion and R compressive strength. Figure 3 indicates that, with an increase of anhydrite content, the free expansion increases and the compressive strength decreases.

Figure 3. Effect of anhydrite content

3.3.4 Effect of anhydrite fineness

The BEA used for this test consists of 40% calcined B4 and 60% anhydrite. Figure 4 shows that the specimens with coarser anhydrite (10E, 0.08mm sieve residue 10%) have larger free expansion compared to those with finer anhydrite (6E, fineness 6%), the compressive strength is not significantly influenced.

Figure 4. Effect of anhydrite fineness

3.3.5 Effect of fineness of calcined bauxite

The BEA used for this test consists of 40% calcined B4 and 60% anhydrite. Figure 5 demonstrates that the fineness of calcined bauxite (fineness 5% and 10%) does not have marked effect on physical properties of expansive cement within bauxite fineness range tested.

Figure 5. Effect of calcined bauxite fineness

Figure 6. XRD powder patterns for anhydrous and hydrated #B6 expansive cement: E=ettringite, C=calcium hydroxide, U=anhydrite, a= α - Al_2O_3 , A=alite, B=belite & S=silicon powder (reference).

3.4 Hydration of BEA Expansive Cement

3.4.1 Hydration products

The hardened cement pastes of BEA expansive cements #0, #B6 and #B7 at various ages were examined by XRD. The XRD powder patterns for hydrated #B6 in Figure 6 indicates main crystalline hydration products CH (4.91Å) and ettringite (9.81 Å) as well as the consumption of anhydrite (3.478Å), alite, belite and α - Al_2O_3 (2.083 Å) dehydrated from diaspor

The relative quantities of CH, ettringite and remaining anhydrite are based on measuring peak heights in X-ray powder patterns. Figure 7 shows these plotted against curing time.

The results in Figure 7 confirm that with the addition of calcined B6 and B7, less anhydrite (Figure 7A) and less CH (Figure 7B) is found in cements #B6 and #B7 when compared with cement #0 without calcined bauxite. This indicates that hydration products α - Al_2O_3 and metakaolinite of bauxite participate in the hydration reaction. It is surprising that the ettringite formed in #B6 and #B7 cement pastes is less than that in #0 paste (Figure 7C); this implies that the α - Al_2O_3 and metakaolinite are not involved in the formation of ettringite. De Silva and Glasser^[4] reported metakaolinite to react with $\text{Ca}(\text{OH})_2$ forming C-S-H, C_4AH_{13} , C_2ASH_8 and in presence of calcium sulfate forming ettringite. Data by EDXA microanalysis^[3] show that C-S-H formed in #B6 and #B7 pastes contain considerable amount of Al_2O_3 and SO_3 , which apparently come from calcined bauxite, anhydrite, C_3A and C_4AF .

Figure 7. Relative quantity of remaining anhydrite(A) $\text{Ca}(\text{OH})_2$ (B) and ettringite(C) formed versus curing time

3.4.2 Morphology of hydration products

SEM secondary electron images of the #B7 paste hydrated for 90d show an earth-like matrix C-S-H gel with varying Al_2O_3 and SO_3 contents (see Figure 8A; 64 and 65 are unhydrated calcium silicates). Large clusters of piled $\text{Ca}(\text{OH})_2$ plates are sometimes observed (Figure 8B). Occasionally hydrating calcined bauxite grains are seen: Figure 8C shows an oolitic grain with surrounding amorphous hydrate; Figure 8D shows a smaller metakaolinite grain with its rim of C-S-H containing 16.5% Al_2O_3 and 8.7% SO_3 . Ettringite crystals consisting of 8-10 μm needles and rods are seldom seen.

3.5 Mechanism of Expansion

Is all the SO_3 released from the anhydrite and the PII 525 cement combined in ettringite? A rough calculation can answer this question.

According to the peak height of the 9.81 \AA diffraction line, the estimated ettringite content in hydrated cement at 28d is about 8% at most referred to anhydrous cement (the same below; for typical OPC pastes, the maximum ettringite formed is 7-11% (as determined by LOI). The 3.5% of SO_3 released from anhydrite at 28d (estimated on Figure 7(A)); in addition, 1.7% of that released from PII 525 is 5.2%. Therefore, the SO_3 entering the ettringite phase is about 31% ($1.6/5.2 \times 100\%$), i.e. more than half of the SO_3 released from the anhydrite in the PC enters the C-S-H.

This result is in agreement with the estimation by Taylor ^[5].

Figure 8. Secondary electron images of B7 expansive cement paste hydrated for 90d

A number of hypotheses have been proposed to explain the cause of expansion, the important ones are as follows:

- (a) directed or anisotropic growth pressure of crystals, e.g. ettringite, CaO and MgO formed through topochemical reaction^[6] or through solution;
- (b) absorbing water by the negatively charged colloidal ettringite^[7] or cement gel^[8];
- (c) expansion due to osmotic phenomena^[9].

As known from section 2.4.1, only a small amount of ettringite crystallizes in hardened BEA expansive cement and large amounts of C-S-H gel with rich Al_2O_3 , SO_3 forms and this appears to play a major roll in producing expansion. The backscattered electron images show the expansive nature of the inner product of C-S-H with appreciable quantity of Al_2O_3 , SO_3 formed during early heat treatment of a Portland Cement mortar ^[10]. There is additional evidence for the expansive properties of C-S-H- $\bar{\text{S}}\text{-A}$: In the hydration of C_3S , C-S-H grows directly over the C_3S surfaces; the hydration of cement differs, in that a space develops between the C-S-H shells and the anhydrous clinker particles. i.e. the C-S-H shells expand since the C-S-H shells formed during cement hydration contain a certain amount of Al_2O_3 , SO_3 .

Further studies are required to understand the essentials of the C-S-H- \bar{S} -A expansion.

4. CONCLUSIONS

Based on the results obtained the following points are concluded:

- Expansive cements with calcined bauxites and modified bauxites have a free expansion of 0.06 to 0.09% at 3 days (0.02% for PC without BEA), 0.13 to 0.21% at 28 days (0.06% for PC without BEA). Thus the use of calcined bauxite or modified bauxite for EA manufacture is possible.
- The suitability of calcined bauxite for making EA is related to its chemical and mineralogical composition. Low-grade bauxite with rich kaolinite is as good as the high-grade bauxite with rich diaspoire.
- Calcined bauxite, increases expansion at all ages, after three days the compressive strength exceeds that of PC by about 30%. The modified bauxites are activated on account for alunite (M1, alunite releases SO_4^{2-} and $\text{Al}(\text{OH})_4^-$) and lime-added C_{12}A_7 (M2), and can increase 3 day and 7 day expansions and compressive strength at all ages by about 30% when compared to PC.
- Anhydrite, gypsum and phosphogypsum are the main components of EA for expansion. Phosphogypsum produces the largest free expansion with the lowest 3 day and 7 day compressive strengths among the three calcium sulfate materials.
- With an increase of anhydrite content in BEA, the free expansion of the BEA expansive cement pastes increases whilst their compressive strength decreases. The BEA expansive cement pastes with the coarser anhydrite have larger free expansion compared with those with finer anhydrite. The fineness of calcined bauxite does not have a marked effect on the physical properties of expansive cements.
- The results of XRD and SEM microanalysis indicate that in BEA expansive cement pastes, only a small amount of ettringite forms. Most of the Al_2O_3 and SiO_2 released from calcined products ($\alpha\text{-Al}_2\text{O}_3$, metakaolinite) of bauxite and SO_3 released from calcium sulfate are combined in C-S-H formed during the hydration of C_3S and C_2S . The sulpho-aluminous C-S-H (C-S-H- \bar{S} -A) has expansion potential. It is suggested that C-S-H- \bar{S} -A is the major hydrate to cause the expansion BEA expansive cement.

HYDROGEL PROCESS - A NOVEL PROCESS FOR LOW TEMPERATURE CLINKERISATION

M.V. Karandikar, S.A. Khadilkar and R.M. Cursetji

The Associated Cement Cos. Ltd., Research and Consultancy Directorate, CRS Complex, L.B.S. Marg, Thane 400 604, India, E-mail: rd3@bom3.vsnl.net.in

ABSTRACT

The Research and Development Division of the Associated Cement Cos. Ltd., India had pursued a comprehensive programme on bulk usage of fly ash. Considering the chemistry of low lime Class-F Indian Fly ashes, one approach, which was successfully attempted at the author's laboratory, was development of a process route (Hydrogel Process) of clinkerisation based on the fundamental principle of fly ash activation.

The Process involves activation of fly ash with alkali under non-hydrothermal conditions. The activated fly ash is reacted with Hydrated lime/ Limestone in predetermined proportions to produce the calcium silicate / aluminate hydrate gels, which are de-watered, dried and sintered at 800-1350°C to produce the cement clinker. The sintering temperature depends on the type of cementitious system intended (Cementitious binder / Belite rich or Alite rich cement) to be produced. The process makes it possible to use about 20-50 % fly ash.

The authors have also attempted to evolve the possible mechanism of phase formation in the hydrogel process, through studies on microstructure and mineralogy of the calcined material at periodic intervals of temperature.

The paper also illustrates the experimental data generated on the compositional parameters and the compressive strengths of neat cements and its behavior in a sulphate environment for cementitious binder, indicating this cementitious binder to have more sulphate resistance than the conventional Portland cement.

Keywords: Hydrogel, Alkali activated fly ash, Reactivity, Clinkerisation

1. INTRODUCTION

In India approximately 95 million tonnes per annum of fly ash is generated from the thermal power plants. Disposal/utilization of these fly ashes is a major issue. It is a challenge to the Research Scientists to convert these fly ash into suitable products. The Research and Development Division of The Associated Cement Companies Limited have been pursuing several approaches for converting fly ash to suitable value added products. One of such approaches investigated in detail was conversion of fly ash (Class-F) to cementitious products through the Hydrogel Process of clinkerisation^[1,2]

The Hydrogel is based on alkali activation of the low lime class – F fly ash. The alkali activated fly ash is reacted with hydrated lime (the proportion of the hydrated lime depends on the type of cementitious system to be produced) to produce the Hydrogel (a gelated mass-produced having

calcium silicate and calcium silicate-aluminate hydrates). The hydrogel on calcination/sintering (temperature dependent on the type of cementitious system to be produced) produces the sinter/clinker, which on intergrinding with gypsum produces the cement/ cementitious binder. The process makes it possible to use about 20-50 % fly ash.

The paper discusses the mechanism of the hydrogel process of clinkerisation indicating the observed mineralogical and micro-structural changes in the hydrogel during the thermal processing. The hydrogel compositions can be tailor made to produce either (i) Low temperature Cementitious Binder or (ii) Belite or Alite rich Ordinary Portland cement Clinker.

The paper presents the optimized composition of the hydrogels, temperature of calcination / sintering of these cementitious systems discussing in detail the hydraulic properties of the resultant cements / binder.

1.1 Hydrogel Process – Mechanism

The possible mechanism^[3] of the hydrogel process is summarised below:

- The alkali reacts with quartz converting to glassy silicates
- Amorphous alumino- silicates of fly ash react to form sodium alumino- silicate hydrates
- When the alkali activated fly ash is suspended in water the meta stable glassy phases are partially solubilised thus producing zeolitic hydrophilic sites with Na^+ ions which act as cation exchangers
- On addition of Hydrated Lime, the Ca^{++} ion gets exchanged forming Calcium Silicate - Aluminate Hydrates, the sequence of reactions can be represented as:

Similar reactions would be expected to occur with the aluminates

The processing steps of the Hydrogel process are schematically represented in Figure 1.

The chemico-mineralogical composition of fly ash and hydrated lime used for Hydrogel preparation is given in Table 1. The mineralogical changes produced in fly ash on activation are shown in Figure 2.

Table 1. Chemico-mineralogical composition of fly ash and hydrated lime

1.2 Mineralogical and Microstructure Characteristics of Hydrogel during Thermal Processing

1.2.1 Dried hydrogel and hydrogel fired at 600⁰ C

- The content of Calcium - Silicate - Aluminate Hydrates (of Hydroglosular series C_3AH_6 , $C_3AS_2H_2$ etc.) along with its crystallinity increases as the gel is heated to 600⁰ C
- The calcite /Calcium hydroxide contents decreases

The morphological and microstructural features are similar except that the gel fired at 600⁰ C shows a greater degree of interlinking and cross linking with higher compaction of the spherical/aggregated grains of the dried gel (Figures 3 (a) and 3 (b)).

Figure 3 (a). SEM Photomicrograph of dried Hydrogel

Figure 3 (b). SEM Photomicrograph of Hydrogel showing Interlinking and Cross linking of spherical grains

1.2.2 Hydrogel fired at 700⁰ C and 800⁰ C

- The content and crystallinity of the Calcium-Silicate-Aluminate Hydrates (C-S-A-H) increases indicating crystallisation of the Hydrates from its amorphous precursors in Hydrogel
- Further decrease in calcite /Calcium hydroxide contents
- Further inter-linking and cross linking of the spherical / aggregated grains is observed
- Microfine β -C₂S grains are observed which are compacted , inter-linked and crosslinked similar in habit to their (C-S-A-H) precursors (Figure 3 (c))

The changes up to 800⁰ C are in hydrogel compositions for Low temperature Cementitious Binder system. The thermal changes in hydrogel compositions for Belite rich and alite rich Ordinary Portland Cement clinker are summarised below:

1.2.3 Hydrogel fired at 900⁰ C and 1000⁰ C

- The calcium - silicate -Aluminate Hydrate (C-S-A-H) decreases from 900⁰ C to 1000⁰ C, till at 1000⁰ C it is absent. This disappearance of the hydrates is also substantiated by the loss observed at 900 - 950⁰ C
- Appearance of C₂S and C₂AS phases at 900⁰ C and an increase in their contents at 1000⁰ C

1.2.4 Hydrogel fired at 1100⁰ C and 1200⁰ C

- The C₂AS phase decreases from 1100⁰ C to 1200⁰ C till at 1200⁰ C it is absent.
- Presence of C₃S and C₃A is observed along with increased C₂S contents at 1100⁰ C
- At 1200⁰ C the microstructure depicts well formed clinker phases.

1.2.5 Hydrogel fired at 1300⁰ C and 1350⁰ C

- Further increase in phase formation (C₃S and C₃A) (Figure 3 (d))
- At 1350⁰ C the clinker shows well crystallized cement clinker phases with α form of belite, the aluminates are coarsely crystallized and lathic in shape. The clinker is observed to be porous.

Figure 3 (c). SEM Photomicrograph of microfine β -C₂S grains

Figure 3 (d). SEM Photomicrograph of well formed Clinker phases

The mineralogical changes during the thermal processing are summarised in Figure 4.

2.1 Reactivity and phase formation during sintering

The reactivity (lime combining ability) of the hydrogel at different temperatures was compared with raw mix prepared from fly ash (unactivated) and hydrated lime. The two mixes were fired at different temperatures from 600 - 1350°C at intervals of 100°C and a retention time of 20 minutes at each temperature. The fired samples at each temperature were analysed for free lime to assess the degree of reaction. The plot of free CaO v/s temperature of the mixes is shown in Figure 5. The results indicate a substantially improved reactivity of the hydrogel compositions.

Figure 5. Comparative Reactivity of Hydrogel Mix and Fly Ash +Lime Mix

2.2 Preparation and Characterisation of clinkers

Using the Hydrogel process clinkers were produced at pilot scale level. The optimum compositional parameters of the alite rich and belite rich clinkers are as follows:

	LSF	SM	AM	POTENTIAL PHASES			
				C ₃ S	C ₂ S	C ₃ A	C ₄ AF
CLINKER – I (Belite Clinker)	0.80	1.98	3.3	8.1	60.9	19.4	8.3
CLINKER – II (Alite rich Clinker)	0.90	2.27	1.47	45.2	31.2	8.9	12.4

Clinker – I (Belite Clinker) and Clinker – II (Alite rich Clinker) were prepared from the hydrogel prepared from alkali activated fly ash. The microstructure of the clinkers is presented in Figures 6 (a) and 6 (b).

Figure 6 (a). Photomicrograph of Clinker – I showing well developed C₂S

Figure 6 (b). SEM Photomicrograph of Clinker– II showing well developed C₃S

The clinkers were co-ground with gypsum in a laboratory ball mill to cements with a fineness of 320 m²/Kg and SO₃ content of 2.7%. The physical properties of cements are given in Table 4.

Table 4. Physical Properties of Cements (Indian Standards)

Physical tests	Belite rich Cement	Alite rich Cement
Blaine's Specific surface (M ² /Kg)	320	320
SO ₃ (%)	2.7	2.6
Consistency (%)	28.3	25.6
Setting Time(mins.)

3.1 Effect of Aggressive Environment on the Cementitious Binder^[4,5]

Mortars prisms were cast with cementitious binder and were cured by immersing in the aggressive solution (0.5M Na₂SO₄+ 0.5 M NaCl solution) after 2 days of hydration in de-mineralised water, and after 3, 7 and 28 days of hydration they were tested for compressive strengths and flexural strengths.

- X-ray diffraction analysis by Philips X'pert MPD
- Chloride and sulphate content of the Outer coat and inner cores of the prisms were analysed by conventional methods.
- SEM analysis of the fractured surface of the mortar prisms cured at 28 days in water and in aggressive environments was carried out on a Jeol JSM 5400 microscope.
- Pore size distribution of the hydrated mortar cubes cured at 28 days in water and the aggressive environment was determined by Hg porosimeter.

3.1.1 Effect of sulphate + chloride solution on cementitious binder mortar

The flexural and compressive strengths of the mortars cured in de-mineralised water and the aggressive environment are graphically shown in Figures 9 and 10.

Figure 9. Flexural strength of Cementitious Binder mortar in water and aggressive environment

Figure 10. Compressive strength of Cementitious Binder mortar in water and aggressive environment

The outer coat of prisms were cut at a distance of 1 cm along all the faces and the averaged outer coat along with the central core was tested for sulphate and chloride concentration and compared with that of the prisms cured in de-mineralised water. The results are tabulated in Table 6.

Table 6. Sulphate and chloride content of the mortar prisms

	3 days Hydration		7 days Hydration		28 days Hydration	
	In Aggr. environment		In Aggr. environment		In Aggr. environment	
	% SO ₃	% Cl	% SO ₃	% Cl	% SO ₃	% Cl
Av. External Coat of all faces of the prism	1.5	0.09	1.5	0.10	1.5	0.09
Core	1.7	0.06	1.6	0.08	1.6	0.06

The SEM photomicrographs showing the hydrated microstructure ^(6,7) of the mortars cured in water and in aggressive environment at 28 days are shown in Figures 11 (a) and 11 (b).

(a) Cured in de-mineralised water

(b) Cured in aggressive medium

Figure 11. Microstructure of the Cementitious binder mortars cured in water and in aggressive medium showing compacted microstructure

The studies indicate that

- Considering the sulphate contents of the cement in the mortars, the SO₃ contents of the mortars is marginally more and it increases with age of hydration in the aggressive medium. The chloride levels in mortars are more or less constant with age of hydration indicating that the diffused chloride in the pore solution is in equilibrium with the curing solution and with age the penetration of chloride seems to have been hindered indicated by precipitation of traces of chloride based compounds in pores at 28 days.
- The XRD of the cementitious binder clinker shows amorphous contents along with C₂S, C₃A, calcium hydroxide, calcite and α -quartz, hydrated mortars in water shows formation of Ettringite Ca₆Al₂(SO₄)₃(OH)₁₂·26H₂O, Hillbrandite (C-S-H) and Hydroglossular Ca₆Al₂(SiO₄CO₃OH)₃ with lesser intensities while in aggressive medium the mortars show much higher levels of these phases along with traces of Hydrocalumite (Ca₄Al₂O₆Cl₂·10H₂O)

- Due to interaction of the water soluble sulphate from the aggressive medium in presence of sodium ions present in the cementitious binder, there is gradual increase in the compaction i.e. decrease in the porosity of the mortar prisms from 7 days to 28 days, this is attributed to the accelerated formation of Ettringite $\text{Ca}_6\text{Al}_2(\text{SO}_4)_3(\text{OH})_{12} \cdot 26\text{H}_2\text{O}$ and Hydroglossular $\text{Ca}_6\text{Al}_2(\text{SiO}_4\text{CO}_3\text{OH})_3$ and Gismondite $\text{CaAl}_2\text{Si}_2\text{O}_8 \cdot 4\text{H}_2\text{O}$ and the subsequent precipitation of the phases inside the pores. Such increased phase formation is not observed in the mortar prisms cured in water and so the porosity is observed to be high - Figures 11 (a) and 11 (b).
- The flexural strengths of the mortar prisms in aggressive medium shows a substantial increase from 3 days to 7 days and to 28 days as compared to those cured in water.
- The porosity of the mortars at 28 days of hydration in aggressive medium is much less, it was observed to have lower porosity in the range of micro pores as compared to those cured in water. (Figure 12)

Figure 12. Pore size distribution of cementitious binder mortars cured in water and in an aggressive medium

CONCLUSIONS

- The Hydrogel process of clinkerisation utilises fly ash up to 50% and opens new avenues for its utilization. The optimum alkali levels required for activation being dependent on the nature of fly ash. The process does not involve hydrothermal activation.
- Depending upon type of Cementitious system intended to be produced viz. Cementitious binder clinker / belite rich or alite rich clinker, the temperature for thermal processing ranges from 800 -1350⁰ C.
- The study establishes the possible mechanism of the Hydrogel process. Alkali activation of fly ash produces sodium aluminosilicate hydrates, these zeolitic structures with hydrophilic sites act as cation exchangers exchanging the alkali ion with the Calcium ion, thus forming calcium-aluminosilicate hydrates. These semi amorphous precursors present in the hydrogel dehydrate to produce the cement clinker minerals.
- The principle of alkali activation can be extended to activation of white china clay for manufacture of white cement, initial experiments have indicated the feasibility of white cement manufacture at lower temperature using this hydrogel process.
- The resistance of cementitious binder to aggressive environment is excellent. Such a binder could have specialised applications.

ABSTRACT

The use of mineral admixtures, such as fly ash, micro-silica, metakaolin, calcined clay pozzolana, volcanic ashes etc. as a blending component in OPC, alters the hydration kinetics of the resultant blended cement. Due to the secondary hydration reactions of these admixtures with the available calcium hydroxide, their use results in a decreased availability of the calcium hydroxide in the hydrated cement matrix, thus forming a much compacted, less pervious hydrated cement paste matrix on hydration. These aspects are however a function of the nature, fineness and pozzolanicity of the mineral admixtures / Supplementary Cementitious Materials (SCM).

At the authors' laboratory, substantial work has been carried out to assess the efficacy of the different blending components through evaluation of the hydrated OPC and the blended cement pastes (made with the blending materials) at different ages of hydration. The evaluations include analysis of free calcium hydroxide, mineralogy of the hydrated products, analysis of the % unhydrated blending materials in the hydrated cement pastes at different ages of hydration viz. 1, 3, 7, 28, 60, 100 days.

Based on these studies the authors evolved a Pozzolanic Index (Q_H). The details of these findings and the comparison of the Q_H with the conventional compressive strength based Hydraulic Index (H_{in}) were discussed in the paper put forward at the PAC RIM IV conference^[5]. A summary of the findings is also presented in this paper.

The Q_H could be used to assess the efficacy / pozzolanic reactivity of blending materials for selection of the reactive size fraction, and also for optimizing the fineness levels of the blending materials like fly ash for improved pozzolanic properties. The paper discusses these applications for fly ashes of different sources.

Keywords: Pozzolanic reactivity, hydraulic index, fly ash

1. INTRODUCTION

The methods of testing the pozzolanic activity of pozzolans or supplementary cementitious materials (SCMs) have been studied by many researchers for over 100 years. However pozzolans are so myriad and of different quality, it is difficult to establish appropriate test methods for assessing the pozzolanic activity. Lea^[1] summarised and discussed various methods of testing the pozzolanic activity at the International symposium on the chemistry of Cement in 1938, while Malquori^[2] discussed the test methods at the Fourth International symposium on chemistry of cement in 1960, which serve as an useful guides for the research on methods of testing the

pozzolanic activity of pozzolans. Moran and Gilliland^[3] divided the test methods into three categories of tests:

- ❖ Tests on the Pozzolans alone
- ❖ Tests on Pozzolans lime mixtures
- ❖ Tests on Pozzolan Portland cement blends

In the light of present knowledge of test methods and techniques, which are a combination of various methods such a classification is difficult, however the relatively frequently used methods could be categorized in the form shown in Table 1.

Some of the test methods are observed to be suitable and correlate well with the strength results of lime mortars. However, they do not correlate to the behavior of cement pozzolan blends. In the widely used standards of various countries, the chemical methods of testing pozzolanic activity are more suited for judging activity of the pozzolanic materials and some of which are time consuming and do not provide a yard-stick to correlate to the strength of standard - cured mortar or concrete. For example, the pozzolanic activity test in the different standards provides the degree to which a pozzolan (fly ash) contributes to strength development of the resultant blended cement mortar, but does not provide a measure of the pozzolanic reaction of the used pozzolans. The compressive strengths of a blended cement mortar / concrete are partly due to the pozzolanic activity and partly due to the packing effect of the added pozzolans.

The estimation of the amount of free calcium hydroxide remaining in the hydrated pozzolana cement has also been used as an indication of the pozzolanic reactivity of the pozzolans. A number of methods^[4] (as shown in Table 2), have been used to determine the free calcium hydroxide content in the hydrated lime pozzolana or pozzolana cement mortar or concrete.

Table 1. Classification of methods of testing pozzolanic activity which are relatively frequently used

Classification		Example of Test Method
Method testing of strength by accelerated curing of pozzolan lime or pozzolan cement mortar		ASTM C 593-66T, ASTM C 402-65T
Method adding Pozzolan to lime solution	Quantitative measurement of lime	Chapelle's Method, Moran and Gilliland's method
	Quantitative measurement of lime and alkali	AFNOR P 15 - 462 Italian standards ISO recommendation No 1156
Method treating pozzolan or pozzolan lime mixture with acid or alkali	Quantitative determination of SiO_2	Florentin's method
	Quantitative measurement of $\text{SiO}_2 + \text{Al}_2\text{O}_3$	ASTM C 379 - 56T, Poliet and Chausson's method, Austrian standards Charisius method
	Quantitative measurement of $\text{SiO}_2 + \text{Fe}_2\text{O}_3$	Steopoe's method
	Quantitative measurement of $\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$	Sestini and Santarelli's modification of Baire's method Feret - Florentin method
	Quantitative measurement of insoluble residue	Guillaume's method AFNOR P - 15 - 301
Method measuring development of dissolution heat of pozzolan		Jambors method
Measurement of electrical conductivity of lime pozzolan solutions		Lea's method

Table 2. Methods used for estimation of free calcium hydroxide

Method	Originally described by	Applied to Pozzolan Mixes by
Sugar	--	Sestini and Santarelli
Glycerol	Emley, Lerch and Bogue	Katherein; Rodt
Ethylene Glycol	Schlapfer and Bokowski	Forsen; Rodt
Phenol	Konarzewski and Lukaszewicz	Sestini and Santarelli; Witterkindt
Lime solution	Bake well and Bessey; Forsen	Forsen; Lea
Calorimetric	Bessey	Lea; Vittori

In such methods presence of the unhydrated cement compounds prevents use of aqueous solutions, as further hydration would occur during extraction. In pozzolana cement mixes most of these methods do not give results having any precise accuracy. However, the methods have been observed to be consistent in themselves and are valuable for comparison of the hydration characteristics.

The pozzolanic activity of the pozzolana has also been reportedly monitored through estimation of the un-reacted pozzolana content of the hydrated blended cement pastes at different ages of hydration. Different chemical extraction methods have been studied by researchers for different pozzolans^[4] and the studies have revealed suitability of specific methods for a given type of pozzolana.

At the authors' laboratory substantial work has been carried out^[5] to assess the efficacy of the different blending components and attempts were made to assess the pozzolanic activity of the different pozzolans in the blended cement hydration through evaluation of the OPC and the blended cement pastes (with the blending materials) at different ages of hydration. The evaluations include analysis of free calcium hydroxide and analysis of the contents of unhydrated blending materials in the hydrated cement pastes at different ages of hydration viz. 1, 3, 7, 28 and 60 days of hydration.

The % hydration of the Pozzolans can be related to the free calcium hydroxide content of the hydrated cement at different ages of hydration and through a comparison of the free calcium hydroxide values for hydrated blended cements with that obtained with the hydration of OPC - sand blends (control). Based on these comparisons the authors have evolved a hydraulic index, to rate the pozzolanic efficacy of the blending materials.

The hydraulic Index can identify differentially the contributions of the pozzolanic reactivity and the packing effect of the blending components, the Index could also be used for selection of the reactive size fraction as also for optimizing the fineness levels of the blending materials like fly ash for improved pozzolanic properties. The paper discusses these applications for fly ashes of different sources in some details.

1.1 Experimental

The Blended cements PPC (with fly ash of two varieties at absorption levels of 20%), PSF (with 7 % Silica Fume), PMK (with 7 % Metakaolin of two varieties, fine and coarse) were prepared by blending Industrial Ordinary Portland Cement with the fly ash, Silica Fume and Metakaolin. The requisite amount of gypsum was added to maintain the % SO₃ in cement to ~2.5%. The chemical composition of OPC, fly ash, Silica fume and Metakaolin GGBS is given in Table 3.

Table 3. Chemical composition of OPC, Fly Ash, Silica Fume, Metakaolin

% Oxides	OPC	Fly Ash	Silica Fume	Meta kaolin I	Meta kaolin II
SiO ₂	21.2	62.4	97.9	51.6	50.8
Al ₂ O ₃	4.4	24.3	0.15	45.7	43.7
Fe ₂ O ₃	4.0	6.3	0.03	0.9	0.7
CaO	64.5	1.6	0.2	<0.1	0.2
MgO	1.0	0.10	0.01	0.1	0.1
LOI	2.0	1.7	1.1	0.9	3.4
Na ₂ O	0.1	0.54	0.01	0.06	0.09
K ₂ O	0.4	1.34	0.3	0.13	0.05
TiO ₂	0.07	1.30	0.01	0.51	1.1
SO ₃	2.3	<0.10	0.2	--	--
LR	0.7	91.9	--	--	--

The physical properties of mortars of OPC, PPC-I (20% fly ash at 15% residue on 350#) and PPC- II (20% fly ash at 1% residue on 350#), PSF (7% silica fume), PMK-I (7% Fine meta kaolin) and PMK-II (7% coarse Metakaolin 20 micron size) at 1,3,7,28 and 60 days tested as per Indian Standards and are shown in Table 4.

1.2 Hydration studies of OPC, PPC, PSF, PMK

The authors at the 7th NCBM International conference, New Delhi, 2000^[6], published results of the comparative hydration studies of OPC, PPC and PSC.

Table 4. Physical properties of OPC, PPC, PSF and PMK (Indian Standards)

	OPC	PPC-I	PPC-II	PSF	PMK-I	PMK-II
Sp.Surface (m ² /kg)	330	344	352	476	498	522
N.C (%)	25.5	28.5	28.8	29.3	30.8	27.8
Setting Time (minutes)						
Initial	95	110	110	95	140	115
Final	135	155	155	135	175	160
Compressive Strength (MPa)						
1 Day	20.0	20.5	19.5	26.5	24.5	24.5
3 Days	39.5	31.0	29.5	44.5	38.0	39.0
7 Days	44.5	34.0	37.5	47.5	48.5	53.0
28 Days	56.5	46.5	49.0	59.5	57.5	59.0
60 Days	64.0	52.0	54.5	63.0	54.0	56.5

The same methodology was followed for assessing the degree of hydration in the neat cements. The neat cement pastes were cast and de-molded after 1 day and were kept at >90% Rh, 27 ± 2 ° C for 1,3,7,28 and 60 days. After each age of hydration, the neat cements were analysed for:

- ❖ Free Ca(OH)₂ content
- ❖ Unhydrated Pozzolan (SCM) content (unreacted mineral admixture or Blending Component)

The above hydration studies were also carried out on corresponding control samples for comparison, the control samples were prepared by blending OPC and ground quartz at the same percentage additions and same fineness as the corresponding blending component, i.e. (PPC-C) with OPC + 20% Fine quartz (of particle size distribution similar to fly ash), (PSFMK-C) with OPC+ 7% fine quartz.

1.3 Analysis methods

1.3.1 Free calcium hydroxide

The free calcium hydroxide content of the hydrated cement at each age of hydration was analysed by using the glycol extraction method as per IS 4032(Indian Standards). The free calcium hydroxide content of the different hydrated blended cements were also compared through XRD quantification so that any errors due to extraction of lower hydrates by the reagent could be corrected.

1.3.2 Analysis of Unhydrated blending components (Fly ash, Metakaolin and Silica Fume)

Mineral admixture (fly ash, silica fume and metakaolin) content in the unhydrated cements and hydrated blended cements at different ages of hydration were analysed by a selective dissolution method using picric acid - methanol as reported by Li et al^[7]. The brief method is given below:

A known weight the hydrated neat cement was treated with aqueous - methanolic picric acid solution with magnetic stirring for a fixed time of 30 minutes. The residue was filtered and washed free of picric acid with methanol and subsequently washed with 300 ml of water at 50⁰ C. The residue was dried and ignited at 1000 ° C. The residue was weighed after cooling. The residue in the blending components and unhydrated cement was determined by the same method separately. Based on the residues of the blending component and the blended cement at each age of hydration the % unhydrated Blending component was determined from which the % hydration of the blending component was computed.

2. RESULTS AND DISCUSSIONS

The free calcium hydroxide contents of the different blended cements and corresponding control blended cements (with fine quartz of same fineness as the blending component) at different ages of hydration is graphically shown in Figures 1 and 2.

The unhydrated blending component in the cements at different ages of hydration was analysed by the selective dissolution method and the % hydration of blending component in the different cements was calculated and is graphically shown in Figure 3.

The pozzolanic reactions of the blending component gradually results in consumption of the calcium hydroxide produced from the hydration of the OPC part of the blending cement as a result there is a decrease in the calcium hydroxide contents of the hydrated cements, due to which the free calcium hydroxide contents of the blended cement would be comparatively lower than the hydrated OPC at the corresponding ages of hydration. Thus the difference in the free calcium hydroxide contents of the hydrated blended cements and OPC would be related to the pozzolanic reactivity of the blending component at that age of hydration.

The generated data indicates that % hydration of the blending component in the blended cement corresponds to the decrease in free calcium hydroxide content at each age of hydration. The higher the degree of hydration, the lower the free calcium hydroxide content. Thus, in order to quantify the pozzolanic reactivity of the blending components, the authors have evolved the Pozzolanic Index (Q_H).

$$\text{Pozzolanic Index} = Q_H = \frac{(\text{Calcium Hydroxide in OPC} - \text{Calcium Hydroxide in PBC})}{(\text{Calcium Hydroxide in OPC} - \text{Calcium Hydroxide in PBC} - \text{control})}$$

The Q_H of the different blending components calculated at 7 days of hydration is given in Figure 4.

Figure 1. Comparison of Free Calcium hydroxide content in OPC, PPC and PPC-control

Figure 2. Comparison of Free Calcium Hydroxide content in OPC, PSF, PMK and PSFMK-control

Figure 3. % Hydration of different blending components at different ages of hydration

Figure 4. Pozzolanic Index of the different blending components at 7 days

The Hydraulic Index (H_{in}) based on compressive strength (as reported in literature) of OPC, Blended cements and their control samples at 28 and 60 days was also calculated from the data on the physical properties of cements and a comparison was made of the applicability of the two indexes.

The formula used for the Hydraulic index (H_{in}) based on compressive strengths is given below.

$$\text{Hydraulic Index } H_{in} = \frac{\text{Strength of PBC} - \text{Strength of PBC-Control}}{\text{Strength of OPC} - \text{Strength of PBC-Control}}$$

The pozzolanic activity of the different blending components based on H_{in} at 7 days and 28 days can be rated as follows:

At 7 days: Fly ash I < Fly ash II < MK I < MK II < Silica fume (1)

At 28 days: Fly ash I < Fly ash II < MK I < MK II < Silica fume (2)

Attempts were also made to correlate the Q_H of 7 days and H_{in} (Hydraulic Index based on compressive strength) at 28 and 60 days of hydration, the data shows a correlation coefficient of 0.91 and 0.72 respectively and is graphically shown in Figures 5 and 6.

Figure 5. Q_H – 7 days v/s H_{in} 28-days

Figure 6. Q_H – 7 days v/s H_{in} 60 days

The results indicates that:

- ❖ The Pozzolanic Index (Q_H) at 7 days relates very well with H_{in} at 28 days.
- ❖ A comparison of the Q_H and H_{in} indicates that the former relates to reactivity while the latter relates to the resultant effect of reactivity and packing effect of the blending component.

Thus the Q_H index at 7 days is related to the pozzolanic reactivity of the blending component. The pozzolanic reactivity of the different blending components (Mineral admixture / SCMs) under study can be rated on the basis of the Q_H as follows:

Fly ash I < Fly ash II < SF < MK I < MK II (3)

While on the basis of % Hydration of the blending components with age shown in Figure 4 indicates the pozzolanic activity of the blending components to be of the following order:

Fly ash I < Fly ash II < SF < MK I < MK II (4)

The pozzolanic activity of the blended component as indicated by Q_H matches well with the % hydration of the blending component (Figure 4). The index however relates very well to the reactivity of the fly ash.

The indexes (Q_H and H_{in}) rate the fly ash II to be more reactive than fly ash I, which is also substantiated by the ~ 7-10% more hydration of the fly ash II at 28 days. This is due to more surface area of fly ash exposed during the hydration of the finer fly ash as compared to coarse fly ash leading to more pozzolanic reaction and lowering of free calcium hydroxide in the hydrated sample (Figure 1). The higher strength gain after 7 days can be partly attributed to improved packing. This observation is in congruence with that reported by Ducreux and Jarriage^[8] who studied the pozzolanic activity of finer fraction by Feret's method.

2.1 Use of Pozzolanic Index (Q_H) for assessing the pozzolanicity of fly ash of different sources

Three fly ash samples of different sources were taken for the evaluation of the Pozzolanic Reactivity. The fly ash A and U is comparatively coarser while fly ash D is finer in its particle size distribution. The fly ash U is different in its nature of amorphous phase having the maxima of the amorphous hump at 2θ value of 26° while the other two fly ash have the maxima at a 2θ value of 23° indicating a possible difference in composition of the amorphous phase^[9].

The amorphous / glassy content of the fly ashes as determined by chemical 1% HF dissolution method^[10] are given below:

% Amorphous glassy content	Fly ash D	Fly ash A	Fly ash U
Chemical method	49.7	64.5	50.9

The morphological features of the fly ashes as observed under Scanning electron Microscope indicates relatively coarser to fine spherical particles (cenospheres) in fly ash A and U as compared to fly ash D. The percentage occurrence of the spherical particles is also higher in fly ash A and U. The chemical analysis and particle size distribution of fly ashes is shown in Tables 5 and 6.

Using the method described above the pozzolanic index at 7 days was determined along with % Reaction (% Hydration of the fly ash at different age of hydration as described above. The Q_H and the % reaction of the fly ash at different ages of hydration in PPC is depicted in Figures 7 and 8 respectively.

The pozzolanicity of the fly ashes can be rated as:

$$\text{Fly ash U} > \text{Fly ash D} > \text{Fly ash A}$$

Table 5. Chemical composition of fly ash of different sources

%	Fly ash D	Fly ash A	Fly ash U
SiO ₂	58.4	63.2	48.0

Figure 7. Q_H of the different fly ash at 7 days

Figure 8. % Hydration of the fly ash in PPC

Figure 9. % hydration of fly ash with increased fineness

2.2 Optimisation of fineness of pozzolana/fly ash:

The reactivity of pozzolana/ fly ash is a function of its fineness and at an optimum fineness maximum reactivity can be achieved. Determination of the Q_H could be useful for optimizing the fineness of pozzolana / fly ash.

Figure 9 illustrates the change in pozzolanic reactivity and the % hydration with increased fineness of fly ash I and D. The fly ash I (D-50 of 35 microns) was ground to D-50 of 6 microns while fly ash D (D – 50 of 9.5 microns) was ground to D-50 of 4 microns.

The grinding of the fly ash produces a substantial change in the reactivity of the fly ashes. Thus the Q_H at 7 days could be used to optimize the fineness of the fly ash for maximized pozzolanicity.

3. CONCLUSIONS

- The Pozzolanic index (Q_H) evolved by the authors based on the free hydrated lime content of the neat cement pastes appears to be applicable for assessment of the pozzolanic activity of the mineral admixtures. The method is comparatively rapid and is applicable for assessing the pozzolanic activity at the absorption levels used in the blended cement or blended concrete and is an indirect measure of the calcium hydroxide consumption by the pozzolanic component.
- The Pozzolanic index (Q_H) at 7 days can be mathematically stated as follows:

All measurements are done at the hydration age of 7 days and a control blended cement is also made at the same absorption levels using fine quartz of similar particle size distribution as that of the blending component under study:

- The reactivity as predicted by Q_H 7 days matches well with the % Hydration (% reaction) of the blending component.
- On the basis of Q_H at 7 days, the efficacy of the different blending components studied could be rated as follows:

Fly ash I < Fly ash II < Silica fume < Metakaolin I < Metakaolin II

- As exemplified by the case study in the paper the determination of Q_H can be used for assessing the pozzolanic reactivity of the pozzolan (fly ash), and also for optimizing the fineness of the pozzolan.
- Further studies are in progress to evolve a rapid analytical technique for analysis of the % hydration (% Reaction), of the blending component at 7 days of hydration of the blended cement for predicting its pozzolanic activity, which would not require a hydration study on control blended cement made with fine quartz.

REDUCTION OF PORTLAND CEMENT PASTE POROSITY BY TEOS IMPREGNATION

Hebert L. Rossetto and Milton F. de Souza

CEPOF, Laboratory of Materials Science, São Carlos Institute of Physics, University of São Paulo, São Carlos, SP, Brazil. E-mail: hebert@ifsc.usp.br

ABSTRACT

Pore-reduced cements, PRC, were prepared by uniaxial pressing of Portland cement powders wetted by the incipient wetting method. Hardened and dried PRC samples were impregnated by tetraethyl orthosilicate, TEOS. Impregnation caused porosity to drop from 8.8% to 0.9% (a 90% decrease) and compressive strength to increase simultaneously from 267 to 317 MPa (a 20% increase). Impedance Spectroscopy measurements showed an almost tenfold increase in resistance. Scanning Electron Microscopy revealed that the impregnated samples' surfaces were more uniform than those of the control samples.

1. INTRODUCTION

Impervious cement surfaces provide the first barrier against attack by deleterious substances, increasing concrete durability. It is well known that porosity is decreased when the water/cement, w/c, ratio of the cement-based products is reduced. Pore reduction can be increased [1] by choosing adequate conformation techniques that can operate with low water/cement ratio powders. One such technique is the uniaxial (or isostatic) pressing of cement powders wetted by the incipient-wetting method, which allows for w/c ratios of close to 0.10. By this method, small water droplets are sprayed on revolving cement particles to produce a thin water layer on each particle; this wetted layer acts as the binder among particles during the pressing operation. These binding forces are sufficiently strong to maintain the body's shape immediately after pressing and to produce bodies sufficiently strong for handling after 24 hours. Further immersion in limewater completes the cement hydration.

Although pore-reduced cements already have little porosity, the introduction of silica via molecular species, such as TEOS, further reduces porosity because this liquid is able to penetrate the cementitious body and to reach nano-sized pores. It is well known, from the literature [2], that TEOS undergoes hydrolysis in basic pH environments, producing highly reactive silica. The cementitious body provides the calcium hydroxide necessary to raise the pH for TEOS hydrolysis and to immediately react chemically with the silic acid produced. Voids and pores within the cement can, thus, be filled by the calcium silicate hydrates that are formed and calcium hydroxide content is reduced.

2. BACKGROUND

2.1 Incipient-Wetting Technique

Although it is often employed in ceramics processing, the incipient-wetting technique is not normally used in cement applications and, to the best of our knowledge, this is the first time it has been used within this scope. This technique plays a potentially important role in the development of

low-porosity and ultra high-strength cement-based products because it allows for the addition of a minimum amount of water necessary for the application of the dry pressing method without causing powder delamination, concomitantly producing sufficient adhesion among cement particles. It also prevents water and calcium hydroxide losses during uniaxial pressing and increases the mechanical strength before full hydration, among other advantages.

Basically, this technique consists of uniformly wetting the cement powder with a minimum amount of water. With the help of a spraying device, which produces micron-sized water droplets, water is uniformly spread all over the Portland cement particles, while the powder is kept under continuous movement during the wetting process. Values of w/c around 0.10 are achieved with this method, corresponding to a deposition of a $\approx 2.0 \mu\text{m}$ water layer on each cement particle.

2.2 TEOS

Tetraethyl orthosilicate, TEOS, is being used, for the first time, to the authors' knowledge, in cementitious products to produce nanometric silica particles inside the cement body's microstructure. Under base-catalyzed conditions, water dissociates to produce nucleophilic hydroxyl anions in a rapid first step. The hydroxyl anion then attacks the silicon atom of the TEOS molecule [3]. This hydrolysis reaction is described as follows:

Such silicic acid gels react promptly with the calcium hydroxide, provided by the hydration of the C_3S from cement particles and by the limewater, resulting in calcium silicate hydrate (C-S-H) formation as follows below:

In contrast, if partially hydrolyzed TEOS is used in the impregnation process, silicic acid polymers are introduced into the pores of the cementitious body, leading to the corresponding chemical reaction of this polymer with calcium hydroxide. Therefore, different results should be expected if pre-hydrolyzed TEOS is used in the impregnation process.

3. EXPERIMENTAL METHODS

3.1 Materials Preparation and Impregnation

PRC samples were produced by uniaxial pressing of incipient-wetted Portland cement powder (see chemical composition in Table 1), with w/c = 0.12, at 20 and 40 MPa compaction pressures. Immediately after compaction, the samples were cured in a room-temperature humidity chamber for 24 hours, followed by curing immersed in a saturated limewater solution.

Table 1. Chemical composition of the Portland cement used.

Components	Weight %
$\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ (CSH ₂)	7.68
$4\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ (C ₄ AF)	7.05
$3\text{CaO} \cdot \text{Al}_2\text{O}_3$ (C ₃ A)	11.50
$3\text{CaO} \cdot \text{SiO}_2$ (C ₃ S)	64.50
$2\text{CaO} \cdot \text{SiO}_2$ (C ₂ S)	3.78

In a first approach, one set of samples was oven-dried at 105°C for 24 hours and another was vacuum-dried at 10^{-3} torr for 4 hours and then placed in a desiccator at 20% humidity for 20 hours. Oven-drying at 105°C may affect the cement pore structure by rearranging the hydrated products

due to internal stresses induced by the removal of adsorbed and free water [4-5]. Although many researchers consider this the standard drying procedure because it is simple, fast and results in effective water removal, a second approach was used in the work reported on here: the samples were oven-dried at 50°C for 24 hours, which permitted the total porosity to be estimated more realistically.

Finally, each set of dried samples was impregnated by immersion for five minutes in TEOS either 28 or 40% SiO₂ (see TEOS properties in Table 2), the one with higher density being the pre-hydrolyzed product. Thereafter, all TEOS-impregnated samples were kept in a limewater chamber for 30 days and then characterized by the techniques below. Samples that were dried by the first method were characterized only through their porosity before and after impregnation, while samples dried by the second method were characterized in terms of their porosity, compressive strength, electrical resistance and the microstructure, observed by SEM.

Table 2. TEOS[#] properties.

Properties	Siliethyl TS 28	Siliethyl TS 40
Density at 25°C	0.930-0.940	1.055-1.065
SiO ₂	28.5-29.5	41- 42

[#] Hergrand Limited, Brazil.

3.2 Characterization

3.2.1 Mechanical Properties

Although the mechanical performance of TEOS impregnated samples was not the main focus of this work, there is a strength-porosity relationship that needs investigating. Sample pieces with parallel faces were cut from a 90-day larger sample using a slow speed water cooled cutting diamond disc to size them down to 20 x 10 x10 mm³, and their mechanical strength was measured using an Instron machine.

3.2.2 Porosity

Measurements by Mercury Intrusion Porosimetry (MIP) (Porosizer 9320, Micromeritics) require the complete removal of water from the sample; this was accomplished by oven-drying it for 24 hours, either at 50°C or 105°C. Because of “bottleneck pores” in cementitious materials, MIP measurements are the subject of much criticism from a great many researchers [6-7], who claim that the pore size distribution is not accurately represented. Nitrogen adsorption measurements were taken to check the predominant pore shapes existing in impregnated and non-impregnated PRC.

Samples from the same large piece used to measure the mechanical properties were sized to 20x10x10 mm³ for MIP measurements. For the nitrogen adsorption tests, samples with dimensions close to that used for the MIP measurements were crushed with a hammer and the fragments collected.

3.2.3 Microstructural Investigation

Changes caused by TEOS impregnation on the surface microstructure of 10x10x4 mm³ samples were observed by SEM (DSM 960, Zeiss).

3.2.4 Electrical Properties

Impedance Spectroscopy is a noninvasive and nondestructive technique that has been applied to study cement-based materials [8] and can sample the microstructure without recourse of water removal by heating, which is known to alter the paste microstructure. 20x10x4 mm³ sample pieces were cut from larger 90-day pieces, TEOS impregnated, cured in limewater for 30 days and then kept at room temperature in the air to reach humidity equilibrium. Control samples were prepared likewise. Thereafter, both types of samples were prepared by applying silver painted electrodes on

the 20x10 mm² faces. Measurements were taken at room temperature using an Impedance Analyzer (Solartron 1296) in the 1.0Hz to 1.0 MHz frequency range.

The measurement of electrical conductivity is related to pore interconnectivity and can be used to predict durability of cement-based materials. In this study, we propose an equivalent electrical circuit model for PRC, based on earlier literature. According to MacPhee et al. [9], four conduction pathways are possible as follows: (i) continuous electrolyte-filled pores connecting the electrodes (CP); (ii) discontinuous or blocked porosity electrolyte-filled pores (BP); (iii) hydration products (HP); and (iv) unreacted cement (UC). As hydration proceeds, the proportion of CP will reduce and the conductivity will occur increasingly through BP and HP. In the present case UC is strongly reduced because the samples are ninety days old. This brought us to the equivalent circuit, Figure 1, in which indexes 1, 2 and 3 represent BP, HP and electrode features, respectively.

Figure 1. Equivalent electrical circuit model for 90-day PRC pastes.

4. RESULTS AND DISCUSSION

4.1 Evaluation of the First Approach

Firstly, the effects of two drying methods (oven-drying at 105°C and vacuum-drying at room temperature), two impregnators (TEOS 28 and 40) and two compaction pressure values of the PRC samples (20 and 40 MPa) on porosity reduction, measured by MIP, were analyzed as the first step in defining the best experimental procedures to achieve the most effective porosity reduction. At this point, it should be noted that the above-mentioned drying methods involve the penetration ability of TEOS. We consider that the dryer the sample, the higher the TEOS intrusion and, hence, the greater the reduction in porosity. Nevertheless, both samples were oven-dried at 105°C before the MIP test so as to complete the removal of water, which revealed the samples' total porosity. The total porosity of the control samples pressed at 20 and 40 MPa were 13.1% and 12.7%, respectively.

Figure 2. Porosity reduction efficiency of TEOS impregnated samples.

Figure 2 shows the efficiency of TEOS impregnation in reducing the porosity of PRC (average of two samples). Note that there is no evidence that compaction pressure on the samples plays any significant role in the reduction of porosity, at least at these levels, unlike the difference between the drying methods and pre-hydrolysis of TEOS, which exert a strong influence.

Figure 3. Mercury intrusion volume curve for 20 MPa pressed samples (T28 and T40 mean TEOS 28 and TEOS 40, OD and VD mean oven-dried and vacuum-dried samples, respectively).

Figure 4. Mercury intrusion volume curve for 40 MPa pressed samples (T28 and T40 mean TEOS 28 and TEOS 40, OD and VD mean oven-dried and vacuum-dried samples, respectively).

The following conclusions were therefore drawn: (i) Vacuum-drying at room temperature does not permit substantial TEOS impregnation; hence, neither of the TEOS types effectively provided total porosity reduction of the PRC samples. (ii) Whereas oven drying is the method that most favors extensive TEOS impregnation, TEOS 40 – with its higher silica content – proved to reduce porosity

more effectively than TEOS 28. These findings, which are illustrated in figures 3 and 4, motivated us redouble our efforts in studying TEOS 40 impregnation.

4.2 Evaluation of the Second Approach

In this approach, samples were oven-dried at 50°C for 24 hours before TEOS 40 impregnation and MIP tests. This procedure appears to be more realistic because only removal of free water occurs at this temperature. Table 3 shows the results of the MIP tests (average of two samples). It can be noted that the final porosity of both the 20 and the 40 MPa pressed samples impregnated with TEOS was around 1%. Moreover, the median pore diameter also dropped by more than one order of magnitude. Table 4 presents the results of compressive strength tests, which confirm the same trend of porosity measurements: an improvement of around 22%. Therefore, this approach produced the best results for TEOS impregnation of PRC pastes, as is illustrated in Figure 5.

Table 3. MIP results for TEOS 40 impregnated samples oven dried at 50°C.

Sample	Pressed at 20 MPa		Pressed at 40 MPa	
	Control	Impregnated	Control	Impregnated
Total Intrusion Volume (mL/g)	0.0387	0.0036	0.0280	0.0048
% Porosity	8.8	0.9	6.0	1.1
Bulk Density (g/mL)	2.2761	2.3315	2.2058	2.3129
Median Pore Diameter (μm)	0.0243	0.0074	0.0295	0.0084

Figure 5. Mercury intrusion volume curve for 20 MPa pressed samples oven-dried at 50°C.

Table 4. Compressive strength results for TEOS 40 impregnated samples oven dried at 50°C.

Sample	Pressed at 20 MPa		Pressed at 40 MPa	
	Control	Impregnated	Control	Impregnated
Compressive Strength (MPa)	238	298	266	317

Figure 6. Adsorption-desorption isotherms of samples oven-dried at 50°C.

Figure 7. Nanopore size distribution of samples oven-dried at 50°C.

The results given by N₂ adsorption tests are shown in Figure 6. Both samples oven-dried at 50°C, pressed at 20 and 40 MPa, displayed similar adsorption-desorption isotherms. In comparison with the classical adsorption-desorption isotherms [10], the PRC paste isotherm is close to type H3, which is characteristic of mesoporous materials with a conical pore shape. With respect to pore size

distribution, TEOS 40 impregnated samples showed a lower nanopore volume than the control samples, as depicted in Figure 7.

Figure 8. Nyquist plots for samples oven-dried at 50°C.

According to the equivalent electrical circuit model proposed earlier, we proceeded to perform IS measurements to verify the effectiveness of TEOS impregnation. Figure 8 shows typical Nyquist plots for PRC paste. There is a good agreement between the samples data measured and the simulated model results. The spectras exhibit two high-frequency arcs contributed by BP and HP, with R_1 and R_2 resistances respectively, and a “tail” or low-frequency arc corresponding to the effect of cement-electrode interfacial capacitance.

The electric properties can be obtained by a simple calculation (see inserts in the Figure 8), demonstrating that electrical resistance increases with TEOS 40 impregnation. It can be concluded that electrical conductivity dropped sharply, indicating that pore interconnectivity was reduced.

Figure 9 shows the differences between the surface layers of the control and TEOS 40 impregnated samples, revealing a strong reduction in large pores.

Figure 9. Surface layer of control (left) and TEOS 40 impregnated (right) samples.

Thus, we can foresee the application of TEOS-impregnated cement-based materials for buildings, dams, bridges and industrial storage facilities, by the advantageous durability feature. Furthermore, the rather high compressive strength achieved can lead to a structure lightening, what results in cost savings.

5. CONCLUSIONS

Impregnation by TEOS was shown to reduce the porosity and improve the mechanical properties of hardened PRC pastes, indicating that this procedure can be used to increase their durability and to lighten the structure. It was also found that oven drying at 50°C is an effective method to prepare samples for TEOS impregnation. The application of TEOS through the surface layer of cured cementitious materials can result in an almost completely sealed surface layer, providing them with greater protection. The previous partial hydrolysis of TEOS (TEOS 40) with a higher silica concentration is more efficient than the monomeric molecule (TEOS 28).

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the financial support of FAPESP. Our special thanks go to Dr. Jean-Claude M'Peko for his assistance in the use of the IS technique. We also thank the Brazilian company Hergrand Ltd. and Datiquim Ltd. for providing the TEOS for this study.

ABSTRACT

Concerning the management of long life radioactive waste, two options are available: storage in surface sites in sealed containers or burying in deep deposits. In both cases, cementitious materials are used as mechanical barriers. The present study was devoted to another aspect: the use of cementitious materials to immobilize pollutants (“chemical barriers”). ¹³⁵Cs constitutes the predominant nuisance of long-life fission products.

Water is the main cause of pollutant dissemination but the mobility of a polluted solution or suspension can be strongly reduced in cementitious environments. Two mechanisms are possible:

1. Reaction between the polluted water and an anhydrous cement to form a trapping phase;
2. Reaction between the polluted water and a reactive aggregate enclosed in cement, which constitutes the trapping phase.

For caesium trapping, we choose the second mechanism with zeolite as reactive aggregate.

1. MATERIALS

The large size of Cs⁺ (1.65 Å) makes its insertion within crystallized minerals difficult. We have shown ([1], [2]) that ceramized cementitious compositions can immobilize caesium within pollucite. Moreover, caesium can be accommodated within zeolites, in particular in large-pore mordenite, clinoptilolite, chabazite, and zeolite P [3]. The present study was conducted using cheap and easy-supply natural chabazite (Ca₆(Al₁₂Si₂₄O₇₂).40H₂O), from Bowie (Arizona) [4], in a 6 µm size. We used three cements: an aluminous cement (*SECAR 71*), an ordinary Portland cement (CPA CEM I 52.5), and a white Portland cement (CPA CEM I - 55). The cement/zeolite ratio was 1.5. The water/solid ratio was 0.6. The cure temperature was 50°C. Various cure times were investigated, at the end of which the solids were ground, dried, and rinsed with acetone, then ether.

2. CHARACTERIZATION

Materials were characterised by XRD and MAS-NMR (²⁷Al or ²⁹Si). Caesium retention was studied by static retention batches. The Cs content in liquid was measured by atomic absorption and the Cs content in solid phase by PIXE (Particle Induced X-ray Emission).

3. RESULTS AND DISCUSSION

3.1 Caesium retention

Caesium retention tests were carried out on ground material (grain size $< 200\mu\text{m}$), by measuring the mass of caesium immobilized per gram of material. The results are in agreement with Langmuir's adsorption ($M_{\text{Cs}} = M_0 + A \cdot \exp[-x/t]$). The fit of experimental data gives M_0 , A , and t , M_0 corresponding to saturation. Results (table I) show that the caesium retention is high in mixes of aluminous or portland cement and zeolite. Several studies ([5], [6], [7]) have proved that caesium is poorly trapped by cement materials. Therefore, caesium retention must be due to the chabazite encapsulated in the blend.

Table 1. Cs retention(mg per gram of mortar) – Function of curing time

Curing time (days)	Portland cement	Aluminous cement
7	95 ± 7	81 ± 6
36	97 ± 6	82 ± 10
74	aberrant	80 ± 7
116	92 ± 10	94 ± 12
408	88 ± 11	120 ± 13
500	86 ± 6	aberrant

3.2 Zeolite-cement reaction

The problem with a zeolite aggregate is its reactivity with cement, but things are improved when using materials with a high zeolite/cement ratio and an adapted composition. One must point out that the pozzolanic reaction can degrade zeolites in cementitious materials [8]; they can also be formed as long-term phases in certain cements [9]. In materials made with aluminous cement, XRD can be used to follow the reaction between zeolite and cement, thanks to the development of crystallized stratlingite C_2ASH_8 (figure 1). Experiments of ^{29}Si NMR confirm that zeolite is still present after 408 days (figure 2).

Figure 1. XRD Aluminous cement + zeolite - Cure time = 50 days.

* stratlingite, ● gibbsite, ◆ chabazite

Figure 2. ^{29}Si NMR Aluminous cement + zeolite - Cure time = 408 days.
* stratlingite, ◆ chabazite

In materials made with Portland cements, the reaction product is poorly crystallized C-S-H, which can be characterized by ^{27}Al and ^{29}Si MAS-NMR. Figures 3 and 4 show that the residual content of chabazite is high.

Figure 3. ^{27}Al MAS-NMR - White cement + chabazite.
Cure time = 50 days.

Figure 4. ^{29}Si MAS-NMR - Portland cement + chabazite.
Cure time = 116 days.
* chabazite, ● anhydrous cement, ■ C-S-H

On the time scale of our study, Cs retention measurements, XRD and MAS NMR proved that zeolite is still in the aged blend. But materials used to trap radioactive waste have to be stable for at least one thousand years. Based on the work done by Damidot and Glasser [10], we have built the 4-D $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-H}_2\text{O}$ diagram.

Starting with cement phases and zeolite, thermodynamic calculations were conducted to find stable phase assemblages of the system. Ten phases were chosen:

- Simple phases containing only Ca, Al or Si : portlandite CH, an amorphous silica gel SH, gibbsite AH_3 .
- Phases containing Si and Ca or Ca and Al : CSH with two different C/S ratios CSH(I) with $\text{C/S} = 1.8$ and CSH(II) with $\text{C/S} = 1.1$, hydrogarnet C_3H_6 (no stable phase is known with Al and Si only).
- Phases containing Ca, Al and Si : $\text{C}_3\text{AS}_x\text{H}_{6-2x}$ with $x=0.3$ et 0.8 representing a solid solution between C_3AH_6 and C_3AS_3 (grossular), a zeolitic phase : a calcic Clinoptilolite $\text{Ca}_{0.56}\text{Si}_{4.88}\text{Al}_{1.12}\text{O}_{13} \cdot 12\text{H}_2\text{O}$.

The thermodynamic data come from Damidot and Glasser [10] for cement phases and from Bennings and al. [11] for zeolitic phases. To find stable assemblages, a thermodynamical and geochemical software –CHESS– is used.

An invariant point of the diagram is a point with an equilibrium between three solids and an aqueous phase. With ten starting solids, 120 points are possible. With CHESS, the equilibrium at each point can be calculated. If three starting solids are equal to the finishing ones, the point is considered to be an invariant. Finally, twelve invariant points were found (Table 2).

Table 2. Invariant points of the zeolite – cement system

Solid 1	Solid 2	Solid 3
CH	C_3AH_6	$C_3AS_{0.3}H_{10.8}$
CH	CSH(II)	$C_3AS_{0.3}H_{10.8}$
C_2ASH_8	$C_3AS_{0.3}H_{10.8}$	$C_3AS_{0.8}H_{9.6}$
C_2ASH_8	$C_3AS_{0.3}H_{10.8}$	AH_3
C_2ASH_8	$C_3AS_{0.8}H_{9.6}$	CSH(I)
C_2ASH_8	AH_3	Clinoptilolite
C_2ASH_8	CSH(I)	Clinoptilolite
C_3AH	$C_3AS_{0.3}H_{10.8}$	AH_3
$C_3AS_{0.3}H_{10.8}$	$C_3AS_{0.8}H_{9.6}$	CSH(I)
$C_3AS_{0.3}H_{10.8}$	CSH(I)	CSH(II)
AH_3	SH	Clinoptilolite
SH	CSH(I)	Clinoptilolite

These calculations confirm that the zeolitic phase can coexist with the cement. The representation of the stable phase diagram is shown in figure 5.

Figure 5. CaO-SiO₂-Al₂O₃-H₂O phase diagram containing both cement phases and zeolite

4. CONCLUSIONS

Hazardous elements can be immobilized in cement hydrates, in ceramized cementitious materials, or in reactive aggregate. The present paper has shown that :

- Chabazite-cement blends offer potential as reactive aggregates to immobilize caesium ;
- In spite of the pozzolanic reaction, zeolite can be thermodynamically stable in a cement system.

Nicolas Lequeux is an Associate Professor in the *Laboratoire de Céramiques et Matériaux Minéraux* at the *Ecole Supérieure de Physique et Chimie Industrielles de la Ville de Paris* in France. Before coming to Paris, he received his Ph.D. in Physic Science from the *Université de Paris-Sud* in 1990. His research interests include the sintering of ceramics (in particular the low-shrinkage sintering, the microwave sintering and the sintering of calcium aluminate cements), and the structure of cement hydrates using spectroscopic methods as NMR and X-ray Absorption. His recent work is concerned with the speciation of pollutants in cement phases, the description of the nanostructure of CSH gels and the development of nanostructured organic-inorganic hybrid cementitious materials. He has published about 20 papers in the field of cement science.

A NEW APPROACH FOR THE ORGANIC-INORGANIC C-S-H

ABSTRACT

In order to synthesize organic layered calcium silicate hydrates (C-S-H), an alternative approach to the intercalation has been used. This approach allows covalent graft of organics on the dreierketten silicium-sheets of C-S-H, to create a true hybrid C-S-H.

This work presents a synthesis of an aminopropyl-hybrid C-S-H and its characterisation by X-ray diffraction and nuclear magnetic resonance. Although high aminopropyl contents have been investigated, the samples did not present evidence of demixion. It was possible to suggest structural models for these hybrids.

1. INTRODUCTION

Organic additives are commonly used to modify concrete properties, as for example fluidity, ease of placement, hardness, etc. Water-soluble polymers are designed to interact with the surface of hydrated Portland cement particles, and particularly with its major component: the calcium silicate hydrates (C-S-H). It has been proved, however, that the interactions between the polymers and the C-S-H are not the same as those found in clays [1, 2, 3]. More precisely, the intercalation onto the inner interlayer surface of the C-S-H is not clear, and may vary strongly with the nature of the polymer and the way the C-S-H is formed [4, 5].

One consequence is that we cannot ascertain that the adjunction of water-soluble polymer is a sure way to create an organic layered C-S-H, able to modify the whole material properties (since the macroscopic properties of a material are intimately linked to its structure).

An alternative to create a stable layered organic-inorganic C-S-H is to covalently graft organics on the dreierketten Si-sheets as shown in figure 1, to make a true hybrid C-S-H (h-C-S-H).

Figure 1. layer of hybrid C-S-H, with $\text{Si}[Q_n] = \text{Si}(\text{OSi})_n$

This approach has already been used to create various hybrid materials [6, 7, 8, 9], including organoclays [10, 11], and has led to various applications in ion exchange, catalysis, photonics, and coatings [12, 13].

Recently, Suzuki and Sinn synthesized a well-defined C-S-H with a Ca/Si ratio of 5/6 using sol-gel route [14]. This room-temperature three-step synthesis consists in: (a) hydrolysis of tetraethyl orthosilicate (TEOS) in solution, (b) addition of an aqueous solution of CaCl_2 , and (c) precipitation of C-S-H by addition of NaOH.

Using this method, the creation of h-C-S-H is possible by addition of trialkoxyorganosilane ($\text{RSi}(\text{OR}')_3$) in solution with TEOS during the first stage, which leads to the co-condensation of silicon alkoxides and the precipitation of h-C-S-H during the third stage.

This article reports the synthesis of hybrid C-S-H with various trialkoxyorganosilane/TEOS ratios, and their subsequent characterisation. The organic investigated (R) is the 3-aminopropyltriethoxysilane (ATES) $\text{NH}_2\text{C}_3\text{H}_6\text{Si}(\text{OC}_2\text{H}_5)_3$. The length of the aminopropyl radical is about 5 Å.

As the hybridization of C-S-H should result in some structural changes, X-ray diffraction was used to follow the modifications of the structural parameters, in particular to follow the expected increase in the c-axis spacing (d_{00l}).

The local environment of silicon, i.e. the way the atoms are connected to each other, was investigated by nuclear magnetic resonance (NMR), with $Q_n = \text{Si}(\text{OSi})_n$, and $T_m = \text{CSi}(\text{OSi})_m$.

2. EXPERIMENTAL

2.1. Synthesis

All the h-C-S-H samples have a fixed Ca/Si ratio of 5/6 but the C/Si ratio is variable. For each synthesis, the starting materials were commercial grades.

TEOS and trialkoxyorganosilane were pre-hydrolysed in an ethanol-water mixture at pH=1 for 1h (with ethanol/water ratio = 2). An aqueous solution of CaCl_2 was added to give a Ca/Si ratio of 5/6 and a water/alcohol ratio = 24, to completely hydrolyse the alkoxysilanes. The solution was then stirred for 1h. Next, 6 ml of a 8,3 M NaOH solution were added dropwise and the solution was stirred and aged for 12h.

The precipitate was separated by centrifugation, redispersed and washed in deionized water and centrifuged again, twice. Finally, the samples were dried with LiCl under relative vacuum.

2.2. Characterisation

X-ray measurements were made with an Inel CPS 120 detector (resolution of $0,029^\circ$), with a germanium monochromator to select the Cu $K_{\alpha 1}$ radiation. Powder samples were placed in 0,5 mm quartz capillary tubes.

Solid state ^{29}Si magic angle spinning nuclear magnetic resonance (^{29}Si -MAS-NMR) experiments were carried out on a Bruker DMX-300 spectrometer, operating at the frequency of 59,63 MHz, with a sample spinning frequency of 4 kHz. Tetramethylsilane was used as a standard.

3. RESULTS AND ANALYSIS

A C-S-H with Ca/Si ratio of 5/6 was synthesized as a reference. X-ray diffraction (figure 2) shows that the material is well defined, with broad reflections consistent with the low Ca/Si ratio tobermorite-like ordered C-S-H [15]. The basal reflection is at 13 Å.

Figure 2. Top: X-ray diffraction, Bottom: ^{29}Si MAS-NMR of the reference C-S-H (Ca/Si= 5/6)

^{29}Si MAS-NMR of the reference (figure 2) presents three distinct environments for the silicon: Q_1 at $-78,3$ ppm, Q_2 at $-84,2$ ppm, and Q_{2B} at $-80,7$ ppm. The relative proportions of those environments are $\text{Si}[Q_1]=27,1\%$ (the terminal site), $\text{Si}[Q_2]=60,0\%$ (dimer site), and $\text{Si}[Q_{2B}]=12,9\%$ (bridging site), which is in good agreement with the dreierketten structure with 5/6 Ca/Si ratio C-S-H [16, 17], as shown in figure 1. The proportion between Q_1 and the (Q_2+Q_{2B}) sites indicates that the average chain length is relatively short (seven silicon atoms), which is similar to the length of the Si chain in pozzolanic synthesized C-S-H.

Two compositions are presented for each of the organics: 20% and 40%, plus a 100% 3-aminopropyltriethoxysilane reference.

The XRD patterns (figure 3) of the 20 % and 40% aminopropyl samples are consistent with the pattern of the C-S-H reference, but they present atypical basal spacings: $16,5 \text{ \AA}$ for the 20% and 20 \AA for the 40%. The 100% ATES XRD pattern is not consistent with the C-S-H reference, although it presents a broad basal spacing at $16,3 \text{ \AA}$. It may be interpreted as an organoclay [10].

Figure 3. X-ray diffraction of ATES samples (with: # NaCl)

Thus, the observable effects on the structure of the presence of ATES of C-S-H are: no modifications in the $[hk0]$ reflections ($2\theta > 15^\circ$) and increase of the basal spacing $[00l]$, function of the ATES content. As no disorder is created in the lamella structure of the C-S-H, and as the basal spacing increases, this demonstrates the hybridization of C-S-H.

^{29}Si -MAS-NMR experiments (figure 4) confirmed the XRD results. The characteristic sites Q_1 , Q_2 , and Q_{2B} are still observable (at the same chemical shift observed in the reference), as well as a site T_1 at $-49,5$ ppm, which is related to an CSiOSi environment.

Figure 4. ^{29}Si -MAS-NMR experiments of ATES samples

The peak intensities change as the ATES content changes: an increase in the proportions of the $\text{Si}[\text{Q}_1]$ and $\text{Si}[\text{T}_1]$ sites are observable, as the proportions of $\text{Si}[\text{Q}_2]$ and $\text{Si}[\text{Q}_{2B}]$ sites decrease with the amount of ATES. Thus, the presence of ATES decreases the length of silicon chains. So an average chain in the 20% ATES sample is composed of four silicon atoms, whereas an average chain is reduced to three silicon atoms in the 40% ATES sample.

Without modifying the global structure of the C-S-H, the insertion of $\text{Si}[\text{T}_1]$ in the dreierketten structure modifies the local environment, thus the silicium chain length decreases as the ATES content increases. This is consistent with the presence of the organic CSiOSi group at the single $\text{Si}[\text{T}_1]$ site, i.e. at the end of the silicon chain, which confirms the hybridization of the C-S-H.

The evolution of the basal distances can be explained by using an h-C-S-H model: at low ATES contents, the interlayer between two neighbouring lamellae is not completely occupied by the aminopropyl radicals. Each radical can point out freely in the interlayer without steric restrictions due to facing radicals. The aminopropyl radicals are in a shifted configuration, and the basal distance increase is $3,5\text{\AA}$, compared to the reference. At higher ATES contents, the radicals are mainly in a face-to-face configuration, so the basal distance increase is doubled to 7\AA (figure 5).

Figure 5. h-C-S-H models, left: radical shifted configuration for low ATES contents; right: radical face-to-face configuration for high ATES contents

4. CONCLUSIONS

Hybrid calcium silicate hydrates were synthesized by co-condensation of 3-aminopropyltriethoxysilane (ATES) and tetraethyl orthosilicate (TEOS) by a sol-gel route. The materials obtained were layered organic-inorganic C-S-H, even for the high ATES content (40%), and did not present evidence of demixing. We proposed structural models consistent with the changes in basal distance: a radical shifted model for low ATES contents, and a radical face-to-face model for high ATES contents.

This simple processing route offers opportunities to explore the influence of nature, length, and quantity of radicals introduced in the nanostructure of C-S-H.

ACKNOWLEDGMENTS

The authors wish to thank B. Besson and F. Babonneau for assistance and discussions on the NMR experiments.

ABSTRACT

During the period 1997 – 1999, “popping” of plaster made with CEM II/A-L from the PPC Slurry factory was experienced. Pops typically 20- to 40 mm in diameter, but occasionally as large as 90 mm, appeared approximately three months after plastering. The number varied from building to building and even on the same wall. The nodules apparently responsible for the popping were visible in the pop craters and were up to 5 mm in diameter.

Initial analysis showed that the core of the popped material consisted predominantly of CaO and Ca(OH)₂. It was therefore concluded that the popping was caused by the hydration of free lime. However, the origin of nodules with high free lime content was not immediately apparent. It was reasoned that it was unlikely to be from the cement, since large particles could not pass through the trommel screens after the finishing mills.

Reflected light microscopy conducted on polished and etched specimens of the nodules showed the presence of clinker minerals and free lime. It was thought that these could represent lumps of cement that formed in the bagged cement. However, careful microscopic analysis proved that the nodules were solid clinker particles and chemical analysis showed that the nodules had a high LSF value.

Further investigation revealed that a small percentage of large clinker nodules and limestone particles had found their way into the cement. A systematic investigation was therefore carried out to establish why the large particles were not screened out after the finishing mill and also the reason for the high LSF value. Process control measures were immediately instituted to remove large particles from the finished cement.

1. BACKGROUND

Towards the end of 1997 popping of internal and external plaster (where CEM II/A-L 32.5 sold under the trade name “Surebuild” was used) was reported from most of the 60 units of a luxury townhouse development. Sporadic reports of plaster popping followed early in 1998. Soon complaints were received almost daily and by the first quarter of 2002 the total number of claims received was greater than 240.

Popping occurred mainly in the Midlands of Kwazulu-Natal, the provinces of Gauteng, Northern Cape and Free State and in Namibia. All the incidences could be linked to Surebuild manufactured at the PPC Slurry factory during the period 1997 – 1998.

2. MANIFESTATION

Popping was manifested by an almost circular piece of plaster, about 30 mm in diameter being pushed off leaving a cone-shaped crater (Figure 1 and 2). Either a black or yellowish orange nodule was usually found in the bottom centre of the crater. The nodules were up to 5 mm in diameter. In many cases they had disintegrated into an off-white powder. As many as 94 pops over an area of 4 m x 9 m were recorded.

Figure 1. Typical incidence of pops in plaster

Figure 2. Pop, 40-mm in diameter, with nodule of about 5-mm diameter in centre

3. NODULES

3.1 X-ray diffraction analysis

XRDA revealed that the nodules contained free lime, $\text{Ca}(\text{OH})_2$ and clinker minerals.

3.2 XRFA

The analysis of the yellowish-orange nodules, the black nodules and clinker particles in the 212-micron residue of Slurry Surebuild is presented in Table 1. Both nodule types had a typical clinker composition but the yellowish-orange type had an unusually high SO_3 content of 1.7%.

3.3 Reflected light microscopy

Microscopy confirmed that the nodules consisted of Portland cement clinker. The yellowish-orange nodules appeared to be under-burnt while the black nodules showed fusion of C_3S (Figures 5) All the nodules contained a high amount of free lime (Figure 7). Clinker particles in the surrounding plaster matrix were relatively coarse, had a normal clinker structure and were different in appearance from the nodules. The differences between the clinker composition of the cement used for the plaster and the two types of nodules that caused the popping were as follows.

Table 1. Chemical composition of a the two types of nodules clinker particles in the +212- μm residue of Slurry Surebuild

Analyte	Result, % (m/m), loss free:		
	Yellow nodule	Black nodule	Clinker
SiO_2	20.0	23.3	23.3
Al_2O_3	3.9	3.1	3.1
Fe_2O_3	2.4	2.2	2.2
Mn_2O_3	0.4	0.2	0.2
TiO_2	0.3	0.2	0.2
CaO	64.3	69.0	69.0
MgO	2.4	1.9	1.9
SO_3	1.7	0.2	0.2
K_2O	0.8	0.8	0.8
Total	96.3	100.9	100.9

3.3.1 Plaster matrix surrounding pops (Figure 4)

- a) Alite crystals predominated.
- b) Alite crystal size varied from fairly large (40 μm) to medium (20 μm) to small (less than 10 μm).
- c) Many alite crystals were fused (Figure 8).
- d) Small belite crystals were deposited on the fringes of the alite crystals.
- e) Very few regular alite crystals were observed.
- f) The interstitial phase, consisting of C_3A and C_4AF , was clearly visible.
- g) Very little free lime was observed

3.3.2 Soft, yellowish-orange nodules (Figure 3,5)

- a) The microstructure was very different from the average clinker microstructure.
- b) Regular alite and belite crystals did not form.
- c) Free lime was visible in the microstructure.
- d) The free lime hydrated very quickly on exposure to the atmosphere.

3.3.3 Black nodules (Figure 7 - the majority of nodules)

- a) The nodules consisted mainly of alite crystals that varied in size from 20 μm to 60 μm , the majority being between 20 μm and 30 μm .
- b) Many alite crystals were fused (Figure 8).
- c) Very few to no belite crystals were observed.
- d) The interstitial phase of C_3A and C_4AF was clearly visible throughout the nodules.
- e) The free lime content was very high and occurred both in clusters and as individual particles.
- f) It took about three weeks' exposure to the atmosphere to hydrate (etch) lime particles for identification by reflected light microscopy.

Figure 8. Brown, fused alite with some free lime in black nodule

4. CAUSE OF POPPING

The popping of the plaster was caused by large clinker particles (nodules) with a high free lime content. When the CaO reacted with moisture, expansion occurred locally according to the well-known reaction:

		CaO	+	H ₂ O	→	Ca(OH) ₂
Molecular weight, g	:	56.08		18		74.08
Relative density	:	3.30		1.00		2.24
Molecular volume, cm ³	:	16.99		18		33.08

The rate at which the popping occurred after plastering depended, amongst other factors, on whether the nodules were hard-burnt. Free lime that results from the under-burning of clinker during upset kiln conditions is usually reactive enough to hydrate during cement grinding or storage. The hard-burnt CaO, which can result from inadequate proportioning or blending of the raw mix, is generally responsible for the delayed hydration and expansion encountered during normal service conditions. Even hard-burnt lime, when milled fine enough and present in a relatively small amount, will not cause problems in practice on hydration. However, when the free lime is concentrated in large nodules, hydration will result in expansion in its immediate vicinity and consequent popping.

4.1 Process Control Investigations

As a result of these problems an audit of cement mills' operation was carried out. During this audit it was noted that there were pebbles in large quantities discharging from the mills. It was also observed that there were significant numbers of pebbles discharging from the packer screen discharge pipes. The members of the audit team found that it was an unusual event and required investigation. The pebbles were grey or brown internally and samples from the packer screen were taken to test for breakability. Reference samples were taken from the mill clinker feed systems and tested.

The findings of the tests were:

- All the nodules were clinker pieces and there were no dolomite or chert pieces, contrary to expectations
- The free lime was very much higher in the nodules than the clinker samples.

- The particles were somewhat elongated and smoothed as a result of their passage through the mills. The width of the particles was commonly 3 to 7mm and the length between 5 and 10mm.
- Hence it was concluded that the particles were passing through the mill screens into the product.
- Microscopic examination showed little or no belite but plenty of alite.
- Under 6.5X magnification there was a huge difference in the appearance of the clinker particles and the packer samples. The clinker was normal grey crystalline while the packer nodules were reddish brown and the brown colour was often streaky.
- Particles were often seen to consist of brown and black layers.

Mill inspections were carried out and a clear indication of the nature of the problem was evident from these inspections when it was clearly observed that clinker particles persisted through the mill first chambers.

Figure 9. Clinker particles in mill

Figure 10. Clinker particles from mill

On breaking them it was found that they appeared to be hard-burnt nodules having brown cores. On attempting to break these in the mill it was also obvious that they required an exceptional effort to break.

Inspection of the hardness of burning on the rotary kilns as measured by the litre weights showed that short periods of hard burning were common and observation of the samples with high results showed that they were brown inside and were hard to break. It was now obvious that a part of the clinker being produced was too hard for the mill's grinding ability. The observations led us to believe that hardness of burning was connected with the problem in some way. It was also obvious that the mill charge levels and unit masses were not suitable under these conditions.

In order to effect the grinding of these hard particles, mill average ball masses were increased and screen cloth in all screens were changed to a smaller size. As a second measure the kiln mix design and control of burning were changed to eliminate hard burning. Finally the highest possible proportion of cement was ground on closed circuit mills.

The pebbles arising from the cement mills were weighed routinely and expressed as a percentage of mill output. The clinker particles were removed and "steamed" in an open pan. The expansive nodules (those that disintegrated) were measured as a percentage of all the clinker nodules. This was used to calculate the potential pops per 10 m² of plaster. The graph below shows how effective the corrective action was on the cement mills.

POTENTIAL POPS PER 10 square metres of PLASTER

4.2 Investigations to Find the Source of the Expansive Nodules.

A number of investigations were undertaken to locate the source of these particles. These are briefly explained below.

4.2.1 Hard burnt particles

The particles found in the mills were very hard and it was first thought that they were caused by overburning. As a result a sampling program was carried out to isolate "Hard Burnt High Free CaO" particles. After some months of sampling some nodules were found on one kiln, but none were found on a larger kiln. The frequency and quantity just did not explain the severity of the problem in the cement. Also the presence of free lime just did not make sense with hard burning.

4.2.2 Testing of individual particles

A special Micro-XRF method was developed to individually analyse the particles discharging from the mills (particle masses were around 0,2 grams). This enabled a small sample to be used to categorise the particles into classes. These categories can be termed "High Free Lime High Lime" and "High Free Lime High Sulphur". This is given below in Table 2. A features which should be noted is the high free lime especially in the high lime family.

It could now be seen that these particles were of quite unusual composition and certainly unlike any normal clinker. Since the composition was similar to kiln dust, it was postulated that the origin could be as a result of kiln ring material originating in the alkali sulphate circulation phenomenon in rotary kilns.

Table 2. Chemistry of two families of particle: "High Free lime High Lime" and "High Free Lime High Sulphur"

	HFL HL	HFLHS
SiO ₂	15	21
Al ₂ O ₃	3	4
Fe ₂ O ₃	2	2
CaO	75	65
SO ₃	0	2
K ₂ O	0	1
TOTAL	98	98
FCaO	28	13
LSF	1.6	1.0
SR	2.7	30
AM	1.4	2.1
CaO/SiO ₂	4.9	3.1

4.2.3 Sampling of Ring Material Discharging from Rotary Kilns

Rotary kilns suffer instability due to the collapse of ring material which releases large volumes of kiln charge material which has built up behind the ring towards the feed end of the kiln and very close to the burning zone. These rings are due to the deposition of material entrained in the kiln gas stream.

The sampling of the ring material gave results very similar to the material of the individual particles analysed by the micro-XRF method. It was quite obvious that this was the culprit material and was assumed that it was from rings.

4.2.4 Sampling of in situ Rotary Kiln Rings

It was decided to confirm the findings by sampling in situ rings during kiln reline stops. These confirmed the findings. In fact it became clear that the rings nearest the burning zone were the source of the hard particles. These rings are hard and consist of layered brownish and black material. This layering had been observed in individual particles when subject to microscopic observation.

5. CONCLUSION

The hard particles were derived from the hard material in the rings, which form near the burning zone coating (but behind - the feed side). These would collapse at irregular intervals, particularly in large diameter kilns and would find their way into normal production clinker as small slabs and chunks. On entering the cement mills, this material would not be ground without special precautions described earlier.

We could now theorise that the material, which became entrapped in the kiln gas-stream consisted of volatile matter and the finer particles in the raw meal. Due to the poor homogeneity of the raw meal with respect to particle size of silica and calcite particles, the calcite would be preferentially entrained, resulting in material which is high in alkalis, sulfate and lime(CaO). Combination of the CaO could therefore not take place, resulting in very high free lime particles.

The hardness can be explained by the fact that the material had been exposed to near flame conditions and on deposition created these hard plate-like rings in the kiln.

Although it took time to identify the source of this material, the corrective action taken early at the cement milling stage completely cured the problem. Corrective action at the burning stage may be possible, but has not been attempted, as it would be complicated if not impossible.

ALKALI ACTIVATED FLY ASHES: PROPERTIES AND CHARACTERISTICS

A. Fernández-Jiménez¹ and A. Palomo²

“Eduardo Torroja” Institute (CSIC). PO Box 19002, 28080 Madrid, Spain.

ABSTRACT

The alkali activation of fly ashes is a chemical process by which the glassy structure of this material is transformed into a very well compacted cement. In general terms the activation process may be considered as a set of destruction-condensation reactions (including the destruction of the initial solid substance) that initially leads to a series of unstable structure units and later produces the formation of thixotropic coagulation structures which can condense to form the hydrated products. The main objective of the present investigation was to determine the existing relationship between the mineralogical and microstructural characteristics of pastes and mortars of activated fly ash and the mechanical properties of said materials as a function of the curing time and temperature. For this purpose a Spanish fly ash and a 8M NaOH solution were used. The results obtained show: (a) the curing time and temperature are especially important; (b) mechanical strengths are notably increased when particles with size higher than 45 μm are eliminated; (c) the main reaction product is an amorphous aluminosilicate gel having a structure similar to that of some zeolitic precursors: 3-dimensional glassy structures in which the Si occurs in a variety of environments with a predominance of $\text{Q}^4(3\text{Al})$ units at short curing times (5 and 8h) and $\text{Q}^4(2\text{Al})$ at long curing times (7 days). The Al is essentially tetrahedrally coordinated.

Keywords: Alkali activation, fly ash, polymerisation degree, mechanical strengths.

1. INTRODUCTION

The production of Portland cement consumes a lot of resources and energy and involves the emission to the atmosphere of CO_2 , SO_2 and NO_x . So, it is very important to look for new resources, (especially industrial by-products) and new environmental friendly technologies. Alkaline cements are interesting and alternative cementitious materials (1-10).

The alkali activation of fly ashes is a chemical process by which the fly ash (FA), when mixed with certain alkaline activators and cured under mild temperature conditions, generates very compact materials. In general terms the activation process may be considered as a set of destruction-condensation reactions (including the destruction of the initial solid substance) that initially leads to a series of unstable structure units and later produces the formation of thixotropic coagulation structures which can condense to form the hydrated products. This set of reactions can be divided into three consecutive stages: (1) Destruction-Coagulation; (2) Coagulation-Condensation; (3) Condensation Crystallisation (8).

With respect to the technological properties of the activated fly ashes it is worthy to mention that:

- A strong material with a network structure is obtained
- It looks like a ceramic: Smooth, glassy and shiny

- Waste materials are used for its fabrication
- The workability of the fresh mixture is very good at low liquid/solid ratios
- Short curing time (a few hours) is needed.

However the chemical and mineralogical composition of the reaction products from the activation of fly ashes have not still been studied in detail, and therefore, the hardening mechanisms of this material are not fully understood. It is partly due to the existence of a wide variety of compositions of fly ashes as well as to the different types of activators that can be used, and also because of the difficulty of studying the amorphous reaction products. Additionally it is also important to emphasize the importance of the curing conditions (time and temperature) in the activation of fly ash (9).

For this the main objective of the present investigation was to determine the existing relationship between the mineralogical and microstructural characteristics of pastes and mortars of an activated fly ash and the mechanical properties of said materials. The factors considered in this research were: curing time, curing temperature and particle size distribution of fly ash.

2. EXPERIMENTAL

A Spanish fly ash was used (the chemical composition is presented in Table 1) together with an 8M NaOH solution as alkaline activator. This fly ash is made up of cenospheres and pleuroospheres with a fraction of 78.5 wt % of particles sizes less than 45 μ m.

Table 1. Chemical composition of fly ash

	LoI	IR	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	K ₂ O	Na ₂ O
Fly ash	1.80	0.40	51.51	27.47	7.23	4.39	1.86	0.15	3.46	0.70

*Loss on Ignition *IR= Insoluble Residue

Mechanical properties of mortars made with activated fly ashes were determined from prisms (4x4x16 cm). The aggregate/fly ash ratio was always = 2/1, and the activating solution / fly ash ratio = 0.38. Some different curing conditions were applied to the prisms: two temperatures (65°C and 85°C), and some different times of reaction. Also, mortars with sieved fly ash (all particles smaller than 45 μ m) were prepared.

The mineralogical and microstructural characteristics of the final products were studied on small samples from pastes and mortars of alkaline activated fly ash. Pastes (cured at 85°C at different times of reaction) were frozen with acetone and ethanol, and finally vacuum dried. Later they were studied by XRD, FTIR, MAS-NMR (9, 11). The pore size distribution was determined in mortars samples by mercury porosimetry. Theses mortars were also studied by SEM/EDX techniques.

Finally the amount of water-soluble sodium of samples was analysed by ion chromatography. For this purpose three grams of alkali activated paste dried under vacuum to a constant weight, were mixed with 250 ml of desionised water. The mix was mechanically shaken during 3 hours and then filtered and leveled up to 500ml with deionised water.

3. RESULTS

3.1. Characterization of alkali activated fly ash

According to the XRD data the fly ash is basically a vitreous material with some minor crystalline phases: mullite (Al₆Si₂O₁₃) quartz (SiO₂), magnetite (Fe₃O₄) and hematite (Fe₂O₃) (see Figure 1 A). In Figure 1 the XRD patterns of the alkali-activated fly ash cured (with NaOH 8M at 85°C) for

different periods of time (2, 5, 8, 20h. and 7 days), are shown. The diffractogramme of a sample cured 20h at 85°C and then 6 days at 25°C is also shown in the same figure.

When the fly ash is put in contact with the NaOH solution and thermally cured an amorphous product is formed (alkaline aluminosilicate); the typical halo appearing in the XRD diffractogrammes gives evidence of this. Comparing the XRD pattern of the original fly ash with those of the hardened paste, it can be seen that the hardened materials contains quartz, mullite, etc (already existing in the starting ash); but also some new minor crystalline phases: hidroxisodalite and herchelite. The intensity of the peaks corresponding to these zeolites increases with the curing time (see Figure 1). Herchelite can be detected after 2 hours of reaction but hidroxisodalite was not detected until 8 hours. Formation of crystalline sodium carbonate was never detected.

Figure 1. XRD patterns: **A**, starting fly ash; **B**, alkali activated fly ash (AAFA) 2h. 85°C; **C**, AAFA 5h. 85°C; **D**, AAFA 8h. 85°C; **E**, AAFA 20h. 85°C; **F**, AAFA 20h. 85°C and then 6 days at 25°C; **G**, AAFA 7 days 85°C.

The FTIR spectrum of the starting fly ash as well as the spectra of AAFA materials are shown in Figure 2. The fly ash FTIR spectra is formed by one broad band at 1060 cm^{-1} , assigned to Si-O and Al-O vibrations and one small band at 454 cm^{-1} assigned to $\nu_4(\text{O-Si-O})$ bending modes of SiO_4 tetrahedra (12). In the activated fly ash samples the 1060 cm^{-1} band moves towards lower frequencies ($\sim 1000\text{ cm}^{-1}$) and the $\nu_4(\text{O-Si-O})$ band towards higher values (465 cm^{-1}). Additionally the band at 789 cm^{-1} in the starting fly ash due to AlO_4 vibrations disappears and a new band at around 730 cm^{-1} (associated with the presence of Al tetrahedrally coordinated in the alkaline aluminosilicate) appear (9).

The FTIR results (see Figure 2) are, once again, indicating the absence of formation of sodium carbonates. We consider it means that the polymerisation of aluminosilicate has consumed all the

sodium hydroxide present in the system. Finally stretching and deformation modes of water were detected at 3500 and 1600 cm^{-1} .

Figure 2. FTIR spectra: **A**, starting fly ash; **B**, alkali activated fly ash (AAFA) 2h. 85°C; **C**, AAFA 5h. 85°C; **D**, AAFA 8h. 85°C; **E**, AAFA 20h. 85°C; **F**, AAFA 20h 85°C and then 6 days at 25°C; **G**, AAFA 7 days 85°C.

The ^{29}Si MAS NMR spectrum of the starting fly ash displays a wide asymmetric signal formed by seven components (see Figure 3 **A** and Table 2). The peaks appearing to -84 , -93.6 , -98.6 , -103.4 ppm are assigned to the glassy part of the fly ash (15,16). The peak at -88 ppm is assigned to crystalline mullite (13) and finally the peaks respectively appearing at -108 and -115 are assigned to different crystalline silicates.

With respect to ^{29}Si NMR MAS spectrum of fly ash activated at 85°C for 2h (Figure 3, **B**) it can be observed that the intense signals of the starting fly ash at -84 -93.6 , -98.6 (previously assigned to the vitreous phase) have disappeared and a new peak at -96.5 ppm appeared. It can be thought that this transformation corresponds with the first stage of the reaction process of the fly ash in which the destruction of the bonds Me-O, Si-O-Si, Al-O-Al y Al-O-Si takes place as a consequence of the modification of the ionic force of the system (8).

After 5 hours curing time two peaks at -92.6 and -98.8 ppm appear (Figure 3 **C**). These peaks together with the one at -86 ppm can be assigned to formation of an intermediate amorphous alkaline aluminosilicate gel. This could correspond to the “*second coagulation-condensation stage*” (8).

The ^{29}Si NMR MAS spectra of fly ash activated at 85°C for 8 hours (Figure 3 **D**) shows intense signals about -93.5 ppm and -98.8 ppm and -103.9 ppm assigned to the formation of an amorphous alkaline aluminosilicate gel similar to natural minerals of the zeolite or feldspar types.

For curing times longer than 8 hours the position of the spectra signals does not modify significantly for the fact of increasing curing time; but the intensity of the peaks can change notably. For example, short curing times (5, 8h) (spectra **C** and **D**) involves the signal at $-93/94$ ppm being the most intense one. However for longer curing times (spectra **E**, **F** and **G**) the most intense peak is the one at $-98/-99$ ppm. These different intensities can be associated to different degrees of polymerisation of the alkaline aluminosilicate hydrate. It might mean that after 8 hours curing time (at 85°C), the last and long “*reaction stage of condensation-crystallisation*” (8) would have begun.

Therefore, sample cured 7 days at 85°C should have developed the maximum reaction degree. Effectively, this particular sample is the one presenting the maximum mechanical strength (Figure 6). The NMR spectra of this material (Figure 3 **G**) shows sharp peaks at -98 ppm, -93 ppm, and -104 ppm, all of them associated with the formation of the alkaline silicoaluminate. The assignment of these peaks is not still clear but according to published data (15,16), the peak appearing at -104 ppm could be assigned to $\text{Q}^4(1\text{Al})$ units, the peak appearing near -98 ppm to $\text{Q}^4(2\text{Al})$ and the one at -93 ppm to $\text{Q}^4(3\text{Al})$. These results would indicate that the main reaction products present a 3-dimensional glassy structure in which the Si occurs in a variety of environments but predominantly those of framework structures saturated in Al (i.e. $\text{Q}^4(2\text{Al})$ and $\text{Q}^4(3\text{Al})$) where the Al is essentially in the tetrahedral site.

In all cases the peak appearing at -88 ppm is assigned to inert mullite. By deconvoluting these spectra (see Table 2) it can be observed that the percentage of mullite in the fly ash ($\sim 11\%$) is similar to that obtained in the fly ash sample activated for 7 days at 85°C (11.79%). Finally the bands at $-108/-109$ ppm and -112 ppm are assigned to unreacted different crystalline silica, and the -81 and -84 ppm signals are assigned to the presence of residual silanol groups.

Figure 3. ^{29}Si MAS NMR spectra: **A**, starting fly ash; **B**, alkali activated fly ash (AAFA) 2h. 85°C ; **C**, AAFA 5h. 85°C ; **D**, AAFA 8h. 85°C ; **E**, AAFA 20h. 85°C ; **F**, AAFA 20h 85°C and then 6 days at 25°C ; **G** AAFA 7 days 85°C .

In Figures 4 and 5 some micro structural characteristics (studied through SEM/EDX) of alkali activated fly ash mortars are shown. The studied samples contain spheres (from the fly ash) joined to each other with a continuous mass of reaction product acting like a cement. On said matrix the presence of pores as well as some tracks left by the reacted ash spheres, can be observed. Inside these hemispherical tracks some groups of crystals (associated with the formation of zeolites, already detected through XRD) can be seen. Finally some crystals of mullite and some unreacted spheres (having high proportions of Al and/or Fe) have also been detected.

From Figure 4 it can be deduced that the main reaction product corresponds to a glassy (6, 9, 17) alkaline aluminosilicate whose average atomic ratios are close to: $\text{Si}/\text{Al} = 1.8\text{-}2.0$ and $\text{Na}/\text{Al} = 0.6\text{-}0.7$ (point A). Point B corresponds to some un-reacted fly ash ($\text{Si}/\text{Al}=1.38$, $\text{Na}/\text{Al}= 0.1$.) and point C corresponds to a crystalline zeolitic structure with $\text{Si}/\text{Al} = 2.23$ and $\text{Na}/\text{Al} = 1.47$. In pastes activated for 7 days at 85°C (see Figure 5) the main reaction product presents less Al ($\text{Si}/\text{Al} = 2.0\text{-}2.2$ and $\text{Na}/\text{Al} = 0.8\text{-}0.9$ (point A). Points B and C respectively correspond to crystalline zeolite (point B, $\text{Si}/\text{Al} = 2.72$ and $\text{Na}/\text{Al} = 1.06$; point C, $\text{Si}/\text{Al} = 2.08$ and $\text{Na}/\text{Al} = 1.48$), and finally point D corresponds to crystalline mullite.

Figure 4. Mortars samples of alkali activated fly ash. Activator: 8M NaOH. Curing: 20 hours at 85°C.

Figure 5. Mortars samples of alkali activated fly ash. Activator: 8M NaOH. Curing: 7 days at 85°C.

In Table 3 percentages of Na fixed in the activated fly ash pastes are shown. These results show that the percentage of fixed sodium increases with the curing time. After 2 hours of curing at 85°C (sample **B**) the percentage of fixed Na is higher than 55% of the Na initially added to the alkaline solution, but for a curing time of 7 days at 85°C (sample **G**), this percentage increases to 77.17%.

Table 3. Na content in the activated fly ash pastes.

	Samples

3.2 Mechanical strength and porosity of AAFA mortars

In Figure 6, values of flexural and compressive strengths of mortars prisms made of alkali activated fly ash are given as a function of the curing temperature and the reaction time. The results obtained show that both factors time and curing temperature, play a very important role in the fly ash activation process. When curing time and curing temperature increase, the mechanical strengths increase too. The most important variation of strength takes place between 5 and 20 hours of curing. After that the mechanical strengths increase slowly. Additionally, it can be observed that the increase of strengths at 65°C is not as quick as in the case of samples cured at 85°C.

An important factor that has been considered in this study is the particle size of the starting fly ash. In this fly ash the percentage of particles with a size bigger than 45 µm is about 20%. When these coarse particles are eliminated the mechanical strengths of the activated material increase by about 15% (flexural) and 30% (compressive) (see Figure 6).

Figure 6. Mechanical strength. The curing conditions were: **M1**, all time at 85°C; **M2**, 20h 85°C and then 25°C; **M3**, 20h 65°C and then 25°C; **M4**, mortars of activated sieved fly ash (<45 µm) cured 20h. 85°C and then 25°C.

In Figure 7 the total porosity and the pore size distribution are presented. It can be seen that mortars presenting the highest mechanical strengths are those presenting the lowest porosity and the highest percentage of small pores (between 0.1-0.01 μm).

Figure 7. Total porosity and pore size distribution of alkaline activated fly ash mortars. The curing conditions were: M1, all time at 85°C; M2, 20h 85°C and then 25°C; M3, 20h 65°C and then 25°C; M4, mortars of activated sieved fly ash (<45 μm) cured 20h. 85°C and then 25°C.

4. DISCUSSION AND CONCLUSIONS

The fly ash used in this study has a high fraction of glassy components together with a minor presence of crystalline phases: mullite ($\text{Al}_6\text{Si}_2\text{O}_{13}$) quartz (SiO_2), magnetite (Fe_3O_4) and hematite (Fe_2O_3). It means that it has high potential reactivity with alkalis. The reactivity can be enhanced by applying appropriate curing conditions and by controlling the specific surface of the fly ash.

The experimental results indicate that the curing time and the curing temperature play a determining role in the process of alkaline activation of fly ash. Increasing the time and the curing temperature the activation reactions are notably accelerated and consequently the gaining of mechanical strengths of the material is stimulated. Other important factor considered in this study (it will be reported with detail in a forthcoming publication) is the effect of particle size average of the starting fly ash on the development of activation reactions. The mechanical strengths are notably increased when particle sizes bigger than 45 μm . are eliminated. In this case compressive strengths reach 66 MPa for 1 day of curing (see Figure 6).

The main reaction product of alkali-activated fly ash is an alkaline aluminosilicate hydrate (6-10). Different microstructures can develop as a consequence of the reactive process. These products are amorphous to XRD but FTIR and ^{29}Si RMN MAS spectra show interesting information: The alkaline aluminosilicate presents a 3-dimensional glassy structure in which the Si occurs in a variety of environments. According with others authors (9,15) the structure contains Si and Al tetrahedra randomly distributed along the polymeric chains that are cross-linked so as to provide cavities of sufficient size to accommodate the charge balancing sodium ions. This arrangement leads to Si environments such as $\text{Q}^4(1\text{Al})$, $\text{Q}^4(2\text{Al})$ and $\text{Q}^4(3\text{Al})$. The predominance of the $\text{Q}^4(2\text{Al})$ or $\text{Q}^4(3\text{Al})$ depends on the polymerisation degree which depends on the curing conditions.

A relationship between the mineralogical and micro structural characteristics and the mechanical properties of pastes and mortars of activated fly ash has been established: At short curing times

(<8h), the percentage of $Q^4(3Al)$ units is higher than the percentage of $Q^4(2Al)$ units and the mechanical strength is relatively low. However when the curing time increases the percentage of $Q^4(3Al)$ is lower than $Q^4(2Al)$ and the mechanical strength goes up.

The study performed through SEM/EDX has also confirmed the existence of minor crystalline reaction products already detected by XRD (herchelite and hidroxisodalite) and non reacted cenospheres from fly ash (rich in Al and Fe).

Finally, results obtained from leaching tests of pastes have proved that the reaction products fix about 56% of the initial Na added to the system, after 2 hours curing. This percentage increases with the curing time (77.17% for 7 days at 85°C, see Table 3). However sodium carbonate was never detected at any of the studied samples.

ACKNOWLEDGEMENTS

The authors wish to thank the General Direction of Scientific Investigation for funding this research through the project COO-1999-AX-038 and the Comunidad de Madrid by the concession a postdoctoral grant associated with this investigation. They also thank Dr J Sanz and Dr I. Sobrados for the recording and discussion of MAS NMR spectra and J.L. Garcia and A. Gil for collaboration with mechanical tests.

ABSTRACT

The activation of metakaolin by alkaline solutions produces the formation of an inorganic polymer with excellent mechanical properties. When calcium hydroxide is mixed with the metakaolin, the reaction produced in the alkaline activation is somewhat different and the products formed consist of the inorganic polymer and C-S-H gel in different proportions (depending on the reaction parameters). Also the type of activator and its concentration result to have a determinant influence on the final product formed.

Metakaolin and metakaolin + calcium hydroxide mixes were activated with NaOH and NaOH+waterglass solutions of different concentrations and they were cured in an oven at temperatures lower than 85°C for between 2 and 24 hours

The aim of the investigation was to structurally characterise the materials formed in the process. Due to the amorphous character of the reaction products, NMR-MAS technique appeared to be the most suitable approach to characterise them, although supplementary studies were done by means of XRD and FTIR.

When the activator concentration is 5M or less, metakaolin activation (in the experimental conditions) occurs only to a minor extent. However, if lime is present in the system, activation takes place, CSH gel being the main reaction product. But if activator concentration is 8M or higher, metakaolin dissolution is very fast and the main reaction product is an alkaline aluminosilicate with high mechanical performance. The formation of CSH gel as the main or secondary reaction product (depending on the activation concentration) is also observed when lime has been added to the reaction mixture.

Therefore, a threshold OH^- concentration exists above which (independently of the lime presence among the reactants) the alkaline polymer is mainly formed. Beneath this $[\text{OH}^-]$ threshold (in the systems containing lime), CSH gel is the main reaction product.

The data collected from the NMR study provides a suitable information for establishing the different routes followed by the activation reactions of metakaolin depending on both the hydroxyl ion concentration of the system and the presence (or not) of lime in the reaction mixture.

1. INTRODUCTION

Thermal treatment of kaolin at temperatures between 450° and 750°C produces its complete dehydroxilation. This process involves the breakdown of kaolin structure and the formation of a quasi-amorphous material, named metakaolin (1).

Mackenzie et al (2) studied the process of dehydroxilation of kaolinite as a function of temperature. The increase of the temperature is responsible for the evolution of the coordination number of aluminium (octahedral in the original kaolin, pentahedral and tetrahedral in the resulting metakaolin), and is also responsible for the distortion of the original SiO_4 tetrahedra.

Granizo (3) characterised the metakaolin (produced by heating the kaolin at 750°C for 24 hours) by means of MAS-NMR. She observed in the ^{29}Si NMR spectrum a broad band centred at -107 ppm confirming the diversity of network environments and also the predominance of tetrahedra of SiO_4 in a three-dimensional structure. Additionally she observed the presence of 3 peaks in the ^{27}Al NMR spectrum (at 2.8, 28.3 and 56.1) respectively indicating the existence in the metakaolin of the three possible coordination states.

The activation of metakaolin by means of alkaline (caustic) solutions leads to high mechanical performance inorganic polymer (4). This polymer (alkaline aluminosilicate) can be considered as a precursor of other crystalline structures like zeolites or feldspars (5).

Glasser et al (6) point out that the alkaline activation of metakaolin (with $[\text{NaOH}] = 0,5\text{M}$), when in presence of $\text{Ca}(\text{OH})_2$, goes through very different ways. They observed the CSH gel being the main reaction product.

It is also very well known the formation of CSH gel when metakaolin is used as an admixture with Portland cement (7).

The authors of the present paper already showed (8) that the nature of the reaction products depend on the concentration of the alkaline solution used for activating the system (when concentration is higher than 10M, the main reaction product is the alkaline aluminosilicate; but if $[\text{OH}]$ concentration drops, then the main reaction product is the CSH gel).

The fact of dealing with amorphous compounds (not only the most important raw material but also most of the reaction products), makes difficult the characterisation studies. However MAS-NMR has proved to be a very efficient tool for solving the characterisation problem. In fact, bibliography on microstructural investigations of CSH gel through MAS-NMR is rapidly increasing (9, 10). The number of papers published on this alkaline aluminosilicate phase is small (11-13).

The aim of this investigation was to characterise through MAS-NMR the different products formed during the metakaolin activation (in the presence and the absence of calcium hydroxide) as a function of the Na_2O concentration.

2. EXPERIMENTAL

A number of metakaolin samples as well as metakaolin plus $\text{Ca}(\text{OH})_2$ samples, were activated with different NaOH solutions or with different sodium silicate + NaOH solutions.

The metakaolin was obtained after treating a Spanish kaolin (57% SiO₂ and 41,5% Al₂O₃) at 750°C for 24 hours.

In the case of the systems not including Ca(OH)₂, the metakaolin was mixed with the activating liquid (NaOH or waterglass + NaOH) in a liquid/solid ratio of 0.55. The resulting paste was kept at 85°C for 2 hours.

For the systems including calcium hydroxide first of all the homogenisation of solids was carried out (ratio: 1/1). After that, the activating solution was added (liquid:solid = 0.7) and the resulting paste cured at 45°C for 24 hours.

Whatever the system studied, the concentration of the NaOH solution used was 5M and 12M. The sodium concentration of the waterglass + NaOH solution was always 8M and 12M.

Finally, the whole of samples were studied through ²⁹Si and ²⁷Al MAS-NMR. Results were complemented by additional data obtained by means of XRD and FTIR.

3. RESULTS AND DISCUSSION

3.1 Activation with NaOH 5M

In the activation process of metakaolin with 5M sodium hydroxide, the hardening of the material is not achieved; there is insufficient precipitation of reaction products to produce mechanical strength.

Figures 1a) and 1b) show the spectra found for the starting material. From the NMR spectra given in Figures 2a) and 2b) it can be deduced that most of original metakaolin has not been attacked by the alkaline dissolution: the broad band at -107 ppm in the ²⁹Si spectrum and the octahedral signal of aluminium appearing at the ²⁷Al spectrum, are both signals which are found in the starting material. (Seen in Figures 1a) and 1b) and consequently confirm the low level of reaction of the metakaolin.

Figure 1. Original no activated Metakaolin (3).
a) ²⁹Si MAS-NMR spectrum and b) ²⁷Al MAS-NMR spectrum

It is true that the presence of (OH) groups in the system should favour the metakaolin dissolution due to the attack on the covalent bonds Al-O and Si-O (14); but it is also true that at this level of (OH) concentration the activation of the material is slow. Effectively, the absence of pentahedral aluminium (see spectrum ²⁷Al of Figure 2b) is indicating that the attack has taken place but it is also indicating that the solubilisation of aluminium selectively occurs as a function of the coordination number. Finally the modifications observed in the position of the signals of these spectra when compared with the starting material spectrum can be interpreted in terms of a deformation of the

silicon tetrahedra and aluminium pentahedra and octahedra of metakaolin because of its partial dissolution.

Figure 2. Metakaolin + (5M NaOH solution); 85°C for 2 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

However, when the material to be activated is a mixture of metakaolin and calcium hydroxide and the activator is again a 5M NaOH solution, the material becomes hardened. The NMR ^{29}Si spectrum of the reaction product (Figure 3a) shows three sharp and very well defined peaks at -82, -84 and -89 ppm, a broad band at -107 ppm and a small shoulder at -77 ppm. This last signal clearly modifies the slope of the spectral line.

Figure 3. Metakaolin + $\text{Ca}(\text{OH})_2$ + (5M NaOH solution); 45°C for 24 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

The broad band at -107 ppm can be assigned to a Q^4 structure with no substitution of aluminium, and can be due to the existence in the sample of a fraction of metakaolin which has not still been activated.

With respect to the three sharp peaks the following can be established: The signal at -89 ppm could correspond to the response originated by the presence in the samples of $\text{Q}^2(0\text{Al})$ units; the signal at -84 ppm, it could be assigned to a $\text{Q}^2(1\text{Al})$ structure; and finally the signal at -82 ppm could be interpreted as the presence of $\text{Q}^2(2\text{Al})$ structural units. The shoulder at -77 ppm could indicate the existence of $\text{Q}^1(1\text{Al})$ units.

This interpretation of the NMR ^{29}Si spectrum of Figure 3a) is in good agreement with the interpretations given by other authors (15, 16); and it reveals a very important fact: the main product of reaction when a mixture of metakaolin and $\text{Ca}(\text{OH})_2$ is activated with a 5M NaOH

solution, is a calcium silicate hydrate (CSH gel) very similar to that produced during the hydration of Portland cement (17). The structure of this product corresponds to a model of chains of SiO_4 tetrahedra which are partially substituted by AlO_4 tetrahedra. Said isomorphic Al substitutions could be responsible for the slight modification observed in the chemical shifts.

The NMR ^{27}Al spectrum of this sample presents two peaks at 9 and 58 ppm (see Figure 3b), respectively representing two types of coordination number of aluminium. The signal at 9 ppm is assigned to an octahedral network environment, and the signal at 58 ppm is indicating the existence of tetrahedral aluminium. This tetrahedral aluminium corresponds not only to the substitutions in the silicate chains but also to the aluminates in the non reacted metakaolin.

3.2 Activation with sodium hydroxide 12M

If we now increase the concentration of the activating solution to 12M and the solution is put in contact with the metakaolin (and calcium hydroxide is not present in the system), then a material with high mechanical properties is obtained. This is the opposite situation to that created when the NaOH activating dissolution was 5M.

The NMR ^{29}Si spectrum of the reaction product basically presents two sharp peaks respectively at -89.8 and -86.7 ppm (Figure 4a). Both peaks can be attributed to three-dimensional structures of SiO_4 tetrahedra with abundant aluminium substitutions: $\text{Q}^4(3\text{Al})$ units for the case of the peak at -89.8 (these units have been associated to a crystalline structure of the type of a zeolite like Hydroxisodalite or Faujasite, both compounds identified in the samples by means of XRD), and $\text{Q}^4(4\text{Al})$ units for the case of the peak at -86.7 (indicating the existence of an amorphous polymer with cementing properties and with a three-dimensional structure made of almost the same number of SiO_4 and AlO_4 tetrahedra).

Figure 4. Metakaolin + (12M NaOH solution); 85°C for 2 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

On the other hand, the absence of signals above -100 ppm, in the NMR ^{29}Si spectrum (Figure 4a), as well as the appearance of one only band in the NMR ^{27}Al spectrum, corresponding to the tetrahedral coordination of Al, (Figure 4b), are indicating the high degree of reaction reached by the system.

When activation of metakaolin is carried out with a 12M NaOH solution but in presence of calcium hydroxide, then in the NMR ^{29}Si spectrum appears an intense signal at -86.7 ppm (Figure 5a). It again indicates the formation of a product with three-dimensional structure at which the maximum aluminium substitutions takes place. Other less intense signal also appears at -82 ppm. It is associated with the presence of a phase with lineal structure and incorporating some AlO_4 tetrahedra

and basically formed by $Q^2(2Al)$ units. And finally a small shoulder at -78 ppm is interpreted as due to $Q^1(1Al)$ units.

The NMR ^{27}Al spectrum of this material (Figure 5b) presents only one peak at 61 ppm, characteristic of tetrahedral aluminium.

Figure 5. Metakaolin + $Ca(OH)_2$ + (12 M, NaOH solution); 45°C for 24 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

In few words: when the alkaline activation of metakaolin is carried out in the presence of calcium hydroxide, the main reaction product is that alkaline polymer of three-dimensional structure which is also produced in the absence of calcium hydroxide. It could be even thought that both materials, due to the similarity of ^{29}Si spectra of Figures 4 and 5, possess the same Si/Al ratio.

But the spectrum ^{29}Si of Figure 5 also presents a signal at -82 ppm. It has been interpreted as a signal belonging to the lineal structure typical of CSH gel. Additionally, the ^{27}Al spectrum shows the peak of the tetrahedral aluminium (there are no signs of non reacted metakaolin).

Therefore, it can be concluded that the alkaline activation of metakaolin with a NaOH solution (independently on the presence or absence of calcium hydroxide in the system) involves the formation of different products of reaction as a function of the concentration of the dissolution:

The presence of calcium hydroxide makes the CSH being the main reaction product in “low” alkaline medium (5M); but when $[OH^-]$ increases, the total desegregation of metakaolin is accelerated and because of the effect of the common ion the dissolution of the calcium hydroxide becomes impeded. In this situation, the only way for the reaction to progress is the formation of the alkaline aluminosilicate. The precipitation of this product involves the fixation of the OH groups

and consequently the hydroxyl ion concentration in solution drops; it means that more calcium hydroxide is dissolved and that calcium is now fixed with the still non precipitated silicates in the form of CSH gel.

3.3 Activation with a mixture of Waterglass + NaOH

When the activation of metakaolin is carried out with a mixture of waterglass and NaOH (concentration of the mixture = 8M), it could be initially thought that a mechanism of reaction similar to that previously mentioned would take place, since the [OH] value of this mixture is lower than the 5M NaOH solution. However, the material hardens regardless of the presence or absence of calcium hydroxide.

When the system is formed by metakaolin and [Na] = 8M (waterglass + NaOH), then the NMR spectrum ^{29}Si of the reaction product (see Figure 6a) presents a broad band at -90.7 representative of a structure containing Q^4 (3Al) units (three-dimensional structure of SiO_4 tetrahedra with 3 substitutions of aluminium). Additionally, the NMR ^{27}Al spectrum shows that the transformation undergone by metakaolin has been a very intense one since the tetrahedral peak of aluminium is the only signal appearing in such a spectrum (Figure 6b).

Figure 6. Metakaolin + ([Na] = 8M, NaOH+Waterglass solution); 85°C for 2 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

The presence of soluble silicates in the activating solution and the quick dissolution of the aluminium from the metakaolin supplies enough reactant species to the aqueous phase for producing the formation of the alkaline polymer. This early precipitation involves the displacement of chemical equilibrium towards a massive formation of reaction products.

The addition of soluble silicates to the activating solution slightly modifies the three-dimensional structure of the final reaction product when compared with the product obtained through activation with NaOH solution. The presence of soluble silicates produces Q^4 (3Al) structures, however the activation with NaOH solutions leads to structures mainly formed by Q^4 (4Al) units.

When calcium hydroxide is added to the system, the observed phenomenon is quite similar to the case of activation with a 5M NaOH dissolution. The NMR ^{29}Si spectrum of the reaction product (Figure 7a) shows a main peak at -81.8 ppm, interpreted as a signal corresponding to a Q^2 (2Al) structure, and other peak at -84.3 ppm also interpreted as a lineal structure formed by SiO_4 chain with few aluminium substitutions [Q^2 (1Al) units]. Finally the presence of a small shoulder at 78 ppm is interpreted as due to Q^1 (1Al) units.

The ^{27}Al NMR spectrum (Figure 7b) shows the tetrahedral coordination of aluminium in the reaction products (signal at 60.1 ppm) but no other coordination number.

Figure 7. Metakaolin + $\text{Ca}(\text{OH})_2$ + ($[\text{Na}] = 8\text{M}$, $\text{NaOH} + \text{Waterglass}$ solution); 45°C for 24 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

The explanation of the formation of a structure like the one of CSH gel instead of the alkaline polymer (main reaction product in the system without calcium hydroxide) should be again looked for in the $[\text{OH}]$ value. The $[\text{OH}]$ of the waterglass+NaOH dissolution used in this part of the investigation is lower than the NaOH dissolution used in the former part; and it means that the dissolution of the calcium hydroxide is not inhibited. Therefore, the existence of calcium ions in the aqueous phase together with silicate ions (from the waterglass) makes the CSH gel precipitate. This precipitation favours the dissolution of more calcium hydroxide and consequently the increase of pH. This pH increase accelerates the dissolution of metakaolin giving place to a intense formation of reaction products..... And this is the reason for which signals from unreacted metakaolin (-107 ppm in the ^{29}Si spectrum and 2.8 and 28.3 in the ^{27}Al spectrum) cannot be observed in Figure 7.

When the system of work is constituted by metakaolin (no presence of calcium hydroxide) and the activating dissolution is a mixture of waterglass and NaOH with a sodium concentration 12M, again the three-dimensional alkaline polymer is formed as deduced from the signal at -90.7 [$\text{Q}^4(3\text{Al})$ units] appearing in the NMR ^{29}Si spectrum of Figure 8a). This reaction product is similar to the one obtained in the same system but activating with lower Na_2O concentration.

Figure 8. Metakaolin + ($[\text{Na}] = 12\text{M}$, $\text{NaOH} + \text{Waterglass}$ solution); 85°C for 2 hours.
a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

When calcium hydroxide is present in the system the NMR ^{29}Si spectrum shows an intense signal at -81.8 ppm and a second signal at -85.2 ppm (Figure 9a). The NMR ^{27}Al spectrum presents one only signal at 61.7 ppm corresponding to the tetrahedral coordination of aluminium, (Figure 9b).

The main reaction product is the CSH gel with aluminium substitutions in the silicate chain (conclusion extracted from the signal at -81.8 ppm in the NMR ^{29}Si spectrum of Figure 9a). The shoulder at -85.1 ppm (same figure) is indicating the formation of a three-dimensional structure of SiO_4 tetrahedra linked to AlO_4 tetrahedra [Q^4 units] corresponding to the alkaline polymer. Again, the different proportion at which the reaction products appear (due to the presence of calcium ions) is a consequence of the chemical priority of CSH gel to be formed against the alkaline polymer in the presence of the dissolved ions.

Figure 9. Metakaolin + $\text{Ca}(\text{OH})_2$ + $[\text{Na}] = 12\text{M}$, NaOH +Waterglass solution); 45°C for 24 hours. a) ^{29}Si MAS-NMR spectrum and b) ^{27}Al MAS-NMR spectrum

This very important difference can also be observed when we modify the type of activator. In the presence of calcium hydroxide, when activation is carried out with NaOH , the main reaction product is the alkaline polymer (there is no dissolution of calcium hydroxide because of the “common ion” effect); but if the activator is a mixture of NaOH and waterglass the precipitation of CSH gel is easier than the precipitation of the alkaline silicoaluminate. However this difference does not exist when calcium hydroxide is not present at the system because in such a case the alkaline polymer is always formed.

Finally it is important to emphasise that the alkaline polymer is richer in aluminium when activation is carried out with NaOH than when is carried out with a mixture of waterglass and NaOH .

4. CONCLUSIONS

- Alkaline activation of metakaolin requires strong concentration of alkaline activator, which depends on the type of activator used. In the experimental conditions a $[\text{Na}] = 8\text{M}$ concentration of a mixture of NaOH + waterglass is needed and a 12M concentration if only NaOH is used.
- In absence of portlandite, the alkaline polymer obtained during the activation reaction is an amorphous compound. It is basically a three-dimensional network of SiO_4 tetrahedra [Q^4] at which Si atoms are partially replaced by Al atoms. The substitution is maximum $\text{Q}^4(4\text{Al})$ when the activator is NaOH and less if the activator is a mixture of waterglass + NaOH .
- The alkaline activation of mixtures of metakaolin + $\text{Ca}(\text{OH})_2$ produces CSH gel and/or alkaline polymer. The relative proportion of the reaction products depends on the concentration and type of activator. Then, the alkaline polymer will be the major phase when $[\text{OH}^-]$ inhibits (due to the common ion effect) the initial dissolution of calcium hydroxide.
- The alkaline polymer is always network structured presenting maximum substitution of SiO_4 by AlO_4 ; independently of the type of activator used.

ABSTRACT

Seven different pure Ferrites ($C_6A_xF_{3-x}$) with $x = 0; 0.5; 1; 1.25; 1.5; 1.75$ and 2 were synthesized at $1250^\circ C$. All synthesis products were characterized by X-ray diffraction including Rietveld-refinement and granulometry. The hydration behavior of pure Ferrites was checked by calorimetric investigation. The calorimeter used is a fully revised, more accurate and more user friendly apparatus based on an arrangement first described by Kuzel 1984 [1]. The improvements are: Sample pans made of polystyrene, defined docking of sample vessels to the thermopile, defined sample compaction, and use of a water dispensing aid. All measurements were carried out under isothermal condition at a temperature of $23.0 \pm 0.2^\circ C$ over a time range between 0 and 72 hours. Ferrites were hydrated with water and additionally in the presence of C_3A , Gypsum and water. Ferrites hydrated with water show a strong heat evolution and clear dependence on chemical composition of hydration heat during the first 72 hours and of time of maximum heat flow. Higher iron contents lead to lower heat evolution at later times. Ferrites hydrated with C_3A and Gypsum show two heat evolution maxima and increasing hydration heat with increasing iron content of Ferrites.

1. INTRODUCTION

The description of hydration properties – beside of rheologic properties - of formulations for construction chemistry products are important for their further optimization. Most of such formulations contain OPC in mixture with further inorganic and organic additives and mainly non reactive aggregates. The prediction of the influence of the inorganic and organic admixtures on the OPC is poor because the reaction mechanisms are misunderstood. This forced engineers to a mainly empirical procedure during the development of new binders. Basic research is necessary to understand the reactions of the hydraulic binders – in the given case of OPC – first with water and then with inorganic and organic additives. For this reason the hydration behavior of the main phases of OPC (Alite, Belite, Tricalciumaluminate and Ferrite) should be regarded in dependence of their chemical composition and their crystallographic modification.

Calcium aluminate ferrite phases are main phases not only in OPC but also in iron containing CAC. They form the solid solution series $C_6A_xF_{3-x}$ with $0 \leq x \leq 2.1$ [2,3]. Figure 1 shows a part of the ternary system $CaO - CA - C_2F$ after Newkirk and Thwaite 1958 where the solid solution series of Ferrites is located. Aluminum and iron are located at 2 different sites in the structure (Figure 2). One site is octahedrally coordinated by oxygen the other tetrahedrally. Depending on the cooling rate the ratio of aluminum and iron which is coordinated tetrahedrally or octahedrally can be changed. Due to the different scattering factors of Al^{3+} and Fe^{3+} the refinement of the occupancy

factors of both elements on tetrahedral and octahedral sites leads to a total amount of iron and aluminum in the structure. This allows calculation of the chemical composition of the Ferrite phase using Rietveld refinement of XRD data.

Figure 1. Pseudo ternary system CaO – CA – C₂F after Newkirk and Thwaite 1958

Figure 2. Orthorhombic (Ibm2) structure of Brownmillerite (C₆A_{1.5}F_{1.5}) given by [2]

The Al-rich members C₆A₂F to C₄AF constitute together with C₃A the so called interstitial phase in OPC clinker and give rise to very rapid setting. For that reason normally Ca-sulfate is added as a retarding agent.

The intention of this investigation was to collect data on the hydration behavior of the complete solid solution series of single phase compounds $C_6A_xF_{3-x}$ with $0 \leq x \leq 2$ by heat flow calorimetry. Furthermore ternary mixtures of $C_6A_xF_{3-x}$ ($x = 1.25/ 1.5/ 1.75/ 2$) with C_3A and gypsum (40ma. %:40ma. %:20ma. %) were investigated with a highly sensitive calorimeter [1,4]. Pure Ferrites were produced on a synthetic basis and characterized very well by means of chemical, granulometric and diffraction methods.

2. EXPERIMENTAL

2.1 Synthesis of Ferrites and C_3A

All syntheses were carried out in platinum crucibles using reagent grade chemicals:

20g batches of stoichiometric ratios of oxides and carbonates were mixed in a disc mill and heated in a laboratory furnace in a first step at 1000°C for calcining purposes. Further sintering was proceeded at 1250°C for 39h to 118h depending on chemical composition of the batch. Sintering was interrupted after 3-41 hours in the laboratory furnace. The duration is increasing with increasing aluminum content of the solid solution. Synthesis was finished after complete reaction to pure Ferrite, which was controlled by X-ray diffraction. Table 1 summarizes sintering time and number of grinding steps for all air quenched syntheses.

Table 1. Sintering duration and number of grinding steps

ss member	Sinter time [h]	Grinding steps
C_6F_3 (C_2F)	39	4
$C_6A_{0.5}F_{2.5}$	36	6
C_6AF_2	36	6
$C_6A_{1.25}F_{1.75}$	43	4
$C_6A_{1.5}F_{1.5}$	69	5
$C_6A_{1.75}F_{1.25}$	118	9
C_6A_2F	118	9

C_3A was synthesized by mixing stoichiometric ratios of Calcite and Corundum in a disc mill. The mixture was sintered using a platinum crucible inside a laboratory furnace which was heated to 1250°C for 118 hours interrupted by 5 grinding steps. Syntheses were air quenched.

2.2 XRD and Rietveld refinement

Pure Ferrites were checked by X-ray diffraction combined with Rietveld-refinement. X-ray diffraction was carried out on a Siemens D5000 using the following adjustments and front loading preparation technique:

Generator: 40 mA, 30 kV
Tube: fine focus
X-ray: Cu $K\alpha$
Filter: Ni
Slits: fixed 0.5°

Detector slit: 0.2°
Detector: scintillation
Step/Time: 0.02° 2 θ / 3s
Range: 10° - 65° 2 θ

All Rietveld calculations were performed using Topas 2.0 with fundamental parameter approach (FPA). The following parameters were refined:

- Background (Chebychev 5th order), zero shift, lattice parameters, scale factor, crystallite size, micro strain and occupancy factors for Al and Fe on tetrahedral and octahedral sites.
- Starting structural data for refinements were obtained from Colville (1970) [5] (SG Pcmn, ICSD 14296) for C_6F_3 and $C_6A_{0.5}F_{2.5}$ and from Colville and Geller (1971) [2] (SG Ibm2, ICSD 9197) for aluminum rich solid solution members.

2.3 Microcalorimetry

A new type of microcalorimeter to determine heat of reaction from hydration of hydraulic binders was described by Kuzel 1984 [1]. The isothermal calorimeter is based on the heat conduction technique. The heat, which is produced during a reaction has to pass a defined heat conduction path. Part of this defined path is a thermopile, which contains 71 in series connected BiTe semi conductor elements. Figure 3 displays a thermopile with the dimensions 32 mm x 32 mm x 4 mm.

Figure 3. Thermopile with 71 BiTe semi conductor elements in planar configuration

The change in temperature, caused by the heat evolution during the hydration, results in a thermovoltage of the thermopile, which can be measured by a digital voltmeter. These μV or nV data are recorded online by a PC. This thermovoltage can be transformed into heat flow by calibration. The noise threshold can be reduced strongly by connecting two thermopiles in difference. One thermopile is used by the sample the other by an inert reference. Sample and reference are placed in vessels on top of the sample holder which is pasted onto the thermopile. Figure 4 shows a sketch of the measuring system setup.

Figure 4. Complete calorimeter measuring system setup

The described calorimeter system is highly sensitive. A change of temperature in the sample vessel of $0.00002\text{ }^{\circ}C$ can be detected properly. Further development of the calorimeter equipment [4] led to the following improvements:

- ⇒ Polystyrene vessels replaced copper or gilded copper vessels. Neither sensitivity nor time constant was affected. Advantages are:
 - Vessels can be replaced after each measurement (no contamination)
 - polystyrene is proved to be inert under hydration conditions
 - sample can be observed during injection (translucent vessels)
- ⇒ Application of 75 μ l thermal conduction paste between vessel and sample holder with the help of a “HandyStep”. Advantages are:
 - strictly defined heat conduction path with a highly repetitive docking area
 - no pollution of the thermopile by oil of low viscosity
- ⇒ Application of a dispensing aid on top of the cement powder. Advantages are:
 - defined sample surface
 - no splashing of cement paste during injection of water
 - perfect lateral spreading of water in the sample vessel
 - fast and perfect mixing of solid and fluid components
 - injection of water is possible down to w/c ratio of 0.35
 - no contamination during compaction
- ⇒ Application of a compaction piston. Advantages are:
 - defined sample surface
 - defined density of the powder
- ⇒ User-friendly data acquisition and data evaluation by OMI and SEP software

The following specifications for the renewed configuration can be given:

Number of calorimetric channels	3
Operating temperature range	5 - 50 °C
Sensitivity at 23°C	about 90 μ V/mW
Time constant (polystyrene vessel)	75 s
Resolution	< 2 μ W
Noise level	1 μ W
Precision (heat flow)	< \pm 2 %
Liquid thermostat temperature fluctuation	\pm 0,02 °C
Maximum sample volume	9 ml
Measuring range (maximum)	2000 mW
Limit of detectibility	2 μ W

1g of Ferrite of different chemical composition was filled into polystyrene vessels after sample splitting. For Ferrite–Aluminate–Gypsum (40ma.%.40ma.%.20ma.%) mixtures 1.25 g batches were homogenized in a sealed bottle followed by manually stirring in an agate mortar. Homogenized batches were filled into polystyrene vessels. Before filling polystyrene vessels have been cleaned with isopropyl and deionized water and were dried at 45°C. Powders were subsequently covered with a dispenser-paper which was exactly fitted to the interior dimensions of the vessel and were compressed by a piston. Afterwards vessels are sealed with polystyrene lids. Deionized water is injected by a syringe. Water/solid ratio was 0.7 in all cases. Hydration temperature was 23.0 \pm 0.3°C.

3. RESULTS

3.1 Characterization of Ferrites

3.1.1 Characterization by XRD of the Ferrites

No additional phases (CF, C, C₃A, C₁₂A₇, CA) could be detected by quantitative Rietveld-analysis. Phase contents were in any case below the detection limits for all possible additional phases. Assuming equilibrium because of the long sintering times, the purity of all Ferrites is higher than 99.4 ma.%. Table 2 summarizes the refined lattice parameters and elementary cell volumina for synthesized Ferrites of different chemical composition.

Table 2. Refined lattice parameters and elementary cell volumina of Ferrites

SS	Lattice parameter in [Å] ± 0.001			V_{EC} [Å ³] ± 0.1
	a	b	c	
C ₆ F ₃ (C ₂ F)	5.600	14.767	5.428	448.8
C ₆ A _{0.5} F _{2.5}	5.595	14.679	5.403	443.7
C ₆ AF ₂	5.588	14.587 ± 0.002	5.375	438.1
C ₆ A _{1.25} F _{1.75}	5.579	14.550 ± 0.002	5.361	435.1
C ₆ A _{1.5} F _{1.5}	5.565	14.514	5.346	431.8
C ₆ A _{1.75} F _{1.25}	5.548	14.490	5.331	428.5
C ₆ A ₂ F	5.526	14.469	5.314	424.8

Elementary cell volumina decrease with increasing aluminum content. Lattice parameters show the same behavior. Lattice parameter c is linearly correlated to the chemical composition, while parameter a is over normal and b is under normal. Lattice parameter and elementary cell volumina simulate a perfect solid solution series. But there is a change in space group from C₆A_{0.5}F_{2.5} to C₆AF₂. The distribution of aluminum and iron might influence hydration properties of Ferrites. The result of the refinement of occupancy factors is displayed in Figure 5.

Figure 5. Refined occupancy factors of aluminum on tetrahedral (TS) and octahedral sites (OS)

Aluminum prefers tetrahedral sites. Ferrite of the chemical composition C₆A₂F is characterized by a nearly completely occupied tetrahedral site. In Table 3 the actual chemical composition of Ferrites are compared with the chemical composition calculated from refined occupancy factors.

Table 3. Comparison of actual chemical composition of C₆A_xF_{3-x} and chemical composition calculated from refined occupancy factors

Actual	Calculated
C ₆ F ₃	C ₆ A _{0.03 \pm 0.02} F _{2.97 \pm 0.02}
C ₆ A _{0.5} F _{2.5}	C ₆ A _{0.33 \pm 0.10} F _{2.67 \pm 0.10}
C ₆ AF ₂	C ₆ A _{1.04 \pm 0.06} F _{1.96 \pm 0.06}
C ₆ A _{1.25} F _{1.75}	C ₆ A _{1.30 \pm 0.03} F _{1.70 \pm 0.03}
C ₆ A _{1.5} F _{1.5}	C ₆ A _{1.57 \pm 0.07} F _{1.43 \pm 0.07}
C ₆ A _{1.75} F _{1.25}	C ₆ A _{1.74 \pm 0.05} F _{1.26 \pm 0.05}
C ₆ A ₂ F	C ₆ A _{2.04 \pm 0.10} F _{0.96 \pm 0.10}

Chemical composition calculated from occupancy factors is in any case in very good accordance to the actual chemical composition.

3.1.2 Specific surface area of Ferrites and C_3A

The Ferrites were ground to a comparable specific surface. The specific surface of Ferrites and C_3A was determined according to Blaine method (Table 4).

Table 4. Specific surfaces of Ferrites and C_3A according to Blaine

SS	Density [g/cm ³]	Spec. surface [cm ² /g]
C_6F_3	4.02	3820 ± 10
$C_6A_{0.5}F_{2.5}$	3.93	3810 ± 10
C_6AF_2	3.83	3830 ± 10
$C_6A_{1.25}F_{1.75}$	3.78	3820 ± 20
$C_6A_{1.5}F_{1.5}$	3.74	3840 ± 10
$C_6A_{1.75}F_{1.25}$	3.69	3830 ± 20
C_6A_2F	3.65	3820 ± 30
C_3A	3.03	5010 ± 30

3.1.3 Ferrous iron content

At a sintering temperature of 1250°C ferrous iron might be present due to reduction. Therefore Fe^{2+} content was checked by colorimetric method (Table 5).

Table 5. Fe^{2+} content of synthesized Ferrites

SS	Fe_2O_3 [ma.%]	FeO [ma.%]	Fe^{2+}/Fe^{3+} [%]
C_6F_3	58.7	0.65	1.1
$C_6A_{0.5}F_{2.5}$	50.7	1.32	2.6
C_6AF_2	42.1	1.57	3.7
$C_6A_{1.25}F_{1.75}$	37.6	1.07	2.9
$C_6A_{1.5}F_{1.5}$	32.9	0.80	2.4
$C_6A_{1.75}F_{1.25}$	27.9	0.83	3.0
C_6A_2F	22.8	0.97	4.3

Ferrous iron could be detected in all synthesized Ferrite samples. The content of ferrous iron is not coupled to the chemical composition of the Ferrite solid solution member. Lowest relative content of Fe^{2+}/Fe^{3+} was detected for C_6F_3 with 1.1 % and the highest for C_6A_2F with 4.3 %.

3.2 Heat flow calorimetry

3.2.1 Hydration of pure Ferrites

Ferrites of the composition $C_6A_xF_{3-x}$ were hydrated using a water/solid-ratio of 0.7 at a temperature of 23.0±0.3°C. All measurements were repeated 2-4 times. Precision of measurements was in any case excellent. Representative calorimetric plots are shown in Figure 6. Hydration of Ferrites is very fast for all chemical compositions. For aluminum rich members the main heat evolution period is finished within the first 20 minutes. Only the heat flow of C_6F_3 stays for 1 hour in the main period. The time of maximum heat evolution is shifted towards later times with increasing iron content. The maximum heat flow of the main reaction is reduced with increasing iron content. Only $C_6A_{1.75}F_{1.25}$ does not follow this trend (Table 6). The specific heat evolution of Ferrites of different chemical composition shows a different behavior. The heat of hydration up to 72 h is increasing from C_6F_3 towards $C_6A_{1.25}F_{1.75}$. Ferrites with higher aluminum content do not produce significantly higher heat of hydration during the first 72 h excepted sample C_6A_2F (Figure 7). The heat of hydration reaches its maximum for C_6A_2F after 72 hours with 485 J/g. C_6F_3 shows the lowest heat of hydration after 72 hours with 307 J/g.

Figure 6. Specific heat flow of Ferrites during the first 30 minutes after contact with water, w/s=0.7.

Table 6. Maximum of specific heat flow of Ferrites

SS	max. of spec. heat flow [mW/g]
C_6F_3	61 ± 2
$C_6A_{0.5}F_{2.5}$	138 ± 3
C_6AF_2	338 ± 4
$C_6A_{1.25}F_{1.75}$	520 ± 9
$C_6A_{1.5}F_{1.5}$	708 ± 19
$C_6A_{1.75}F_{1.25}$	654 ± 19
C_6A_2F	706 ± 30

Figure 7. Specific heat of hydration of Ferrites with increasing hydration times, (■) vessel broken

3.2.2 Hydration of Ferrite - C_3A - Gypsum mixtures

Ferrites with the chemical composition $C_6A_xF_{3-x}$ $1.25 < x < 2$ were hydrated with C_3A and Gypsum (40 ma.% : 40 ma.% : 20 ma.%) using a w/s-ratio of 0.7 at a temperature of 23.0 ± 0.3 °C. Figure 8 displays the heat evolution of Ferrite mixtures during the first 2 hours after contact with water.

Figure 8. Heat evolution of Ferrite mixtures during hydration w/s=0.7, 23°

Mixtures with C_6A_2F or $C_6A_{1.75}F_{1.25}$ are showing only one maximum of heat like the pure Ferrites. In contrast to this hydration of ternary mixtures of $C_6A_{1.5}F_{1.5}$ and $C_6A_{1.25}F_{1.75}$ with C_3A and gypsum is different. Both hydration reactions are characterized by a 2nd maximum of heat evolution within 1.5h. The overall heat flow is increasing with Fe-content of the solid solution members (Table 7).

Table 7. Specific heat of hydration during the first 72 h for Ferrite mixtures

Mixture		C_6A_2F C_3A Gypsum	$C_6A_{1.75}F_{1.25}$ C_3A Gypsum	$C_6A_{1.5}F_{1.5}$ C_3A Gypsum	$C_6A_{1.25}F_{1.75}$ C_3A Gypsum
Specific heat evolution [J/g] during 72 h	Average value	477	509	578	587
	max. deviation from average value	19	8	9	19

4. DISCUSSION

Hydration reaction with w/s ratio of 0.7 is always characterized by a maximum of heat flow within the first quarter of an hour of reaction. This is corresponding with the investigations of Drabik (1988) [6]. Puertas (1992) [7] determined the maximum heat flow of $C_6A_{1.5}F_{1.5}$ with comparable specific surface as 700 mW/g at 0.5 h which is in very good accordance to this work with 708 ± 19 mW/g. Only the heat flow maximum is shifted towards earlier times by about 5 minutes. The time of maximum heat flow is increasing from Al-rich to Fe-rich calcium aluminate ferrate phases, which is in accordance with former investigations [8,9,10]. XRD analysis of the hydrated samples of the single phase compounds $C_6A_xF_{3-x}$ with $x = 0/ 0.5/ 1.0/ 1.25/ 1.5/ 1.75/ 2$ yielded different hexagonal calcium aluminate hydrates like Mono-/Hemicarbonate, C_3AH_6 , as well as Goethite as crystalline hydration products. XRD investigation of hydrated Ferrites $C_6A_xF_{3-x}$ ($1 \leq x \leq 2$) after 96h showed predominantly iron substituted C_3AH_6 (compare Fortune (1983)[11]). Whereas

hydration of Al-rich C_6A_2F and $C_6A_{1.75}F_{1.25}$ leads to additional hexagonal calcium aluminate hydrates. In hydrated samples with Ferrites ($x > 1.5$) no hexagonal aluminate hydrates could be detected. This allows the assumption that higher iron content in Ferrites support the conversion from laminar hexagonal hydrates to Hydrogarnet. The only crystalline phases in hydrated C_6F_3 and $C_6A_{0.5}F_{2.5}$ could be determined as Goethite and Fe-Monocarbonate. Hydrogarnet could not be formed because of the low aluminum content and the low maximum heat of hydration which was lower than 140 mW/g. This interpretation is supported by the results of Ecker (1998) [12]. The 1st maximum of heat flow can presumably be attributed to formation of the hexagonal calcium aluminate hydrates and its conversion to C_3AH_6 , which is promoted at higher temperatures [7]. The specific heat of hydration of $C_6A_{1.5}F_{1.5}$ was 380 J/g after 24 hours and 420 J/g after 48 hours at 23°C. The 48 hours value is in fairly good agreement with the 500 J/g at 20°C published by Drabik (1988) [6]. But the comparison of heat of hydration is problematic because of the strong influence from parameters like specific surface, grain size distribution, w/s-ratio and temperature.

Reaction of Ferrite or C_3A with Gypsum was reported in [6,7,8,13]. Mixtures of C_3A and Gypsum show two heat flow maxima during hydration. The first one is attributed to the formation of Ettringite the second one to the conversion of Ettringite to Monosulfate (if sulfate content is too low). Mixtures of Ferrites, C_3A and Gypsum containing Ferrites of the composition $C_6A_{1.50}F_{1.50}$ and $C_6A_{1.25}F_{1.75}$ show the same behavior as C_3A - Gypsum mixtures. There is a first strong heat evolution after a few minutes caused by hydration of Ferrite, C_3A and Gypsum and the Formation of Ettringite. After 0.4 hours a second heat flow maximum is observed which can be attributed clearly to further hydration of Ferrite and C_3A and the conversion from Ettringite to Monosulfate. XRD investigations of 72 h hydrated products confirm this statement. The mixtures containing aluminum rich C_6A_2F and $C_6A_{1.75}F_{1.25}$ are missing a second heat flow maximum. XRD investigation of hydrated products after 72 h yielded Monosulfate as main hydration product. This proves that conversion from Ettringite to Monosulfate is accelerated by aluminum rich Ferrites. The specific heat evolution of mixtures containing Ferrites, C_3A and Gypsum after 72 h is increasing from 477 J/g to 587 J/g with increasing iron content of the Ferrites.

ABSTRACT

The main phase of high alumina cements Monocalcium aluminate (CA) is determining the setting behaviour of formulations in building chemistry applications. Until recently it was not completely understood what factors favour good performance of CA in technical products. In order to solve mechanisms occurring in technical systems with Calcium Aluminate cements (CAC) neat CA and several binary model systems of CA with admixtures of Li_2CO_3 and Ferrite phase $\text{C}_6\text{A}_y\text{F}_{3-y}$ ($0 \leq y \leq 1$) were analysed.

CA, iron doped $\text{CA}_{1-x}\text{F}_x$ solid solutions and three Fe-rich Ferrite solid solutions were synthesised in laboratory furnaces at 1250°C from reagent grade chemicals. All phases were checked for minor phases and characterised by X-ray powder diffraction analysis. Lattice and structural parameter refinement by Rietveld analysis with fundamental parameter approach (TOPAS) was employed for crystallographic characterisation of the anhydrous phases.

The neat compounds CA and iron doped $\text{CA}_{1-x}\text{F}_x$ and mixtures with Ferrite phases $\text{C}_6\text{A}_y\text{F}_{3-y}$ were hydrated at 23°C in a heat flow calorimeter based on a quadruple arrangement first described by [1] and fully revised by [2]. In accordance with calorimetric data the hydrating mixtures were investigated by X-ray powder diffraction analysis in order to interpret the recorded caloric effects of the first 48 hours of hydration.

1. INTRODUCTION

Monocalcium aluminate determines the setting behaviour of Calcium Aluminate Cements. CACs with different Fe-contents are used in a wide range of formulations for building chemistry applications because of their very rapid early strength. Hydration behaviour of formulations for construction chemistry products is a very important property for their further optimisation. Most formulations with CAC in the mixture are combined with inorganic and organic additives and non reactive aggregates. Until recently it was not completely understood how CA reacts in a cement paste and what factors favour good performance in technical products. The influence of admixtures on CAC is poor because reaction mechanisms depend on a combination of factors like homogenisation, grain size, hydration temperature, and w/s values.

In order to get an overview on mechanisms occurring in technical systems with Calcium aluminate cements (CAC), neat CA and three binary model systems of CA with Ferrite phases $\text{C}_6\text{A}_y\text{F}_{3-y}$ ($0 \leq y \leq 1$) were studied by heat flow calorimetry in combination with kinetic XRD investigations.

Table 1. Investigated model systems

Model system		Additive	w/s ratio
CA _{1-x} F _x with x = 0, 0.03, 0.06, 0.1		---	0.45
CA _{1-x} F _x with x = 0, 0.05, 0.1	+	Li ₂ CO ₃	0.45
CA	+	C ₆ A _y F _{3-y} with y = 0, 0.5, 1.0	0.5

2. EXPERIMENTAL PARAMETERS

2.1 Synthesis of the calcium iron ferrites CA_{1-x}F_x and C₆A_yF_{3-y}

CA, iron doped CA_{1-x}F_x solid solutions and three Fe-rich Ferrite solid solutions were synthesised in laboratory furnaces at 1250°C from reagent grade chemicals by solid state reaction.

Table 2. Synthesis parameter for the synthetic CAC clinker phases

Phase	Trivial name	Temperature [°C]	Synthesis time [h]	Grinding
CA _{1-x} F _x	Monocalcium-aluminate	1250	16	5 min every 4h
C ₆ A _y F _{3-y}	Ferrite phase	1250	70	10 min every 12h

All pure synthesised phases were ground in a disk mill (agate, 50g, 30min) and sieved <36µm prior to all the following experimental procedures.

2.2 X-ray diffraction powder analysis

The synthesis products from CA_{1-x}F_x and C₆A_yF_{3-y} solid solutions were checked for minor phases and characterised by X-ray powder diffraction analysis. Preparation of the investigated samples, which were ground in a disc mill to get the required grain sizes for X-ray powder diffraction, was performed in frontloading technique. XRD data were collected using a D5000 Bragg-Brentano diffractometer with CuK_α-radiation.

For XRD data collection for Rietveld analysis the fixed slit arrangement was utilised. The qualitative phase composition of hydrated samples from calorimetric experiments was investigated after 4 days. XRD patterns were recorded with V20 slit and 0.6mm receiving slit arrangement.

Table 3. XRD instrumental conditions

	Rietveld refinement	Qualitative phase analysis of hydrated samples
Tube voltage	40 kV	40 kV
Tube current	30mA	35mA
Time/step	3s	2s
Step width	0.02° 2θ	0.02 °2θ
Divergence slit	0.5°	V20
Receiving slit	0.2 mm	0.6mm
Monochromator	Ni-filter	Secondary graphite
Range of scan	10-65 °2θ	5-60 °2θ

2.3 Rietveld refinement of XRD data

Lattice and structural parameter refinement by Rietveld analysis with fundamental parameter approach (TOPAS) was employed for crystallographic characterisation and for determination of the solid solution limit of the calcium aluminate ferrite solid solutions. The following ICSD-data were used for the structural refinement:

Table 4. Used structure models from the ICSD- database [3]

Phase	ICSD- Code	Reference
CA	260	Hörkner & Müller-Buschbaum (1976) [4]
$C_6(A,F)_3$	9197	Colville & Geller (1971) [5]
C_2F	14296	Colville (1970)[6]
CaO	61550	Natta & Passerini (1929) [7]

2.4 Specific area analysis

The specific area of the synthesised calcium aluminate ferrites was determined by Blaine method.

2.5 Heat flow calorimetry

For the hydration of the model systems a heat flow calorimeter operating in isothermal mode was employed [2]. Three samples can be investigated simultaneously. The temperature during hydration was kept constant at a value of $23.0^\circ\text{C} \pm 0.3^\circ$. The deionised water used for hydration experiments was injected with a syringe through the top of polystyrene vessels. Table 5 summarises the instrumental parameter.

Table 5. Instrumental parameter of the heat flow calorimeter

Hydration time [h]	48-100
Integration time / cell [s]	5
Interval time [s]	19

3. RESULTS

3.1 Characterisation of $CA_{1-x}F_x$ by XRD-analysis

The substitution limit of $CA_{1-x}F_x$ was determined from the refined cell volume of the solid solutions with $x = 0, 0.3, 0.5, 0.6, 0.1, 0.15$, and 0.20 . In Figure 1 the determined cell volumes are plotted against the iron oxide ratio in the synthesis mixture. Standard deviation from six independent preparations and refinements was $\pm 0.015 \text{ \AA}^3$. The cell volumes increase with rising iron ratio, up to a composition of 11.7 ± 0.2 mole% Fe_2O_3 substitution. With higher Fe_2O_3 contents no further increase of the lattice parameter could be detected but increasing amounts of $C_2(A,F)$ and CF_3A .

Figure 1. Determination of substitution limit of Fe_2O_3 in $CA_{1-x}F_x$

3.2 Characterisation of $C_6A_yF_{3-y}$ by XRD-analysis

For refinement of $C_6A_yF_{3-y}$ with $y=0$ and 0.5 the structure data of Colville [6] and for $y=1$ the data of Colville and Geller [5] were used. Figure 2 shows the average values of lattice parameter refinements from four measurements of each of the three solid solution members plotted versus to the chemical composition. Standard deviations of lattice parameter and of the cell volumes are very low with 0.001 \AA and 0.1 \AA^3 .

Figure 2. Average values of lattice parameter refinements from four measurements of each of the three solid solution members plotted versus the chemical composition

3.3 Heat flow calorimetry of $CA_{1-x}F_x$ pastes at $w/s=0.45$

Neat CA pastes with w/s ratio of 0.45 and specific surface area of $4000 \text{ cm}^2/\text{g}$ show no reproducibility with respect to the length of induction period and the time of maximum heat evolution t_{\max} (Figure 3). During the induction period heat flow is very low. Additionally to the results in Figure 3, another batch of CA was hydrated at different w/s values from 0.4 to 2.5 and a specific surface area of $2200 \text{ cm}^2/\text{g}$. The determined average values from 245 to $264 \text{ J/g} \pm 20 \text{ J/g}$ give rise to the assumption that neither constant w/s nor specific area values play a dominating role with respect to reproducibility of CA hydration.

Figure 3. Heat flow diagrams of CA($T = 23^\circ\text{C}$, 100h , $w/s = 0.45$)

With increasing iron content of the solid solution, e.g. $CA_{0.94}F_{0.06}$, with w/s ratio of 0.45 and specific surface area of $4000 \text{ cm}^2/\text{g}$ the hydration again shows no reproducibility with respect to the length of the induction period and the time of maximum heat evolution (Figure 4).

Figure 4. Heat flow diagrams of $CA_{0.94}F_{0.06}$ ($T = 23^\circ\text{C}$, 100h, w/s = 0.45)

The induction period lies between 11.9h (CA) and 16.9h ($CA_{0.94}F_{0.06}$). After investigation of the different solid solution members of $CA_{1-x}F_x$ with $x = 0, 0.03, 0.06, 0.1$ with w/s=0.45 we could not determine a correlation of average specific heat and the time of maximum heat flow with the Fe-content (Figure 5). The average value of maximum heat flow increases up to $CA_{0.94}F_{0.06}$ and slightly decreases for $CA_{0.90}F_{0.10}$ but the standard deviations are overlapping and therefore no general statement on a correlation can be concluded. An influence of Fe-content on hydration behaviour of $CA_{1-x}F_x$ could not be observed.

Table 6. Heat flow values of CA and iron doped $CA_{1-x}F_x$

Specific heat flow [J/g] of $CA_{1-x}F_x$ with $x = 0, 0.03, 0.06, 0.1$				
$T = 23^\circ\text{C}$, 100h, w/s = 0.45				
Composition of solid solution	CA	$CA_{0.97}F_{0.03}$	$CA_{0.94}F_{0.06}$	$CA_{0.90}F_{0.10}$
Specific surface area [cm^2/g]	4000	4024	3999	4091
\varnothing Specific heat flow H_{100} (6 data sets) [J/g]	340	331	320	358
Minimum value[J/g]	307	308	273	343
Maximum value[J/g]	352	346	353	372
Max. deviation from \varnothing specific heat flow	33	23	47	26
Standard deviation[J/g]	15	14	25	11

The average values of overall heat evolution after 100h with a standard deviation determined from six measurements of 11-25 J/g (Table 6) is better reproducible than the time of maximum heat flow t_{max} (Figure 5).

Figure 5. Comparison of average H_{100h} and t_{max} of $CA_{1-x}F_x$ with $x = 0, 0.03, 0.06, 0.1$ at $w/s=0.45$

3.4 Heat flow calorimetry of $CA_{1-x}F_x$ pastes with 0.02% Li_2CO_3 -solution at $w/s=0.45$

With the application of aqueous 0.02% Li_2CO_3 -solution instead of pure H_2O for heat flow calorimetry of the solid solution $CA_{1-x}F_x$ ($x = 0, 0.05, 0.1$) with w/s ratio of 0.45 and specific surface area of 3266 to 3421 cm^2/g , the hydration shows good reproducibility with respect to the average values for the heat flow of $CA_{1-x}F_x$. In Figure 6 the heat flow diagram of CA hydrated with aqueous 0.02% Li_2CO_3 -solution is plotted. After injection only a short induction period was observed with heat flows from 2.5-6.5 mW/g.

Figure 6. Heat flow diagram of CA accelerated with Li_2CO_3 -solution

The standard deviations and the values for maximum deviation from average specific heat are noticeably lower than for hydration with pure H_2O . The time of maximum heat evolution is shifting to 2.1h (CA), 3.7h ($CA_{0.95}F_{0.05}$), and 3.1h for $CA_{0.90}F_{0.10}$ solid solution (Figure 7). The induction period is reduced and the times are much more reproducible by addition of Li_2CO_3 -solution.

But again no correlation time of maximum heat evolution with the Fe-content of the solid solution could be observed.

Figure 7. Comparison of average H_{48h} and t_{max} of $CA_{1-x}F_x$ with $x = 0, 0.03, 0.06, 0.1$ at $w/s = 0.45$ with aqueous Li_2CO_3 -solution

The average values for overall heat flow has the lowest values for CA and is increasing with the Fe-content of the hydrated $CA_{1-x}F_x$ solid solution member from 304 to 331 J/g. But standard deviations of $CA_{0.95}F_{0.05}$ and $CA_{0.90}F_{0.10}$ are overlapping slightly and specific surface area of $CA_{0.90}F_{0.10}$ is higher than for $CA_{0.95}F_{0.05}$. Because of the experimental data only the difference between CA and $CA_{0.95}F_{0.05}$ could be determined by heat flow calorimetry.

Table 7. Heat flow values of CA and iron doped $CA_{1-x}F_x$ accelerated with Li_2CO_3 -solution

Specific heat flow [J/g] of $CA_{1-x}F_x$ $x = 0, 0.05, 0.1$

3.5 Heat flow calorimetry of CA with different Ferrite solid solutions at $w/s=0.7$

Ferrites of composition C_6F_3 , $C_6A_{0.5}F_{2.5}$ and C_6AF_2 (spec. surface area ~ 3800 cm²/g) were mixed with CA (spec. surface area ~ 4400 cm²/g). Ferrite to CA ratio of the mixes was 30:70. Three mixes were hydrated at 23°C with w/s value of 0.5 in the heat flow calorimeter from 0-72h.

For Ferrite $C_6A_{0.5}F_{2.5}$ in mix with CA the induction period of hydration is finished after 6.5h and the time of maximum evolution can be set at 15.7-17.4h. After 25h the heat flow is very low with 0.4 ± 0.1 mW/g. In Figure 8 are plotted the heat flow diagrams of this mix for three measurements. The maximum heat flow and the times of maximum heat flow show good reproducibility.

Figure 8. Heat flow diagrams of CA- $C_6A_{0.5}F_{2.5}$ -mix70:30 ($T = 23^\circ\text{C}$, 72h, w/s = 0.5)

Hydration reactions of CA in mixes with the three Fe-rich Ferrites are not very different with respect to the value and the time of maximum heat flow (Figure 9). The overall heat of hydration after 63 h decreases slightly with the Fe-content of the Ferrites in the mixture with CA (Table 8). During the induction period the heat flow is very low.

Figure 9. Heat flow diagrams of all mixes of CA with different Ferrite solid solutions; w/s = 0.5

Table 8. Specific heat flow H_{63} of CA with different Ferrite solid solutions; w/s = 0.5

Standard deviation[J/g]	4	3	11

3.6 Qualitative XRD-analysis of the hydration products from heat flow calorimetry

Qualitative XRD investigation of the hydrated samples could show that C_2AH_y , CAH_x and AH_3 are forming from $CA_{1-x}F_x$ and mixtures with $C_6A_yF_{3-y}$. Although C/A value of the mixture of CA with ferrite was greater than for pure $CA_{1-x}F_x$ no difference in phase composition of the hydrated phases could be determined for this two-model system. In the case of the samples $CA_{1-x}F_x$ hydrated with 0.02% Li_2CO_3 the phase CAH_x could not be observed.

Table 9. Phase composition of hydrated samples from calorimetric investigations

Model system	w/s ratio	$CA_{1-x}F_x$	$C_6A_yF_{3-y}$	C_2AH_y	CAH_x	AH_3
$CA_{1-x}F_x$ (x = 0, 0.03, 0.06, 0.1)	0.45	X	.-	X	X	X
$CA_{1-x}F_x$ (x = 0, 0.05, 0.1) + 0.02% Li_2CO_3	0.45	X	.-	X	.-	X
CA + ($C_6A_yF_{3-y}$ with y = 0, 0.5)	0.5	X	X	X	X	X

4. DISCUSSION

Neat pastes of $CA_{1-x}F_x$ (x = 0, 0.03, 0.06, 0.1) with w/s ratio of 0.45 and specific surface area of $4000 \text{ cm}^2/\text{g}$ are showing no reproducibility of hydration behaviour. Neither length of induction period, overall heat of hydration nor time of maximum heat flow are showing a clear trend with increasing Fe-content of the solid solution [8]. This has not been reported yet and has absolutely to be taken into account when discussing hydration of CA. Our investigation could show that in spite of constant temperature, grain size distribution, and w/s value, the hydration can not be characterised to follow a certain course. Under the assumption of ideal reproducibility of preparation and taking into account the highly sensitive calorimeter arrangement with outstanding reproducibility we could only attribute this to phase depending on local and global effects. After hydration of $CA_{1-x}F_x$ at 23°C the hydrates CAH_x (x=7-10) and C_2AH_y (y≈8) were identified by X-ray diffraction analysis. C_2AH_y is known for better nucleation properties than the less CaO-containing CAH_x [9]. Investigation of synthetic iron free CAC mixtures led to the same not reproducible results for length of induction period and time of maximum heat evolution [10]. The observed formation of predominantly CAH_x in our investigated hydrated samples is another indicator for too low CaO/ Al_2O_3 -ratio being responsible for poor reproducibility of hydration.

Hydration experiments of the other two model systems are showing the expected increase in reproducibility with addition of Li_2CO_3 -solution and with addition of Ferrites. Hydration of CA is little accelerated by Ferrite phase and very strongly accelerated by 0.02% Li_2CO_3 -solution.

The accelerative effect of Li-salts is attributed to an elimination of the nucleation barrier by formation of Li-metahydrate, which is acting as nucleus for heterogeneous nucleation [9]. In the Li-accelerated system C_2AH_y could be determined as the only calcium aluminate hydrate phase. The absence of CAH_x is indicative of a more reproducible hydration behaviour.

Hydration reactions of CA in mixes with three Fe-rich Ferrites (70:30) exhibit only small differences. The mixtures were chosen to simulate hydration of Fe-rich CAC. In any mix with Ferrite CA is influenced by addition of the CaO-rich phase with shortening of the induction period and by producing a more repeatable course of hydration. Heat evolution and the time of maximum heat flow are not dependent on Fe-content of the Ferrite [11]. With our experiments we could show that CA hydrates more reproducibly in the presence of a CaO-rich phase. From investigations of several calcium aluminates (C_3A , CA, CA_2) it is known that CA_2 is hydrating less reactively than CA and C_3A is more reactive than CA [12]. This allows the conclusion that CaO/ Al_2O_3 -ratio of the

bulk composition favours the formation of C_2AH_y which is more spontaneous forming than CAH_x . But Ferrites are less accelerative than 0.02% Li_2CO_3 -solution.

From our studies on hydration of CA with inorganic additives we can conclude that there are at least two mechanisms responsible for accelerating CA and getting more repeatable hydration behaviour:

- CaO-content of the bulk composition which must support higher CaO-concentration after addition of H_2O
- Nucleation of C_2AH_y is processing more reproducibly than nucleation of CAH_x . For that reason any change in the hydrating system which is favouring the formation of C_2AH_y leads to acceleration and better repeatability (as shown with addition of Li_2CO_3 -solution)

QUANTITATIVE PHASE ANALYSIS OF VARIOUS FE-RICH CALCIUM ALUMINATE CEMENT CLINKERS BY SELECTIVE DISSOLUTION AND XRPD

Friedlinde Goetz-Neunhoffer

Department of Mineralogy, University Erlangen, Germany.

E-mail: goetz@geol.uni-erlangen.de

ABSTRACT

A technical problem of manufacturing Fe-rich Calcium Aluminate Cement (CAC) by fusion, which was not considered, is that phase composition depends strongly on production conditions. Chemical composition of the raw meal mixture (chemical parameter) together with kiln type, kiln atmosphere, and cooling of the clinker (process parameter) are the most determining parameters for phase composition and solid solutions with ferric or ferrous iron. Since constant quality is very important for usage in building chemistry applications of CAC, many attempts for quantitative phase analysis have been started in the last years.

For this investigation quantitative phase compositions of four Fe-rich CAC clinkers from different manufacturers were determined by calibrated Rietveld analysis using TOPAS. Some of the minor phases could only be detected in CAC clinker after selective dissolution of the main phases C(A,F) and Ferrite phase $C_4A_{2-x}F_x$. The range of C(A,F) content lies within 45-51ma.% whereas the Ferrite phase varied between 10 and 21ma.%, which implies higher dependence of the Ferrite phase on chemical and production parameters. Perovskite together with the structural related C_3FT -phase could be quantified in all Fe-rich CAC clinkers with 5-13ma.%.

1. INTRODUCTION

Almost all producers use the fusion process to produce Fe-rich CAC from the raw mixture of limestone and bauxite in L-shaped reverberatory kilns. The molten product is cast into pans and allowed to cool and solidify as clinker. Lime and Al_2O_3 as the principal oxides combine to give Monocalcium aluminate C(A,F) as the principal reactive phase in the cement, which reacts with water to form calcium aluminate hydrates. The alumina content of the raw materials mixture dictates the amount of hydraulic C(A,F) in the clinker. Selection of raw materials and the optimised chemical composition of the raw mix therefore play a major role for final product properties. From investigation of new production methods it is now known, that kiln atmosphere also very much determines the mineralogical phase composition of Fe-rich CAC [5]. The same raw meal can lead to quite different phase compositions in reducing kiln atmospheres. In order to guarantee constant quality of Fe-rich CAC, the amount of the main hydraulic phases, like C(A,F) and $C_4A_{2-x}F_x$, must be controlled by the producer. The need for constant quality is very high for application of Fe-rich CAC in building chemistry special products (e.g. tile adhesives, tile grouts, floor levelling compounds, rapid floor screeds, repair mortars).

2. PREFACE TO EXPERIMENTAL PROCEDURE

Besides C(A,F) and $C_4A_{2-x}F_x$ up to 9 minor phases occur in Fe-rich CAC clinker, which leads to strong peak overlapping in X-ray powder patterns. A very powerful method to solve peak overlapping is Rietveld refinement of X-ray powder diffraction data from CAC clinker, which was reported by several authors in the past [1, 2, 3, 4]. Before Rietveld quantification can be applied, full qualitative phase analysis of all clinker minerals must be performed.

Some of the minor phases can not be detected directly in CAC clinker but only after selective dissolution of the main phases C(A,F) and $C_4A_{2-x}F_x$ [5]. For the investigation of four CAC clinkers enrichment of minor phases was performed by different solvents, for different times, and in successive combinations.

Most of the clinker phases form solid solutions and tend to incorporate foreign ions, which has direct influence on their density. Rietveld quantification is strongly related to phase density and therefore the exact chemical compositions even of minor phases are needed for determination of phase amounts in the mixture. Chemical composition of the main phases of all investigated Fe-rich CAC clinker was determined by EPMA or Rietveld refinement of occupancy factors in the structure.

For calibration of the Rietveld quantification all identified phases were synthesised from reagent grade chemicals for the determined composition. XRD pattern of the pure phases were checked for impurities of minor phases. Mixes with known amounts of 8-10 phases were prepared and the recorded diagrams were quantified by Rietveld method with a fundamental parameter approach (TOPAS).

In the following all essential steps performed for development of a quantitative phase analysis of Fe-rich CAC clinker are listed:

- Investigation of the main phases C(A,F) and $C_4A_{2-x}F_x$ in the clinker
- Enrichment and investigation of the minor phases
- Rietveld refinement of the all identified minor phases in the residues
- Synthesis of all phases with the determined chemical composition
- Rietveld refinement of the pure synthetic phases
- Mixing of different clinker-like phase compositions from single phases
- Calibration of Rietveld quantification and determination of accuracy and precision for any phase
- Transfer of quantification method on each technical CAC clinker with use of residues from selective dissolution

3. EXPERIMENTAL PARAMETER

3.1 Selective dissolution methods

Four different solvents were applied to each technical clinker with solution times from 15min to 1h. The less active solvent 1n acetic acid was used to dissolve Mayenite ($C_{12}A_7$) from CAC clinker. The mixture of Salicylic acid /Methanol is known to dissolve Calcium silicate phases. For our purposes 20g Salicylic acid was dissolved in 200ml Methanol and 5g CAC clinker was added. The beaker was covered and at 60°C stirred for 1h. The residue was filtered, washed with Methanol, and dried at 100°C. The most effective method to dissolve the main phases C(A,F) and $C_4A_{2-x}F_x$ from the clinker was a solution of 20g KOH and 20g Sucrose in 200ml H_2O . The mixture was heated in a covered beaker to 95°C and after adding 5g CAC clinker the solution was stirred for 30 min. The residues were filtered, washed with 50ml H_2O , and finally with 100ml Methanol. For the application of 1n HCl as dissolving agent 20g CAC clinker was needed. The HCl/clinker suspension was stirred for 30min at 60°C. The residue of Magnetite and Wuestite can be washed with H_2O and dried prior to XRD investigation.

Table 1. Effects of different solvents on phase enrichment resp. selective dissolution of Fe-rich CAC clinker

Solvent	1n HCl	1n Acetic acid	1g Salicylic acid in 10ml Methanol	10% KOH/ Sacch.-Solution
Solution time	30 min, 1h	30 min, 1 h	1h	15 min, 30 min, 1h
Predominantly enriched phases (residues)	Fe ₃ O ₄ Magnetite FeO Wuestite		Ca ₄ A _{0.5} F _{1.5} Ferrate	Magnetite FeO Wuestite β-Ca ₂ SiO ₄ Belite Ca ₂ AS Gehlenite Ca ₃ Fe ₂ TiO ₈ CaTiO ₃ Perovskite
Predominantly dissolved phases		Ca ₁₂ Al ₁₄ O ₃₃ Mayenite	β-Ca ₂ SiO ₄ Belite	

3.2 Synthesis of CAC clinker phases

For the calibration of quantitative phase analysis all identified CAC clinker phases were synthesized from reagent grade chemicals in a laboratory furnace in air. The chemical compositions of solid solutions were chosen according to the compositions determined in the technical clinker (ref. 4.1.2). The quenched mixtures were ground several times in a disk mill (agate) during the synthesis procedure.

Table 2. Synthesis parameter for the synthetic CAC clinker phases

Phase	Trivial name	Temperature [°C]	Synthesis time [h]	Grinding
CA _{0.94} F _{0.06}	Monocalcium-aluminate	1250	16	5 min every 4h
C ₄ A _{1.5} F _{0.5}	Ferrite phase	1250	70	10 min every 12h
C ₁₂ A ₇	Mayenite	1150	70	15 min every 24h
β-C ₂ S (Al-doped)	Belite	1550/ 1350(final step)	8	15 min every 2h
C ₂ A _{0.8} F _{0.2} S	Gehlenite	1250	8	5 min every 2h
CT	Perovskite	1250	10	5 min every 2h
C ₃ FT		1350/ 950 (final step)	14	15 min every 3h
C ₂₀ M ₃ A ₁₃ S ₃	Pleochroite	1300	60	5 min every 10h

All pure synthetic phases were ground in a disk mill and sieved <36µm prior to the following experimental procedures.

3.3 X-ray diffraction powder analysis

3.3.1 Sample preparation for X-ray diffraction analysis

Preparation of the samples was standardized. The four technical Fe-rich CAC samples and their residues after selective dissolution were ground in a disc mill (Tungsten Carbide, 50g, 30min) to get the required grain sizes for X-ray powder diffraction. The specific area (Blaine) of the clinker was determined to 3600 ± 100 cm²/g. Samples of the calibration mixtures were homogenized in a disc mill (agate, 20g, 3min).

3.3.2 Accuracy and precision of quantitative mineralogical phase analysis

Accuracy (absolute error E_a) and precision (standard deviation s) of Rietveld quantification for Fe-rich CAC phase composition was verified on eight different synthetic mixtures, which were prepared from the pure synthetic clinker phases. Measurement of ten independent preparations led to determination of the values for accuracy and precision as shown in Table 3.

4. RESULTS

4.1 Qualitative phase composition of Fe-rich CAC clinker and residues from selective dissolution by X-Ray powder diffraction analysis

Comparison of XRD diagrams of residues from KOH selective dissolution gave a much better insight into the differences of qualitative phase composition of CAC clinker from four producers (Figure 1) than analysis of the untreated clinker. In clinker CAC-4 neither Mayenite nor Wuestite could be detected in the residues. But instead quite a lot of Gehlenite could be observed in the clinker, where CA and Ferrite phase are dissolved by the KOH dissolution technique.

After successive removal of Belite (Salicylic acid /Methanol) and Mayenite (Acetic acid) the from the KOH-residues, the samples were comprised of Magnetite, Wuestite, C₃FT-phase and Perovskite and residue from clinker CAC-4 additionally Gehlenite (Figure 2).

Qualitative phase composition of the analysed clinker was found to be variable. Some phases like Gehlenite (C₂AS) and Wuestite (f) did not occur in all Fe-rich CAC clinkers investigated.

Table 4. Qualitative phase composition of Fe-rich CAC Clinker

Phase in Fe-rich CAC Clinker	Abbreviation	Phase in Fe-rich CAC Clinker	Abbreviation
Monocalcium-aluminate	CA bzw. C(A,F)	C ₃ FT-phase	C ₃ FT (Ca ₃ Fe ₂ TiO ₈)
Ferrite	C ₆ A _x F _{3-x}	Gehlenite	C ₂ AS

Belite	β-C ₂ S	Magnetite/ Magnesioferrite	Ff/MF
Perovskite	CT	Wuestite	f

Figure 1. Comparison of residues from KOH dissolution of Fe-rich CAC clinker

Figure 2. Comparison of residues from combined KOH, Salicylic/Methanol, Acetic acid dissolution of Fe-rich CAC clinker

4.2 Chemical composition of main clinker phases

Chemical compositions of the main phases of all investigated Fe-rich CAC clinkers were determined either by EPMA or Rietveld refinement of occupancy factors in the structure and found to be variable within the following ranges:

Structural data and occupancies of minor phases were refined from the XRD pattern of the different residues of selective enrichment for clinker CAC-1 to CAC-4. Because of different chemical compositions of main and minor phases from clinker to clinker a specially adapted quantification method had to be designed for each of the four investigated Fe-rich CAC clinkers.

4.3 Chemical analysis of the clinker

Chemical analysis of the four Fe-rich clinkers by XRF-analysis could prove that there are only small differences in chemical composition of the clinker from the different producers. The contents of SiO₂ are higher for CAC-2 and CAC-4. TiO₂-content ranges between 1.60 and 1.80 ma.%, Al₂O₃ between 38.07 and 40.83ma.%. Fe₂O₃ shows the largest relative difference and values for CaO are all lying within 36.29 and 38.72 ma.%. CAC-2 and CAC-4 have MnO-contents of about 1 ma.%. Remarkable are the very low LOI of all samples due to oxidation of ferrous iron during analysis.

Table 5. Quantitative chemical composition of the investigated Fe-rich CAC Clinker

	CAC-1	CAC-2	CAC-3	CAC-4
SiO ₂	2.65	3.45	2.70	3.70
TiO ₂	1.84	1.60	1.82	1.67
Al ₂ O ₃	40.8	38.1	40.3	39.5
Fe ₂ O ₃	15.4	16.7	14.7	16.7
MnO	0.03	0.96	0.02	1.03
MgO	0.30	0.72	0.52	0.85
CaO	38.7	37.5	38.4	36.3
Na ₂ O	< 0.12	< 0.12	< 0.12	< 0.12
K ₂ O	< 0.12	< 0.12	< 0.12	< 0.12
P ₂ O ₅	0.03	0.20	0.06	0.26
LOI	0.00	1.17	0.95	0.55

4.4 Quantification results of the technical clinker

All results are average values from ten independent preparations followed by Rietveld quantification of XRD-pattern. None of the values for precision exceeded 1 ma.%. The results of calibrated Rietveld quantification of four Fe-rich CAC clinkers are presented in Table 5 and Figure 2.

The dominating phases in all investigated Fe-rich CAC clinkers are CA and Ferrite phases. In clinker CAC-1 the highest CA content was determined with 51.1 ma.% whereas the lowest content could be found in clinker CAC-3 with 45.8 ma.%. The highest values for the Ferrite phase were observed again in clinker CAC-1 (21.2 ma.%).

For CAC-3 the highest content for Mayenite with 5.9 ma.% could be determined and for clinker CAC-4 the lowest content with 0.9 ma.%. Belite content is not much different for CAC-1, CAC-2, and CAC-3 with 5-6.5 ma.%. And again clinker CAC-4 is marked by low Belite content of 3.1 ma.%.

Table 6. Results of quantitative phase composition of four different Fe-rich CAC clinker determined by calibrated Rietveld analysis

Phase	CAC-1 [ma.%]	CAC-2 [ma.%]	CAC-3 [ma.%]	CAC-4 [ma.%]	Precision
CA	51.1	47.7	45.8	48.4	0.6-1.0
Ferrite phase	21.2	12.2	18.3	10.4	0.4-0.5
Mayenite	2.9	3.4	5.9	0.9	0.2-0.4
Belite	5.0	6.5	5.7	3.1	0.3-0.4
Sum hydraulic phases	80.2	69.8	75.7	62.7	
Gehlenite	1.3	2.0	1.4	8.7	0.2-0.5
Pleochroite	3.6	7.4	5.9	1.7	0.1-0.5
Perovskite	2.3	4.1	3.6	6.2	0.2-0.6
C ₃ FT-phase	3.3	6.3	2.5	6.6	0.4-1.0
Magnetite	5.7	8.4	3.0	14.0	0.4-0.6
Wuestite	3.5	1.8	7.3	0.0	0.1-0.5

Figure 3. Quantitative phase composition, determined by calibrated Rietveld analysis of four different Fe-rich CAC clinkers

As a very interesting result of the quantification of four different Fe-rich CAC clinkers it can be shown that the sum of the hydraulic phases CA, Ferrite phase, Mayenite, and Belite varies within 80.2 and 62.2 ma.%. In CAC-4 with 8.7 ma.% Gehlenite and 14 ma.% Magnetite the ratio between hydraulic and non hydraulic phases is about 2:1, whereas the phase composition of clinker CAC-1 is characterised by a ratio of about 4:1 (hydraulic:non hydraulic).

The non hydraulic minor phases of the Fe-rich CAC-clinkers differ more than the hydraulic main phases. Two Titanium-containing phases could be quantified in all clinkers, Perovskite (CT) and a ternary phase C₃FT. Both phases are structurally related with each other and therefore can not be

quantified with the same high precision and accuracy as the other minor phases like Gehlenite. In all of the Fe-rich CAC clinkers Magnetite could be quantified from 3.0 (CAC-3) to 14.0 ma.% (CAC-4). Wuestite could be observed at the highest concentration of 7.3 ma.% in CAC-3.

5. DISCUSSION AND CONCLUSIONS

After performing full qualitative phase analysis of all clinker minerals a clinker specific Rietveld quantification method was developed by mixing of phases with chemical compositions determined from the technical clinker. With this calibration the values of quantitative phase analysis can be taken as true values. Systematic errors can only be excluded by calibration, which is the most time consuming part of any quantitative phase analysis. The calibrated quantification method needs further adaptation to the technical product by refining the residues from selective dissolution.

Although only small differences in chemical composition of the four investigated clinkers could be found the phase composition is much more different. Quantitative phase analysis of clinker CAC-2 and CAC-4, which are of very similar chemistry, show quite strong differences. In CAC-4 only Magnetite and no Wuestite was found, which indicates less reducing atmosphere during fusion. But the sintering atmosphere is only one of the process parameters that affect phase composition of Fe-rich CAC. In CAC-4 the Mayenite content is reduced to very low values whereas the non hydraulic Gehlenite has a much higher value than in all other investigated clinkers. It is well known from experimental clinker with CAC composition [6] that cooling rate is a decisive parameter for some clinker phases like CA and probably the Ferrite phase and Gehlenite, which can incorporate more Fe^{3+} in the crystal lattice phases on very rapid cooling. Faster cooling enhances iron in the aluminate phases.

The difference in the amount of hydraulic phases to non hydraulic phases is, surprisingly, very high. In clinker CAC-1 the highest values for CA as well as for Ferrite phase were determined. But chemical composition of the clinker is not characterised by higher iron or calcium oxide content than the other CAC clinker.

Figure 4. Influencing factors on phase composition of Fe-rich CAC-clinker

These complex interactions with an influence on phase composition (Figure 4) is only playing a role for Fe-rich CAC clinker, with ions like Fe and Mn which can be incorporated in crystal lattices of different phases in more than one valence.

The possibility of phase composition determination gives very useful information for producers on optimising the production process. Less desired phases in the clinker can be eliminated and other favourable phases can be enhanced by changing the raw mix chemistry or by varying process parameters. From our investigations it is known that iron content of Ferrite phase solid solution

determines hydration behaviour. With the knowledge of phase composition, correlation with hydration behaviour is made possible. New or special products can be developed by using data from hydration experiments together with phase compositions during hydration.

The most important perspectives of quantitative phase analysis of Fe-rich CAC-clinker are:

- On-line process and quality control
- Optimisation of product quality
- Development of special cements
- Research on hydration kinetics
- Investigation of hydrated CAC in building chemistry

ABSTRACT

Samples with different phosphate contents were prepared at 1720 K and 1820 K in air to form the γ -, β -, α' -, and α -modifications of dicalcium silicate. Determination of the phase content by XRD showed that the stability fields of the phases in the quenched system differ considerably from the phase diagram in equilibrium. Samples which consist only of one C_2S polymorph were X-rayed and the structure models were refined by the Rietveld method. Refinements of the γ - and β -modifications yielded good results. Data from the α' -modification were refined with different structure models of which a distorted α'_L - C_2S structure led to the best results. The refinement of α - C_2S structural data was not satisfactory, because all models for this structure were determined from high-temperature X-ray diffraction. So the lattice parameters and structural data differ considerably from those at room temperature. Hydraulic behaviour of the single phase samples was investigated with the help of a heat conduction calorimeter, which was developed and revised at our department. All samples show very low hydration energies and remarkably different hydration behaviour.

1. INTRODUCTION

It is increasingly common to use high temperatures in the cement manufacturing process to burn waste materials. Burning materials like scrap tires or waste oil saves some of the fuel used in the clinkering process [1]. Substances like sewer sludge or meat and bone meals, however, can save fuel *and* raw meal. These materials have organic components which burn without residues in the rotary kiln and form a substitute for fuel. Their inorganic components can act as a substitute for raw meal, because of their similar chemical composition (after the addition of lime) [2]. However, these substances have a high phosphate content, which is usually not present in Portland cement raw meals. Therefore, the effect of phosphate on the clinker has to be examined.

It has been known for years that phosphate in Portland cement clinkers is incorporated mainly in the dicalcium silicate phase (C_2S , Belite) [3]. C_2S shows a relatively complex pattern of phase transformations (figure 1; [4], altered after [5]).

Figure 1. Phase transformations of C_2S

All C_2S polymorphs are nesosilicates. Investigations of the crystal structures of the high temperature polymorphs are often difficult, because some of them show complex twinning and hardly any single crystals can be obtained [6]. Also the high temperatures at which these phases are stable lead to experimental difficulties. Therefore, the crystal structure of α - C_2S has not yet been fully determined [7], [8]. There have been proposals of structures in the space groups $P_{-3} m 1$ [9], [12], $P_{6_3} m c$ [10], and $P_{6_3/m} m c$ [11], [7], [12]. These structure models differ in the orientation of the $[SiO_4]^{4-}$ -tetrahedra [12]. The crystal structure of α'_H - C_2S is a derivative of the β - K_2SO_4 structure type (space group $P_{n m a}$) [9], while α'_L - C_2S shows a superstructure based on α'_H - C_2S [13], [14], [15]. β - C_2S has a monoclinic structure (space group $P 1 2_1/n 1$) [16] and γ - C_2S shows a crystal structure of the olivine type (space group $P b n m$) [17], [18]. The phase transformation from β - C_2S to γ - C_2S is associated with a significant increase of volume which leads to the effect known as “dusting”.

γ - C_2S is the thermodynamically stable phase at room temperature while β - C_2S forms the Belite component in clinkers. Here this polymorph is stabilized by rapid cooling and the incorporation of foreign ions. Most of the C_2S -polymorphs can be stabilized at room temperature by incorporation of phosphate. The phase diagram dicalcium silicate - tricalcium phosphate (C_3P) is presented in figure 2. It can be seen that with increasing phosphate content phases are present which are structure derivatives of high temperature modifications of C_2S . Probably just one of the α' - C_2S modifications can be stabilized by phosphate [7], [22]. Phosphorus is incorporated in C_2S by replacing the silicon atoms on tetrahedra positions by the following mechanism [20]:

\square_{Ca} represents a Ca^{2+} vacancy.

Because of the Ca^{2+} vacancies and the shorter P-O bonds, the structures of the phosphate stabilized C_2S phases are distorted with respect to the pure C_2S polymorphs [20], [21], [22]. This process leads to the formation of commensurate and incommensurate superstructures at higher phosphate contents [20], [22].

S: silico-carnotite

A: A-Phase $Ca_7(PO_4)_2Si_2O_8$

While all polymorphs form CSH gel and $Ca(OH)_2$ (Portlandite) during hydration, their reactivity towards water is different [23], [24], [25]. It has been observed that α - C_2S and γ - C_2S are almost not hydraulically active [23], [24]. α' - C_2S shows a slower reaction than β - C_2S but results in higher strength [26], [27], [28]. Remarkably, the stabilizing ion has a stronger effect on the reactivity than the fact which polymorph was stabilized [29], [30], [37]. For example, the reactivity of BaO and P_2O_5 stabilized C_2S polymorphs descends in the following order (stabilizer in parenthesis): α' - C_2S (BaO) > β - C_2S (BaO) > α' - C_2S (P_2O_5) > β - C_2S (P_2O_5).

2. EXPERIMENTAL

2.1 Sample preparation

Reagent grade C_2S and C_3P were mixed in the relations given in table 1. The samples were homogenized in an agate vibratory disk mill (RETSCH) and filled in platinum crucibles. Syntheses were carried out in a chamber furnace in air. Samples were calcined over night at 1270 K and ground in a tungsten carbide vibratory disk mill. All samples except RM 0.00 were sintered at 1720 K for six hours with two intermediate grinding steps. After that, samples were taken out of the furnace, cooled rapidly on a refractory brick in air and ground in a tungsten carbide vibratory disk mill to a grain size of < 36 μm , which was controlled by sieving.

Table 1. Sample composition in Mol-%

sample	Ca_2SiO_4	$\text{Ca}_3(\text{PO}_4)_2$	formula of the synthesized phase
RM 0.00	100.00	0.00	$\text{Ca}_2 \square_0 \text{Si}_1 \text{P}_0 \text{O}_4$
RM 0.03	98.25	1.75	$\text{Ca}_{1.9828} \square_{0.0172} \text{Si}_{0.9656} \text{P}_{0.0344} \text{O}_4$
RM 0.06	96.91	3.09	$\text{Ca}_{1.9700} \square_{0.0300} \text{Si}_{0.9400} \text{P}_{0.0600} \text{O}_4$
RM 0.11	94.29	5.71	$\text{Ca}_{1.9460} \square_{0.0540} \text{Si}_{0.8920} \text{P}_{0.1080} \text{O}_4$
RM 0.20	89.00	11.00	$\text{Ca}_{1.9009} \square_{0.0991} \text{Si}_{0.8018} \text{P}_{0.1982} \text{O}_4$
RM 0.25	85.71	14.29	$\text{Ca}_{1.8750} \square_{0.1250} \text{Si}_{0.7500} \text{P}_{0.2500} \text{O}_4$
RM 0.31	82.00	18.00	$\text{Ca}_{1.8475} \square_{0.1526} \text{Si}_{0.6949} \text{P}_{0.3051} \text{O}_4$
RM 0.42	73.42	26.58	$\text{Ca}_{1.7900} \square_{0.2100} \text{Si}_{0.5800} \text{P}_{0.4200} \text{O}_4$
RM 0.50	66.67	33.33	$\text{Ca}_{1.7500} \square_{0.2500} \text{Si}_{0.5000} \text{P}_{0.5000} \text{O}_4$

Sample RM 0.00 was sintered twice for two hours at 1820 K with intermediate grinding. Then it was sintered for 1.5 hours at 1820 K and cooled with 1 K/min to 1620 K. After that, it was taken out of the furnace and treated like the other samples. This procedure was chosen to ensure a complete transformation to $\gamma\text{-C}_2\text{S}$ (after [31]).

2.2 Investigation methods

X-ray powder diffraction measurements were carried out with a D5000 diffractometer (SIEMENS) using Ni-filtered $\text{CuK}\alpha$ radiation. Samples were prepared in front and side loading technique to investigate possible preferred orientation effects. Qualitative phase analysis was used to determine samples containing only a single phase. Rietveld structure refinement was carried out on these single phase samples with the program TOPAS (BRUKER) using a fundamental parameters approach (FPA). By this method, the peak profile is calculated based on physical properties of the measurement device instead of using pure mathematical peak shape functions. Different structure models and refinement procedures were used (cf. 3.2).

Hydration of the single phase samples was investigated. For this purpose, all samples were ground to a comparable specific surface, which was determined by the BLAINE method. After that, they were measured in a differential heat conduction calorimeter designed in our department [32], [33]. In this device, three samples can be measured simultaneously connected in difference to an inert reference sample (quartz powder). Of each single phase sample, three measurements of 1 g were carried out with a water/cement ratio of 0.45 and a measurement time of 145 hours. Temperature during the measurements was kept constant at 296.7 ± 0.5 K.

3. RESULTS

3.1 Investigation of the phase compositions

The phosphate content of the samples was confirmed by chemical analysis. Qualitative phase analysis yielded the results given in table 2. The single phase samples on which further investigations were performed are marked separately. Of the two samples containing only the $\beta\text{-C}_2\text{S}$ polymorph, RM 0.03 was chosen because the composition of RM 0.06 is located at the edge of the $\beta\text{-C}_2\text{S}$ phase field in the phase diagram (cf. figure 2). There are considerable differences between the powder diffraction diagram of RM 0.11 and RM 0.20. RM 0.11 shows broader peak profiles and slightly different peak positions. Additional sintering could not produce sharper profiles. Therefore, RM 0.20 was chosen for further investigations.

Table 2. Results of the qualitative phase analysis with the help of X-ray powder diffraction

sample	phase composition	further investigated sample
RM 0.00	γ -C ₂ S	+
RM 0.03	β -C ₂ S	+
RM 0.06	β -C ₂ S	
RM 0.11	α' -C ₂ S	
RM 0.20	α' -C ₂ S	+
RM 0.25	α' -C ₂ S + α -C ₂ S	
RM 0.31	α -C ₂ S	+
RM 0.42	α -C ₂ S + ?	
RM 0.50	α -C ₂ S + ?	

In sample RM 0.42 and sample RM 0.50, the occurrence of additional reflexes compared to RM 0.31 was detected. The intensities of these peaks increase with increasing phosphate content. They could not be assigned to any phase known to be present in the system. Especially they are not related to the silico-carnotite phase, which should occur at higher phosphate contents.

By comparing diffraction diagrams of in front and side loading technique prepared samples and from structure data calculated diagrams, different reflex intensity distributions could be detected in diagrams of α -C₂S and γ -C₂S. A preferred orientation effect was presumed in these samples.

3.2 Rietveld analysis

Refined parameters for all refinements were: scale factor, zero displacement, background as Chebyshev polynomial of the 5th grade, crystallite size, microstrain, lattice parameters, and atomic coordinates on general positions. All parameters were refined simultaneously. Refinement of γ -C₂S (RM 0.00) included the March-Dollase correction of a preferred orientation on the (1 3 0) plane. During refinement of α -C₂S (RM 0.31) the correction of a preferred orientation on the (2 -1 0) plane led to the best results. For each silicon position, a phosphorous position was included in the refinements of RM 0.03, RM 0.20, and RM 0.31. Because of the similar scattering factor of Si and P, the refinement of the occupancy factors yielded no sensible results. The occupancy factors of the Ca, Si, and P positions were calculated from the chemical composition and distributed statistically.

Refinement of the samples RM 0.00 and RM 0.03 yielded good results, while the refinements of RM 0.20 and RM 0.31 were not satisfactory. Therefore, different structure models and refinement strategies were tested for both samples. For the refinements of RM 0.20 given in table 3, scale factor, zero displacement, background as Chebyshev polynomial of the 5th grade, crystallite size, microstrain, and lattice parameters were refined in one step and atom coordinates on general positions were refined in a second step. It can be seen that the structure models for α'_L -C₂S yielded better results than the models for α'_H -C₂S. The best fit can be obtained with a structure model for a *a 4b c* superstructure based on α'_H -C₂S (last line of table 3). Here the R-values and the fit were quite good, but a structure plot of the refined data showed physically untrustworthy bond distances. Therefore, additional constraints were introduced by defining the [SiO₄]⁴⁻-tetrahedra as rigid bodies. The Si-O bond distances and bond angles were defined as variable in boundaries of 15.4 nm - 16.2 nm and 94° - 126°, respectively. Because of the already distorted [SiO₄]⁴⁻-tetrahedra, the initial orientation of the tetrahedra could not be calculated without significant effort. Therefore, the tetrahedra were rotated near their initial position using a trial and error method.

Table 3. Results of different Rietveld refinements of sample RM 0.20

structure model	polymorph	stabilizing ion in structure model	R_{wp}	R_{Bragg}	GOF
[7]	α'_H	P^{5+}	17.20	11.435	3.44
[12]	α'_H	-	30.98	23.317	6.21
[13]	α'_H	Sr^{2+}	30.86	24.779	6.18
[34]	α'_L	Sr^{2+}	15.98	11.520	3.22
[12]	α'_L	-	15.88	10.197	3.20
[35]	α'_L	Sr^{2+}	15.64	10.065	3.15
[20]	distorted α'_L	P^{5+}	11.39	4.869	2.31

For the refinements of RM 0.31, different structure models were tested [7], [12], [36]. The best results were achieved using the trigonal structure data from [12]. The used structure models and the results of the final Rietveld refinements are given in table 4.

Table 4. Results of the Rietveld structure refinements

sample	space group	lattice parameters	R_{wp}	R_{Bragg}	GOF	structure model
RM 0.00 (γ -C ₂ S)	P b n m	a = 50.806 nm b = 112.22 nm c = 67.621 nm	10.16	5.84	2.01	[17]
RM 0.03 (β -C ₂ S)	P 1 2 ₁ /n 1	a = 55.076 nm b = 67.564 nm c = 93.173 nm $\beta = 94.28^\circ$	8.95	3.72	1.78	[16]
RM 0.20 (α' -C ₂ S)	P n m 2 ₁	a = 93.921 nm b = 217.16 nm c = 68.282 nm	13.29	8.55	2.69	[20]
RM 0.31 (α -C ₂ S)	P -3 m 1	a = 54.040 nm b = 71.182 nm	13.07	11.60	2.56	[12]

3.3 Investigation of the hydration behaviour

The specific surface of samples RM 0.00, RM 0.03, RM 0.20, and RM 0.31 was determined by the BLAINE method. It was recognized that sample RM 0.00 had a high specific surface of 5650 cm²/g caused by the dusting process. The other samples were ground to a comparable specific surface of 3190 - 3250 cm²/g. (cf. table 5). It was refrained from grinding all samples to the high specific surface of RM 0.00 because this value is not common for ordinary cement phases. Calorimetric investigations showed that all four samples develop very low heat of hydration. It can also be seen that the individual polymorphs show distinctly different heat flow development. Heat flow graphs of the different phosphate stabilized C₂S polymorphs are given in figure 3, while determined values for heat of hydration are given in table 5. In figure 3, one of the three measured heat flow graphs for each sample was chosen. The heat flow graphs show remarkably high instrumental noise (cf. 4.3).

Figure 3. Heat flow graphs of the different dicalcium silicate modifications stabilized by phosphate

It is visible that α -C₂S shows no detectable heat of hydration during the measurement, while γ -C₂S develops a considerable heat at the beginning of the reaction (compared to β -C₂S). After about 20 hours, no further reaction is visible. β -C₂S has a short induction period and low heat of hydration, which is developed until the end of the measurement. α' -C₂S shows no hydraulic activity in the first 50 hours, but reaches the highest heat of hydration of the examined polymorphs.

Table 5. Results of the calorimetric investigations of dicalcium silicate modifications stabilized by phosphate

sample	start of reaction [h]	heat of hydration after 72 hours [J/g]	heat of hydration after 140 hours [J/g]	time of max. heat flow [h]	specific surface in cm ² /g
α -C ₂ S	-	0	0	-	5650
α' -C ₂ S	53	4	45	84	3250
β -C ₂ S	0.7	17	22	6	3260
γ -C ₂ S	0.3	8	9	0.9	3190

4. DISCUSSION

4.1 Phase composition of the samples

It was recognized that the phase composition of the samples differs considerably from the phase composition derived from the phase diagram and other literature data [19], [20]. With increasing phosphate content, phases were detected which should occur further towards the phosphate rich side of the phase diagram. Also, the additional reflexes in the diffraction diagrams of RM 0.42 and RM 0.50 could not be explained by literature data. The detected phase relations are in better agreement with results of FUKUDA et al. [22], [26]. In the work of FIX et al., the samples were cooled very slowly, while in the work of FUKUDA et al., the samples were quenched. In this work, the samples were cooled rapidly (about 25 g sample material in a platinum crucible was put on a cold refractory) but not in a controlled way. Probably the high temperature polymorphs of C₂S can be stabilized at lower phosphate contents if cooled more rapidly. It could not be determined whether the additional reflexes can be assigned to a new structure type or if an additional phase is present.

4.2 Rietveld structure refinement

Rietveld refinements of RM 0.00 (γ -C₂S) and RM 0.03 (β -C₂S) led to good results. It can be seen that the structure models used correspond with the synthesized phases. Refinements of RM 0.20 (α' -C₂S) and RM 0.31 (α -C₂S) raised certain difficulties. In the case of α' -C₂S, a relatively good fit could be achieved, but the structure model was strongly distorted. After the introduction of the rigid bodies refinement model, bond lengths and angles had satisfactory values. However, the given limit for some of them was reached. Furthermore, simplified structure data had to be used in the refinements: In literature data, not all tetrahedra positions have the same occupation factor. The occupation factors of Si and P had to be calculated, because they could not be sensibly refined (cf. 3.2), and distributed statistically. The refined structure model can be regarded as an approximation to the real crystal structure of phosphate stabilized α' -C₂S. Therefore, it could not be determined definitely whether the stabilized phase has an α'_H -C₂S or an α'_L -C₂S structure. Because the α'_L -C₂S structure models yielded better results, a crystal structure based on the α'_L -C₂S type is probable for this phase. Refinement of sample RM 0.31 (α -C₂S) showed the highest R-values of all polymorphs and a plot with considerable differences between calculated and observed intensities. Difficulties arise from the fact that the crystal structure of α -C₂S is not yet definitively known and that all available structure models were determined at temperatures of about 1800 K. At these temperatures, lattice parameters differ considerably from those of a phosphate stabilized polymorph at room temperature. Also, no structure model determined for samples with foreign ions was available, which would include certain distortions similar to those in the phosphate stabilized phase. It can be concluded that the crystal structure of phosphate stabilized α -C₂S can not be sufficiently described by the used literature data. Also, the formation of a commensurate superstructure is possible [22].

4.3 Hydration behaviour

It is clearly visible that the individual phosphate stabilized C₂S polymorphs show different hydration behaviour. It is common for all samples investigated that just very low heat flows are set free on hydration. The high amount of un-reacted water in the samples and the low heat flows lead to the effect that instrumental noise is visible in the heat flow graphs in figure 3. Therefore, it was difficult to determine a zero heat flow value for these experiments. Remarkably, γ -C₂S, which is mostly described as not reactive in the literature, shows more heat development than phosphate stabilized α -C₂S, which is still very low. These results are in accordance with long term experiments [23], [24], although the α -C₂S phase was stabilized here by incorporation of Al³⁺, Fe³⁺, and K⁺. It has to be noted that the specific surface of γ -C₂S was much higher than that of the other samples. Overall and maximum heat of hydration during the first 145 hours was determined to be much higher for α' -C₂S than for β -C₂S which was reported in literature [27], [28]. Also the remarkably long induction period of α' -C₂S is in accordance to literature data [26]. Comparison between hydration data from sample RM 0.03 (β -C₂S) with data from earlier investigations of Al₂O₃ stabilized β -C₂S at this department [38], [33] showed distinctly different heat flow development: Al₂O₃ stabilized β -C₂S has a notably high initial heat of hydration and shows two further peaks at about three hours and at about eleven hours. Furthermore, the overall heat of hydration after 72 hours is 22 J/g. This value is reached by sample RM 0.03 only after 140 hours. The decisive effect of the stabilizing agent on the hydration behaviour of individual C₂S polymorphs was reported in the literature (cf. 1).

5. CONCLUSIONS

Different phases in the system C₂S – C₃P could be synthesized. The crystal structures of these substances are derivatives of polymorphs of C₂S (namely γ -C₂S, β -C₂S, α -C₂S, and probably α'_L -C₂S). Because of the different experimental parameters, the phase relations were shifted towards the C₂S rich side in relation to the phase diagram in equilibrium from literature data. Rietveld refinements of the single-phase samples were carried out. It was noted that with increasing

phosphate content the structure fit was more difficult. γ -C₂S and β -C₂S structure models could be refined to good results, while in the case of α' -C₂S additional restraints had to be induced. The refinement of α -C₂S structure models determined at high temperature experiments yielded unsatisfactory results. Increasing structure distortions with increasing phosphate content lead at a certain phosphate level, to crystal structures which are too different from the ideal models for a reliable refinement. Hydration behaviour of the different phosphate stabilized C₂S polymorphs differs distinctly from each other. While α -C₂S and γ -C₂S show almost no reaction with water, β -C₂S develops low heat of hydration over a long time. α' -C₂S shows the highest maximum and overall heat of hydration and a remarkably long induction period of over 50 hours. Also, the comparison between phosphate and Al₂O₃ stabilized β -C₂S shows that the stabilizing ion is more decisive for the hydration behaviour than the stabilized polymorph.

ABSTRACT

This research is a microstructural study of calcium aluminate cements, hydrated with water and alkaline solutions. Further microstructural alterations due to carbonation have also been studied in those systems. Finally, a relationship between developed microstructure and final material strength has been evaluated.

The presence of KOH solutions has an effect over hydrated calcium aluminate formation. This effect generates a different microstructure from the ones produced by the hydration with water. There is no proof of the direct relationship between alkali presence and the CaCO_3 type obtained on the later carbonation. However, it can be proved that there is an indirect relationship, considering that the presence of alkalis modifies the morphology of the hydrated phase and, therefore, the CaCO_3 type generated in such carbonation.

The mechanical strength of pastes shows a relationship with the hydrate morphologies. The accelerated carbonation process over the calcium aluminate hydrates always affects the mechanical strength positively, without any dependence over the developed CaCO_3 polymorph. The weathering carbonation process does not always affecting the mix in the same way as the mechanical strength. After carbonation process, the strength evolution has shown a relationship with aluminium hydroxide morphology formed in hydration and carbonation reactions.

Keywords: Calcium aluminate cement, carbonation, alkalis effect, morphology development, mechanical strength.

1. INTRODUCTION

In the past, Calcium Aluminate Cement (CAC) had been largely used thanks to its special properties, such as rapid hardening, resistance to aggression acids, and sulphates [1], refractory properties, an ability to withstand low temperatures and abrasion and impact resistance [2].

However, further research has shown that CAC, as well as Portland Cement (PC), can be susceptible to CO_2 ; provoking calcium aluminate hydrate carbonation [3-11]. Although that carbonation process might increase mechanical strength, it could also promote steel corrosion.

Other special processes can take place with CAC such as cement carbonation in the presence of alkalis (alkaline hydrolysis) [12-19]. According to the latest research into the alkaline hydrolysis process, calcium aluminate hydrates react with alkalis and CO_2 developing calcium carbonate and

an alkali aluminium carbonate similar to dawsonite; later that alkali aluminium carbonate evolves into aluminium hydroxide and alkali bicarbonate [20, 21].

However, there are several issues to be clarified when studying the carbonation with or without the presence of alkalis. Such issues are basically the parameters determining one or more calcium carbonate polymorph formations and also the relationship between the calcium carbonate polymorph and mechanical strength evolution.

The aim of this work is to establish the alkali effect on the nature and morphology of developed calcium aluminate hydrates, as well as to determine the final products generated in the carbonation processes of these hydrates. Moreover, a relationship between the developed morphologies and the material strength evolution is established.

2. EXPERIMENTAL

1x1x6 cm prismatic cement paste specimens were manufactured. The CAC chemical composition and specific surface are given in Table 1. The water/cement ratio used for pastes manufacture was 0.8.

Table 1. CAC Chemical Composition (%) and Specific Surface.

CaO	Al ₂ O ₃	Fe ₂ O ₃	SiO ₂	CaO free	I.R. (UNE)	L.O.I.	Na ₂ O equivalent	Specific Surface (m ² /Kg)
40.21	40.60	15.84	3.89	0.07	2.82	0.36	0.129	321.5

L.O.I.: loss of ignition. I.R.: Insoluble residue.

Three mixing liquids were used for paste manufacture: distilled water and two KOH solutions of 1M and 3M concentration, respectively.

The specimens were cured at 4° and 40°C. During a 14 days curing process, specimens were placed inside sealed boxes where relative humidity (RH) was close to 99%. Table 2 shows prepared samples and the nomenclature used.

Table 2. Non Carbonated Samples.

Temperature (° C)	Distilled water	KOH solution	
		1M	3M
4	P ₄ ⁰	P ₄ ¹	P ₄ ³
40	P ₄₀ ⁰	P ₄₀ ¹	P ₄₀ ³

After the curing process, specimens went through an accelerated carbonation process inside a carbonation chamber. The conditions inside the carbonation chamber were: CO₂ saturation, 20 ± 1°C and RH of 75%.

The samples, after the curing process, were characterised by X Ray Diffraction (XRD), Fourier Transform Infrared Spectroscopy (FTIR) and Scanning Electron Microscopy (SEM). The samples were analysed on the 2nd and 6th month of CO₂ exposure.

Twelve specimens of each type were mechanically tested (compression), at the end of curing period and also at specified carbonation times. The average strength values for each type and age were determined.

3. RESULTS AND DISCUSSION

3.1. Mineralogical Composition of Pastes

Calcium aluminate hydrates formed in specimens and analysed after curing period by XRD and FTIR are shown in Table 3.

Table 3. Hydrates Formed in Pastes.

Sample	P ₄ ⁰	P ₄ ¹	P ₄ ³	P ₄₀ ⁰	P ₄₀ ¹	P ₄₀ ³
Hydrates	CAH ₁₀	CAH ₁₀ C ₂ AH ₈	C ₃ AH ₆	C ₃ AH ₆	C ₃ AH ₆	C ₃ AH ₆

The results show that KOH presence in mixed liquid provokes alterations in the formed calcium aluminate hydrate. At 4°C, when 1M KOH concentration is used, C₂AH₈ is the main hydrate formed while when KOH concentration is 3M, even at 4°C, the final product generated is the stable cubic hydrate C₃AH₆. At 40°C; cubic hydrate is generated in all pastes.

The hydration products of P₄₀³ sample are identical to those of P₄₀¹ and also calcium aluminate hydrate, C₃AH₆, is developed with the same morphology, in plate form without a preferential orientation. Due to this identical result, only the carbonation of the P₄₀¹ sample is displayed, as carbonation products are similar in both samples.

Mineralogical characterisation of 2 months' carbonated samples shows that only the alkali hydrated samples presented calcite (see Table 4). The vaterite and also aragonite were the carbonates generated in the other samples; that is, in those pastes made without alkalis.

Table 4. Calcium Carbonates and Aluminium Hydroxide Formed in Pastes.

Exposition time (months)	P ₄ ⁰	P ₄ ¹	P ₄ ³	P ₄₀ ⁰	P ₄₀ ¹
2	vaterite aragonite AH ₃ gel	vaterite aragonite □calcite b	vaterite calcite aragonite* n	vaterite aragonite* g	calcite aragonite* g
6	vaterite aragonite g, b*, n*	vaterite aragonite □calcite n	vaterite aragonite* calcite* n, b, g	vaterite aragonite* g, b*, n*	calcite aragonite* g, b*, n*

g: gibbsite, b: bayerite, n: nordstrandite.

*Minor phases, likely from the evolution of vaterite with time.

□ Only in the external part of pastes.

Nevertheless at 6 months of carbonation (Table 4), in hydrated samples without an alkalis content, and not only 4° C but also at 40° C, calcium carbonate polymorphs detected were vaterite and aragonite.

On the other hand those samples made with alkalis contained a high proportion of calcite. With regard to aluminium hydroxide, at 4° C all polymorphic forms were detected but gibbsite was the main AH₃ developed; however in the presence of alkalis, the bayerite portion was greater and evolved towards nordstrandite. At 40° C, the gibbsite was the polymorphic form mainly detected.

The bibliography contains reference to the existence of a notable difference between the gibbsite and bayerite precipitation rate [22]. A fast precipitation would ease the formation of bayerite type structures whilst slow precipitation would tend to the gibbsite type. It has been described too that

nordstrandite is formed from bayerite aging [23], structure being an intermediate state between gibbsite and bayerite.

The carbonation of 4°C water prepared samples appears to happen more slowly than those without an alkali presence. Therefore, in the P_4^0 specimens, the aluminium hydroxide precipitation is slow, and generates gibbsite. Nevertheless, the presence of other AH_3 polymorphic forms can also be caused by high pH of the CAC pastes, as a high pH tends to help the formation of bayerite and gibbsite.

It is important to mention that carbonation without alkalis, at 4° and 40°C, did not generate calcite. Moreover, either CAH_{10} , C_2AH_8 or C_3AH_6 carbonation generate the same polymorphic forms of $CaCO_3$. With reference to the aluminium hydroxide, gibbsite is the polymorph mainly generated.

3.2 Mechanical Strength Development

Table 5 gives the values obtained from the compressive tests carried out on the specimens.

Table 5. Pastes Compressive Strength (N/mm²)

Sample	P_4^0	P_4^1	P_4^3	P_{40}^0	P_4^1
Non carbonated	31	6.6	---	13.9	---
2 months carbonated	49.3	11.2	5.3	15.7	3.2
6 months carbonated	65.2	10.1	10.2	18.6	3.6

Alkali presence in the mixing water has a very negative effect on the paste's strength development, both cured at 4° and 40° C. At high KOH concentrations, alterations in nature and rate of formation of hydrated compounds are produced. Those alterations are responsible for the resistance decrease. A comparative study of the total heat and the maximum rate of heat evolution curves, through the isothermal calorimetry technique, shows that CAC hydration reactions are accelerated with temperature but also in the presence of KOH [21, 24].

The samples that are carbonated in a CO_2 saturated chamber always show an increase of compressive mechanical strength as time goes by. The mass deposition of carbonation products in all the cases studied leads to a reduction of porosity of the pastes, and as a consequence a progressive increase of the mechanical strengths is produced [25].

In general, it can be seen in Table 5, that samples show a better mechanical behaviour as a consequence of specimen' exposure to CO_2 . Only those samples made without alkalis at low temperature presented an acceptable strength value and also the gain with CO_2 exposure is significant.

An important strength increase was observed in those samples which initially presented AH_3 on a non crystalline form (P_4^0) and evolving to gibbsite by crystallisation. Such samples initially presented AH_3 on a non-crystalline form, evolving to gibbsite by crystallisation. It is for this reason that the strength increase of the P_4^0 specimens between two and four months of carbonation ascribed to the AH_3 crystallisation.

3.3 Microstructural Studies

In P_4^0 sample, the CAH_{10} is developed initially as a needle form but after 14 curing days the sample was mainly constituted by parallel oriented plates [26]. Due to the carbonation chemical process it can be proved, using XRD and FTIR, that the sample evolves towards the formation of calcium carbonate in vaterite and, in minor portion, into the aragonite form. In addition, there is aluminium hydroxide. Figure 1 shows developed morphologies in samples prior and after the carbonation process.

The P_4^0 carbonated sample was highly compacted, even though it could be found the calcium carbonate morphology mainly as plates (Figure 1b). Aluminium hydroxide was developed as a smooth film.

Figure 1. Morphology of sample P_4^0 . a) prior carbonation b) carbonated.

When CAC was hydrated with 1M KOH solution at 4°C, the developed morphology was mainly a plate and needle structure without any preferential orientation. At 14 days of curing the plates were the main constituents. TEM analysis showed the needles were CAH_{10} and plates were C_2AH_8 [26]. Carbonation specimen study through XRD and FTIR indicated that calcium aluminate hydrate evolved into vaterite, aragonite and also calcite and aluminium hydroxide. In Figure 2, P_4^1 sample microstructure can be seen.

The element average composition of CAH_{10} , C_2AH_8 and C_3AH_6 was analysed by TEM. The percentage of calcium and aluminium reduces at the same time the percentage of iron and potassium increases, for the CAH_{10} formed in the presence of potassium; nevertheless the developed morphology is not modified. The presence of potassium does not favour isomorphic substitution of Al^{3+} ions by Fe^{3+} ions in the C_3AH_6 hydrated phase. It was also found that gel phases in samples mixed with KOH solution have higher potassium and iron contents [26].

Figure 2. Morphology of sample P_4^1 . a) prior carbonation b) carbonated.

After carbonation, P_4^1 surface was formed by groups of large polyhedric shapes of calcium carbonate (Figure 2b). A smooth film was also detected as $CaCO_3$ and dense prisms of AH_3 .

The P_4^3 sample was formed by C_3AH_6 plate-like morphology placed with no order -roselike- and aluminium hydroxide. Due to CO_2 action over the sample, calcium carbonate in calcite, vaterite but also aragonite forms were developed. Figure 3 presents C_3AH_6 and $CaCO_3$ morphologies.

The calcium carbonate developed in the P_4^3 sample was as needle and plate morphology as can be seen in Figure 3b.

Figure 3. Morphology of sample P_4^3 . a) prior carbonation b) carbonated.

At the highest temperature, $40^\circ C$, with and without alkali presence, the calcium aluminate hydrate developed was C_3AH_6 as well as AH_3 (gibbsite). In the absence of alkalis the cubic hydrate was developed as parallel plates and aluminium hydroxide was disposed between the plates. Figure 4 displays the mentioned C_3AH_6 morphologies formed in the absence of alkalis. In alkali presence, C_3AH_6 was developed as spheres.

Figure 4. Morphology of sample P_{40}^0 . a) prior carbonation b) carbonated.

In the P_{40}^0 sample, the calcium carbonate was developed as little plates disposed following an ordered orientation. Aluminium hydroxide was found shaped as dense microstructures in rounded form between the plates.

Different morphologies of calcium carbonate in sample P_{40}^1 were observed: as grouped plates and as grouped needles and also $CaCO_3$ was seen as needle form growing from spherical particles with a high aluminium and potassium content (Figure 5b).

Figure 5. Morphology of sample P_{40}^1 . a) prior carbonation b) carbonated.

From microstructural studies it was possible to determine the existence of a relationship between the morphology of the formed hydrate of either hexagonal or cubic structure, and the calcium carbonate, developed due to CO_2 action over such hydrates (see Table 6). Calcium aluminate hydrates with needle and/or ordered plate morphology due to CO_2 effect, evolve towards the formation of calcium carbonate as vaterite and aragonite. Those hydrates with disordered plate or sphere morphology evolve towards calcite formation. Afterwards, the vaterite form evolves towards calcite and aragonite.

Table 4. Calcium Aluminate Hydrate and Calcium Carbonate Morphologies

Sample	Hydrate type	Morphology	Carbonate Type
P_4^0	CAH_{10}	needles/ordered plates	vaterite/aragonite
P_4^1	C_2AH_8	disordered plates	vaterite/aragonite/calcite
P_4^3	C_3AH_6	disordered plates	calcite/vaterite/aragonite *
P_{40}^0	C_3AH_6	ordered plates	vaterite/aragonite *
P_{40}^1	C_3AH_6	spheres	calcite/aragonite *

* Minor phases.

From the results obtained, a relationship between the developed morphology of hydrated phases and mechanical strength was observed. Those samples constituted by hydrates with morphology in spherical form presented the minor strength value. When calcium aluminate hydrates were developed as plates without a preferential orientation, the specimens did not have good strength behaviour and only those samples with morphology developed as ordered plates gave high strength values.

4. CONCLUSIONS

Hydration of CAC with alkalis provokes a modification in the developed calcium aluminate hydrate and also the hydrate's morphology is different. Therefore the alkali presence modifies the calcium carbonate type developed.

The mechanical strength behaviour can be explained through the sample's morphology. Those samples with a needle or ordered plate morphology show the best mechanical strength behaviour; while those samples with a spherical or disordered plate spherical morphology gave the worst strength behaviour.

As illustrated in this paper, a relationship between calcium aluminate hydrate morphology and the developed calcium carbonate type is established. This is to say that those calcium aluminate hydrate with needle or plate morphology evolve towards vaterite and/or aragonite and those hydrated calcium aluminates with sphere morphology generate calcite.

Mechanical strength evolution over time is positively influenced by aluminium hydroxide: the morphological change of aluminium hydroxide from amorphous towards crystalline shape is reflected by an increase in mechanical strength.

ABSTRACT

Synthetic Calcium Aluminate Cements (CAC) were prepared from pure synthesised CA, CA_2 and/or corundum to investigate the influence of accelerating additives on the hydration and the development of the hydration products of Calcium Aluminate Cements. The hydration experiments of two synthetic mixtures were performed with a isothermal heat flow calorimeter [1] over a period of 72h at $23.0^\circ\text{C} \pm 0.3^\circ\text{C}$ ($w/c=0.45$). Synthetic CAC M3 was mixed from 50 ma.% CA and 50 ma.% CA_2 whereas the composition of mixture M4 was formulated to resemble technical CAC clinker with 60 ma.% CA, 34 ma.% CA_2 and 6 ma.% A. Each calorimetric measurement was performed three times. By adding inorganic additives to the synthetic CAC, either 5 ma.% CH or 0.02% Li_2CO_3 -solution, the maximum of heat flow is shifting to shorter hydration times and the measurement becomes very reproducible. The combination of heat flow calorimetry with in-situ XRD of the synthetic CAC proved that the heat of hydration can be related to the dissolution of CA and CH (only one mixture) and the formation of hydration products, C_2AH_8 and $\text{C}_2\text{AH}_{7.5}$.

1. INTRODUCTION

According to the results of several authors [2,3,4] the setting time of a Calcium Aluminate Cement is influenced by the addition of small amounts of inorganic additives. The influence of the ions acting as accelerator can be put in the following order [5]:

To get more basic information about the influence of the accelerating additives on hydration of Calcium Aluminate Cements and on the development of hydration products an investigation of the hydration behaviour of two synthetic mixtures was carried out. One composition of the two synthetic Calcium Aluminate Cements, prepared from pure synthesised phases, are defined in Table 1.

Table 1. Composition of the synthetic mixtures

phase	M3 [ma.%]	M4 [ma.%]
CA	50	60
CA_2	50	34
A	-	6

As accelerating additives 5 ma.% CH and 0.02% Li_2CO_3 -solution were chosen.

2. EXPERIMENTAL

2.1 Synthesis and characterisation

The pure phases for the synthetic mixtures CA and CA₂ were obtained by sintering an equimolar mixture of CaCO₃ and Al₂O₃ in a laboratory furnace at 1400°C in platinum crucibles interrupted by several grinding procedures. The CA phase was free of minor phases after 8h and CA₂ after 16h. The corundum used for the mixtures contained a slight amount of θ -Al₂O₃ which disappeared after a short thermal treatment of 15 min at 1200°C. The CH used as an accelerator was synthesised by slow diffusion by keeping freshly prepared CaO and deionised CO₂-free water over 8 weeks in a sealed glass. After drying for 8h at 35% r.h. over a supersaturated CaCl₂-solution the remaining free water content of the CH was below 0.4 ma.%. The synthesised CA, CA₂, and CH were checked by XRD for minor phases. The purity was determined by Rietveld quantification to be higher than 99.7 ma.%.

The specific surface area was determined to be 3735±14 cm²/g for CA and 4810±12 cm²/g for CA₂ (blaine). The corundum used for the synthetic mixtures was sieved to minus 25µm and SEM confirmed that the apparent particle size was below 10µm.

The synthetic mixtures were homogenised in an agate mortar over a period of 15 minutes.

2.2 Heat flow calorimetry

For the hydration of the synthetic Calcium Aluminate Cements a heat flow calorimeter operating in isothermal mode as described by [5], was employed. Each synthetic CAC was measured three times. The temperature during hydration was kept constant at a value of 23.0°C±0.3°. The water used for hydration experiments was injected with a syringe. Table 2 shows the instrumental parameters.

Table 2. Instrumental parameter of the heat flow calorimeter

Hydration time [h]	72
Integration time / cell [s]	5
Interval time [s]	19

2.3 In-situ XRD-analysis of hydration

The examination of the hydrated mixtures and the in-situ XRD were performed with a Siemens D5000 diffractometer. The mixtures for hydration experiments were stirred manually and filled in a sample holder for XRD. To prevent carbonation the sample surface was covered with Capton foil. Another portion of the same batch of sample was used for the calorimetric investigation. Measurement parameters for X-ray diffraction are given in Table 3.

Table 3. XRD parameters

Radiation	Cu K α
Tube voltage	40 kV
Tube current	30mA
Time/step	2s
Stepwidth	0.02° 2 θ
Divergence slit	V20
Receiving slit	0.2 mm

The qualitative phase composition of samples hydrated in the calorimeter was investigated after 4 days. XRD pattern were recorded from 5 to 65° 2 θ .

Quantitative phase development of sample M3 using CH as additive was recorded by scanning CA from 29.5 to 30.7° 2 θ and C₂AH_x (C₂AH₈ + C₂AH_{7.5}) from 5.0 to 9.8° 2 θ . The scan was repeated every 10 minutes.

Quantitative phase development in sample M4 with addition of Li₂CO₃ was detected by scanning from 5.5 to 30.5° 2 θ . The scan was repeated every 40 minutes.

3. RESULTS

3.1 Hydration of the synthetic mixtures

Heat evolution of synthetic mixture M3 measured by calorimetric investigation is presented in Figure 1. The values of the heat of hydration after 72 hours and the time of the maximum heat flow are the average values of three measurements.

Figure 1. Hydration of mixture M3 without additives, with Li₂CO₃-solution and with CH (each mixture was measured three times)

The hydration of the synthetic mixture M3 without any additive shows poor reproducibility; note the time to the maximum heat flow and to the total heat of hydration (Figure 1). After injection of water the heat flow decreases and stays very low during the induction period, which lasts for several hours. The begin of the acceleration period of each sample of M3 without additive is variable. After the maximum of heat development the heat flow decreases but the hydration is not finished after 72h (>0.1mW/g).

By adding inorganic additives to the synthetic mixtures a different hydration behaviour can be observed. Hydration of mixture M3 with 0.02% Li₂CO₃-solution shows a very short induction period and an acceleration period starting at 0.5h after injection of water. The course of hydration of mixture M3, using 5 ma.% CH, shows a low heat flow during induction period up to 2h. After a slight decrease in heat flow the acceleration is very rapid.

For mixture M3 the course of hydration is decelerated showing humps in the heat flow suggesting several overlapping reactions. The heat evolution for mixture M3 with Li₂CO₃-solution is strongly accelerated and seems to belong to one homogenous reaction. Heat evolution after induction period

of mixture M3 with 5 ma.% CH starts at later times than the Li_2CO_3 accelerated sample but has even faster peak heat flow.

Figure 2 demonstrates the influence of the admixtures on the maximum of heat flow during the first 0.5h.

Figure 2. Hydration of mixture M3 during the first 0.5h (each mixture was measured three times)

Heat evolution for M4 (Figure 3) with corundum is nearly comparable with mixture M3. Only M4 without additive is slightly different to M3 because of added corundum which seems to promote crystallization. The time to the acceleration of M4 without additives is more reproducible than M3 without additives. Hydration of mixture M4

Figure 3. Hydration of mixture M4 without additives, with Li_2CO_3 -solution and with CH (each mixture was measured three times)

Table 4 summarizes that the heat of hydration during the first 0.5h is doubled by adding 0.02% Li_2CO_3 -solution and is six times larger by adding 5 ma.% CH compared to M3 without additives.

Table 4. Heat of hydration of mixture M3 during the first 0.5h after injecting
(mean of three measurements)

	M3 without additive	M3 0.02% Li_2CO_3 -solution	M3 5 ma.% CH
heat of hydration after 0.5h [J/g]	4.9	11.0	30.5
maximum of heat flow [mW/g]	12	27	150

The maximum heat flow is reached during the first six minutes and is twice as high by the use of Li_2CO_3 and is over 12 times larger by adding 5 ma.% CH compared to the mixture M3 without additive.

Figure 4 shows that the heat of hydration of all mixtures lies in a narrow a range from 328 to 352 J/g. The maximum of heat evolution t_{max} is shown for all investigated mixtures in Figure 5. It is notable that no distinction between M3 and M4 can be made from heat of hydration and t_{max} because of the overlapping maximum and minimum values of three measurements.

Figure 4. Heat of hydration of hydrated synthetic calcium aluminate cements M3 and M4

Figure 5. Maximum of heat development t_{max} of all hydrated mixtures

3.2 Hydration products of the synthetic mixtures

The phase composition of hydrated samples were determined after 4 days (Tables 5 and 6).

Table 5. Phase assemblage in the hydrated mixture M3

mixture	identified phases					
	CA	CA ₂	C ₂ AH _{7.5}	CAH ₁₀	AH ₃	CH
M3 without additive	X	X	X	X	X	-
M3 0.02% Li ₂ CO ₃ -solution	X	X	X	X	X	-
M3 5 ma.% CH	X	X	X	X	X	X

Table 6. Phase assemblage in the hydrated mixture M4

mixture	identified phases						
	CA	CA ₂	A	C ₂ AH _{7.5}	CAH ₁₀	AH ₃	CH
M4 without additive	X	X	X	X	X	X	-
M4 0.02% Li ₂ CO ₃ -solution	X	X	X	X	X	X	-
M4 5 ma.% CH	X	X	X	X	X	X	X

The hydration products C₂AH₈, C₄AH₁₉ and C₃AH₆ were not detected, but C₂AH_{7.5} a phase described by SCHELLER & KUZEL[6], was identified as a hydration product with lower water content than C₂AH₈.

3.3 In-situ-XRD of the synthetic mixtures

The in-situ measurement of the hydration reaction by XRD was performed for mixtures which are reproducible according to t_{\max} and heat of hydration. Therefore only mixtures accelerated with additives were investigated.

No other hydration products other than C_2AH_8 , $C_2AH_{7.5}$, AH_3 occur and the CA_2 content remains constant. Even CAH_{10} was not detected during the first twelve hours of measurement. Table 7 gives the single peaks used for peak area measurement. The temperature during in-situ measurement was $25^\circ C \pm 2^\circ C$.

Table 7. Peak areas analysed during hydration

phase	peak (hkl)	peak area [$^\circ 2\theta$ CuK α]
CA	triplet (12-3), (123), (220)	29.5-30.5
C_2AH_8	(006)	7.0-9.3
$C_2AH_{7.5}$	(004)	7.0-9.3

Before determining the peak area, the background was subtracted from each scan. In case of C_2AH_8 and $C_2AH_{7.5}$ not a single peak area but the whole area under both peaks was integrated. Figure 6 shows the continuous transformation from C_2AH_8 to $C_2AH_{7.5}$ of mixture M3 with 0.02% Li_2CO_3 at the beginning of the measurement (red line) and after a period of 12h (blue line).

Figure 6. Transformation of C_2AH_8 to $C_2AH_{7.5}$ in M3 with 0.02% Li_2CO_3 -solution

3.4 Hydration development of mixture M3 with 5ma.% CH

In Figure 7 two different investigations are plotted together: Heat flow calorimetry and quantitative XRD analysis of hydration of M3 with 5 ma.% CH. The decrease of CA and the increase of C_2AH_x were determined as described by peak area measurement; in situ measurements allow quantitative measurements.

Figure 7. Quantitative in-situ XRD of M3 with 5 ma.% CH combined with heat flow calorimetry

For M3 with 5 ma.% CH the reaction can be divided into four different stages:

- $t=0-10\text{min}$: C_2AH_8 is present from the very early contact of the dry mixture with water. A minor amount of $\text{C}_2\text{AH}_{7.5}$ was also detected as a asymmetric broadening of the (006) peak of C_2AH_8 towards higher 2θ -values (Figure 6). The transformation from C_2AH_8 to $\text{C}_2\text{AH}_{7.5}$ is taking place immediately after mixing with water. No statement about dissolution of CA is possible because the first measurement of CA peak was performed after more than 10 min. Heat evolution is very strong (initial period) during the first 10 minutes.
- $10\text{min}<t<2\text{h}$: In this period the amount of CA present in the paste remains nearly constant. The amount of crystallised C_2AH_x increases slightly during this period. At the same time the heat evolution is low (induction period).
- $2\text{h}<t<3\text{h}$: After about 2 hours the decrease of the CA content accelerates very strongly. At the same time the amount of C_2AH_x increases. The heat evolution shows that the maximum of heat development correlates with the maximum rate of CA decrease and increase of C_2AH_x (end of acceleration period).
- $3\text{h}<t<11\text{h}$: The decrease of CA decelerates; only small amounts of C_2AH_x crystallize. The heat flow shows a constant decrease at the same time (deceleration period).

3.5 Hydration development of mixture M4 with 0,02% Li_2CO_3 -solution

Mixture M4, with Li_2CO_3 -solution, displays a different hydration. Figure 8 summarises the quantitative phase content of CA and C_2AH_x combined with the heat evolution of the paste from calorimetric investigation.

Figure 8. In-situ XRD of M4 with 0.02% Li_2CO_3 -solution (left-hand scale) combined with heat flow calorimetry (right-hand scale)

- $t=0-10\text{min}$: Neither C_2AH_8 nor $\text{C}_2\text{AH}_{7.5}$ are detected. No statement about the decrease of CA content can be made because the first measurement of CA peak was performed after 10min. The heat flow is very strong during this period (initial period).
- $10\text{min}<t<2\text{h}$: The amount of dissolution of CA remains constant during this period (first detection of CA was after 42 minutes). Crystallisation of C_2AH_x can be detected during this period. The heat evolution during this period is low (induction period).
- $2\text{h}<t<3\text{h}$: During this period the content of CA decreases strongly. The content of C_2AH_x is increasing. C_2AH_8 is dehydrating and converting to $\text{C}_2\text{AH}_{7.5}$. The maximum of heat flow coincides with the maximum change in CA and C_2AH_x content (end of acceleration period).
- $3\text{h}<t<12\text{h}$: During this period the CA content is nearly constant like the C_2AH_x content. The heat evolution decelerates very fast to low values (deceleration period).

4. CONCLUSION AND DISCUSSION

The results in this paper show that the combination of two methods, heat flow calorimetry and in-situ XRD-analyses of hydration, are in good agreement according to the maximum heat flow. For the in-situ XRD-analyses the error for each measured value is $\pm 5\%$ of the peak area. The maximum rate of transformation and dissolution may be shifted $\pm 1\text{h}$ because of the temperature difference between in-situ XRD and heat flow calorimetry.

We could show that by adding small amounts of inorganic admixture, whether Li_2CO_3 -solution or 5 ma.% CH, to a synthetic calcium aluminate cement mixture the measurement becomes very precise and accurate. The maximum heat flow is shifted to shorter times by adding Li_2CO_3 -solution or 5 ma.% CH. The course of phase development during the in-situ XRD does not depend very much on the composition of the mixtures but on the additive used, which also has a dramatic influence on the total heat of hydration at very early stages. For that reason the heat of hydration

from two different sample preparation methods for heat flow calorimetry (injection of water with a syringe or stirring the mixture manually) cannot be compared with each other directly.

The accelerating effect of both additives is a combination of C_2AH_8 transformation to $C_2AH_{7.5}$, which is accompanied by a release of H_2O , with the rapid dissolution of CA. The peak of heat flow calorimetry can be attributed to two overlapping exothermic reactions: first of all dissolution of CH and CA and secondly crystallization of C_2AH_8 together with formation of $C_2AH_{7.5}$. By ongoing dehydration of formed C_2AH_8 to $C_2AH_{7.5}$ some H_2O is liberated which can react with CA to more calcium aluminate hydrate. The H_2O -content added to the anhydrous mixture determines how much CA can react, because for the low w/c ratio of 0.45 not all of the CA in the mixture can be hydrated. Therefore the H_2O -content and the C/H ratio of the hydrates formed determine the overall heat flow during hydration.

ABSTRACT

In OPC clinker, C_3A forms solid solutions with some minor components such as alkali oxides, Fe_2O_3 etc., present in OPC clinker. In the cubic crystal structure of C_3A , Fe^{3+} can substitute Al^{3+} up to a certain concentration.

For this investigation syntheses of $\text{C}_3\text{A}_{1-x}\text{F}_x$ in the range of $0 \leq x \leq 0.20$ were performed at 1250°C in a laboratory furnace. By Rietveld refinement of the $\text{C}_3\text{A}_{1-x}\text{F}_x$ lattice parameters a limit of $\text{Fe}^{3+} \rightarrow \text{Al}^{3+}$ substitution of 6 ± 0.2 mole% has been determined for the used synthesis parameter employed.

Influence of Fe^{3+} -doping of C_3A on its hydration behaviour was investigated with and without gypsum as retarding agent ($w/c = 0.7$; $t = 72\text{h}$; 23°C) with a heat flow calorimeter. The investigation has shown that overall heat flow and the ferric content of $\text{C}_3\text{A}_{1-x}\text{F}_x$ are correlated. Irrespective of the addition of gypsum as retarding agent, the heat of hydration declines with increasing ferric content. Reduction of overall heat flow is notably stronger when gypsum is added to $\text{C}_3\text{A}_{1-x}\text{F}_x$, whereas the maximum heat flow and its point of time do not depend on the ferric content of $\text{C}_3\text{A}_{1-x}\text{F}_x$ solid solutions. Similarly, the ferric part does not influence the beginning of the transformation from Ettringite to Monosulfate.

1. INTRODUCTION

The setting of cement products is a property of particular importance for consumer and manufacturer, which is determined by the requirements of the market. Because there are several clinker phases present together with a large number of additives, which are altogether involved in the reaction with water, only the hydration behaviour of one separate clinker phase, Tricalciumaluminate (C_3A) was investigated in this study.

C_3A reacts very intensively with water and it is responsible for the initial reaction of OPC clinker [1]. To avoid a too early setting of the OPC (flash-set) it is necessary to add a retarding agent, like gypsum or anhydrite to the cement.

Iron oxide is one of the main oxides in the raw materials utilised for OPC. Iron oxide is not exclusively incorporated in the Ferrite phase, but also in C_3A . Normally C_3A crystallises in the cubic space group $\text{Pa}\bar{3}$. The structure of cubic C_3A is built of six-fold rings of two types of distorted AlO_4 -tetrahedra centered on threefold axes. The rings of $(\text{Al}_6\text{O}_{18})^{18-}$ are arranged closely, so that the aluminum atoms are almost placed near to six of the corners of a cube. [2]

In the C_3A cubic crystal structure Fe^{3+} can substitute for Al^{3+} up to a certain concentration. (substitution limit). If the Fe-concentration exceeds this substitution limit, $C_3A_{1-x}F_x$ solid solution with constant composition coexists together with Ferrite phase $C_2(A_{0.48}F_{0.52})$ and CaO [3,4,5,6].

In this study the substitution of the Fe^{3+} in C_3A was investigated and the hydration behaviour of iron- substituted C_3A was observed. Lattice parameter of the $C_3A_{1-x}F_x$ solid solution members and the substitution limit for the synthesis parameters used was determined by Rietveld refinement. Influence of Fe^{3+} -doping of C_3A on its hydration behaviour was investigated with a heat flow calorimeter [7,8]. Measurements with and without gypsum as retarding agent were performed.

2. EXPERIMENTAL

2.1 Synthesis Parameter

The samples were prepared from mixtures of $CaCO_3$, Al_2O_3 and Fe_2O_3 . As a first step, the samples were homogenised in a disk mill (agate, 10 min, 700 rpm). After that the mixture was decarbonated in a platinum crucible at $1000^\circ C$ for 12 hours in a laboratory furnace and sintered at $1250^\circ C$ in air atmosphere.

Then the sinter cake was cooled in a desiccator, crushed and re-sintered. This procedure was repeated at least three times. The total sinter time was 42 hours.

2.2 Characterisation of the Samples

All samples were sieved to $<36 \mu m$ and prepared with front loading technique for XRD investigations. The qualitative examination was performed with the software $DIFFRAC^{plus}$ EVA 4.0 from BRUKER AXS. For reproducibility all samples were prepared and measured at least three times with a X-ray diffractometer (D 5000) with Cu $K\alpha$ radiation.

For the qualitative examination of the hydration products after the setting in the heat flow calorimeter the samples were dried 12h in a CO_2 - free atmosphere to a relative humidity of 35%.

The refinement of the structure data was performed with the Rietveld method with the software TOPAS 2.0 from BRUKER AXS. The program works with the fundamental parameter approach from Cheary & Coelho [9]. Table 1 shows the structure models used in the analysis.

Table 1. Structure models from the ICSD- database [10]

Phase	ICSD- Code/ Reference/ Year
C_3A	1841 Mondal & Jeffery (1975)
CaO	61550 Natta & Passerini (1929)
$C_2(A,F)$	9197 Colville & Geller (1971)
C_3AH_6	202315 Lager, Armbruster, Fabry (1987)

2.2.1 Surface Area Measurements

The surface area of all samples was measured by Blaine method. The samples were ground to a specify surface area between $3560-3690 \text{ cm}^2/\text{g}$.

2.2.2 Heat Flow Calorimetry

Hydration behaviour was investigated in a revised heat flow calorimeter after Kuzel [7,8].

The following parameters were used:

- temperature in the calorimeter $23.0^\circ C (\pm 0.3^\circ C)$
- w/c ratio 0.7
- measurement time 72h

All iron- doped C_3A samples were hydrated for two ways. One with distilled water alone an another with gypsum and distilled water. The optimal gypsum ratio of 21.6 mass% was calculated (after Haskell in Stark & Wicht [11]).

3. RESULTS AND DISCUSSION

3.1 X- Ray Powder Diffraction Measurements

The structure of Mondal & Jeffery [2] was used for the Rietveld refinement of the pure C_3A structure. Figure 1 shows the good fit of the calculated and the measured profiles.

Figure 1. Measured and calculated profiles and difference plot of iron free sample A00

The substitution limit was determined from the refined a-lattice parameter of the $C_3A_{1-x}F_x$ - solid solutions. In Figure 2 the determined a-lattice parameter is plotted against the iron oxide ratio in the synthesis mixture. The lattice parameter increases with rising iron ratio, up to a composition of 6 ± 0.2 mole% (3.5 ± 0.1 mass%) Fe_2O_3 substitution. No further increase of the parameter could be detected with higher Fe_2O_3 contents.

The noticeable rise of the minor phases CaO and $C_2(A,F)$ in the samples with higher iron oxide content than 6 mole%, also indicates a substitution limit of 6 ± 0.2 mole% (3.5 ± 0.1 mass%) Fe_2O_3 . The ratio of Ferrite phase increases from 5 ± 1.5 mass% (sample A08) to 29.5 ± 1.5 mass% of sample A20 (Table 2). The CaO ratio also increases from 0.9 ± 0.8 mass% to 6.5 ± 0.8 mass%. The growing amount of minor phases also explains the different value of the lattice parameter of sample A20. The higher amounts of the minor phases reduces the quality of the refinement of the $C_3A_{1-x}F_x$ solid solution structure.

Figure 2. Determined a-lattice parameter of $C_3A_{1-x}F_x$ solid solutions increasing with substitution up to the limit of 6 mole%

Table 2. Quantitative phase composition (mass%) of the synthesis products of $C_3A_{1-x}F_x$ solid solutions with increasing x

Sample	Theoretical chemical composition	$C_3A_{1-x}F_x$ [mass%]	$C_2(A,F)$ [mass%]	CaO [mass%]
A00	C_3A	99.4 ± 2.0	---	< 0.8
A01	$C_3A_{0.99}F_{0.01}$	99.2 ± 2.0	< 1.5	< 0.8
A02	$C_3A_{0.98}F_{0.02}$	99.2 ± 2.0	< 1.5	< 0.8
A03	$C_3A_{0.97}F_{0.03}$	99.3 ± 2.0	< 1.5	< 0.8
A04	$C_3A_{0.96}F_{0.04}$	99.2 ± 2.0	< 1.5	< 0.8
A05	$C_3A_{0.95}F_{0.05}$	99.2 ± 2.0	< 1.5	< 0.8
A06	$C_3A_{0.94}F_{0.06}$	98.9 ± 2.0	< 1.5	0.8 ± 0.8
A08	$C_3A_{0.92}F_{0.08}$	94.1 ± 2.0	5.0 ± 1.5	0.9 ± 0.8
A10	$C_3A_{0.90}F_{0.10}$	92.9 ± 2.0	6.1 ± 1.5	1.0 ± 0.8
A15	$C_3A_{0.85}F_{0.15}$	76.9 ± 2.0	19.2 ± 1.5	3.9 ± 0.8
A20	$C_3A_{0.80}F_{0.20}$	64.0 ± 2.0	29.5 ± 1.5	6.5 ± 0.8

The determined substitution limit applies to the chosen synthesis parameter (see section 2.1). The limit is lower than comparable data reported in the literature. Table 3 lists the determined iron oxide limits of some authors at different synthesis temperatures.

In sample A20 29.5 ± 1.5 mass% Ferrite phase was detected. From the occupancy factors for Fe/Al a composition of $C_2(A_{0.54}F_{0.46}) \pm 0.04F$ was calculated. The results match very well with the data of Majumdar, Taylor and Lee et al. [4,6,12], who determined a composition of 48 mole% Al_2O_3 and 52 mole% Fe_2O_3 of the Ferrite phase coexisting with the $C_3A_{1-x}F_x$ solid solution.

Table 3. Substitution limits and sinter temperatures of $C_3A_{1-x}F_x$ solid solutions of different authors

Author	Substitution limit [mole%]	Sinter temperature in air [°C]
MAJUMDAR (1965) [4]	7.0	1325
TAYLOR (1990) [6]	7.6	1325
IMLACH & GLASSER (1973) [3]	<10	1150
TARTE (1965) [5]	10.0	1310
This study	6.0	1250

3.2. Investigations of the hydration behaviour of synthesised $C_3A_{1-x}F_x$

Each synthesised $C_3A_{1-x}F_x$ sample was investigated in the heat flow calorimeter three times with and without addition of gypsum.

3.2.1 Investigations of synthesised $C_3A_{1-x}F_x$ without gypsum

The hydration of the $C_3A_{1-x}F_x$ - solid solution are featured by an extremely high heat of hydration within the first hour. Collepardi et al. also observed this effect [13]. The heat of hydration within the first hour is half the value of the total heat of hydration over 72 hours (Table 4).

The hydration of C_3A usually leads after the formation of hexagonal metastable hydration products C_2AH_8 and C_3AH_{13} - to the cubic C_3AH_6 (Scrivener & Pratt [14]). The transformation time to C_3AH_6 hydration products depends on temperature and can be achieved after minutes, hours or days (Lea [15] and Feldman & Ramachandran [16]). In this study by qualitative X-ray analysis of the hydration products after more than 72 hours only cubic C_3AH_6 was identified.

Figure 3. Part (0-0.35h) of representative heat flow curves of $C_3A_{1-x}F_x$ solid solution ($0 \leq x \leq 0.05$) without gypsum addition and for increasing iron oxide content ($w/c=0.7$; $T=23.0^\circ\text{C}$)

No influence could be detected of the increasing iron oxide content in the $C_3A_{1-x}F_x$ solid solution on the height and the time of the maximum heat flow. But the total heat of hydration decreases with increasing iron oxide content from 793.7 J/g (Sample A00oG without Fe_2O_3) to 567.0 J/g (sample A05oG with 5mole% Fe_2O_3) (Table 4).

Table 4. Comparison of the hydration heat of the $C_3A_{1-x}F_x$ solid solutions ($0 \leq x \leq 0.05$) without gypsum addition and increasing Fe_2O_3 content (w/c=0.7; T=23.0°C)

Fe_2O_3 - content	0 mole%	2 mole%	4 mole%	5 mole%
W_{max} [mW/g]	1714.9	1601.0	1770.1	1572.2
t_{max} [h]	0.029	0.028	0.032	0.041
Hydratation heat [J/g]				
After 72h	793.7	702.7	642.3	567.0
After 1h	366.2	346.4	361.1	349.0
Ratio [%]	46.1	49.3	56.2	61.6

3.2.2 Investigations of synthesised $C_3A_{1-x}F_x$ with gypsum

For the hydration with gypsum addition two reactions were recognised (Figures 4 and 5). A first reaction during the first 0.35h and a second reaction after about 4h. Many authors [6,13,15,17,18] have described the second reaction as the transformation of Ettringite to Monosulfate. The starting point of this transformation could not be correlated with the Fe_2O_3 content of the $C_3A_{1-x}F_x$ - solid solutions. (Figure 5)

Figure 4. Time dependent heat of hydration (0-72h) of the $C_3A_{1-x}F_x$ - solid solutions ($0 \leq x \leq 0.05$) with increasing iron oxide content and with gypsum (w/c=0.7; T=23.0°C; 21.6 ma.% gypsum)

Figure 5. Part (0-25h) of the heat flow curves of the $C_3A_{1-x}F_x$ - solid solutions ($0 \leq x \leq 0.05$) with increasing iron oxide content and gypsum addition ($w/c=0.7$; $T=23.0^\circ\text{C}$; 21.6 mass% gypsum)

Sample A02 (2 mole% Fe_2O_3 - content) shows a second reaction after about 3h, the samples A00 (0 mole% Fe_2O_3) and A04 (4 mole% Fe_2O_3) after about 5h and sample A05 (5mole% Fe_2O_3) after about 13h. Scrivener & Wieker [18] stated that the kinetics of the transformation from Ettringite to Monosulfate depends on other factors, like gypsum/ C_3A - ratio, the grain spectrum, grain size distribution or the presence of CO_2 . The qualitative X-ray investigations of the hydration products with gypsum showed Monosulfate, un-reacted $C_3A_{1-x}F_x$ - solid solutions and a laminar phase of TCAH- type. Cubic hydrate could not be detected. The same phase composition was observed by Collepardi et al. [13].

The observed heat of the hydration is correlating with the iron oxide content of the $C_3A_{1-x}F_x$ - solid solutions (Figure 5, Table 5). According to the investigations without gypsum heat of hydration $C_3A_{1-x}F_x$ - solid solutions with gypsum after 72h of is decreasing with increasing Fe_2O_3 - content.

Table 5. Comparison of the hydration heat of $C_3A_{1-x}F_x$ solid solutions ($0 \leq x \leq 0.05$) with gypsum for increasing Fe_2O_3 content ($w/c=0.7$; $T=23.0^\circ\text{C}$; 21,6 mass% gypsum)

Fe_2O_3 - content	0 mole%	2 mole%	4 mole%	5 mole%
W_{\max} [mW/g]	309.1	380.5	347.3	296.8
t_{\max} [h]	0.014	0.014	0.014	0.012
Hydratation heat [J/g]				
After 72h	807.1	796.2	756.5	739.5
After 1h	95.8	105.0	96,9	78.1

3.2.3 Comparison of the $C_3A_{1-x}F_x$ hydration with and without gypsum

The main difference when comparing the hydration with and without gypsum are the noticeable lower heat flows with gypsum at the beginning of the reaction (Figures 3 and 5) and the second peak after about 4h.

The heat of hydration after 72h of hydration samples without gypsum is always lower than for the samples when gypsum was added to $C_3A_{1-x}F_x$ (Table 6 and Figure 6). Furthermore, the reduction of the hydration heat with increasing iron oxide content of $C_3A_{1-x}F_x$ -solid solution with gypsum is lower than for the hydrated samples without gypsum (Figure 6). The total heat of hydration after 72h of the samples with gypsum decreases from 807.1 J/g to 739.5 J/g, in contrast to the samples without gypsum (793.7 J/g to 567.0 J/g).

The ratio of the heat release after 72h without gypsum to the heat release of the samples with gypsum (Table 6) decreases from 98% (iron free C_3A samples) to 77% (Sample with 5 mole% Fe_2O_3).

Table 6. Comparison of W_{max} , t_{max} and the hydration heat (H) after 1h and 72h of all investigated $C_3A_{1-x}F_x$ - solid solutions with and without gypsum addition

Sample (Fe_2O_3 - content)	A00oG (0 mole%)	A00 (0 mole%) + gypsum	A02oG (2 mole%)	A02 (2 mole%) + gypsum	A04oG (4 mole%)	A04 (4 mole%) + gypsum	A05oG (5 mole%)	A05 (5 mole%) + gypsum
W_{max} [mW/g]	1714.9	309.1	1601.0	380.5	1770.1	347.3	1572.2	296.8
H after 72h	793.7	807.1	702.7	796.2	642.3	756.5	567.0	739.5
H after 1h	366.2	95.8	346.4	105.0	361.1	96.9	349.0	78.1
Ratio [%] H^{72h} with/without gypsum	98	100	88	100	85	100	77	100

Figure 6. Comparison of the hydration heat after 72h of the $C_3A_{1-x}F_x$ - solid solutions with and without gypsum (w/c = 0.7; T=23.0°C)

The addition of gypsum noticeably improves the total heat volume of the $C_3A_{1-x}F_x$ - solid solutions richer in iron oxide. The iron substitution is clearly showing a correlation to the hydration behaviour of the $C_3A_{1-x}F_x$ - solid solutions. For the hydration without gypsum the influence is stronger than for the hydration with gypsum.

4. CONCLUSIONS

The substitution limit for the exchange of $Fe^{3+} \rightarrow Al^{3+}$ in C_3A was found to be 6.0 ± 0.2 mole% at $1250^\circ C$ in air in this study. By exceeding the substitution limit additional to $C_3A_{0.94}F_{0.06}$ increasing amounts of CaO and $C_2(A_{0.54}F_{0.46}) \pm 0.04F$ are formed in the samples. This is consistent with the investigations from Majumdar, Taylor and Lee et al. [4,6,12].

The hydration process of the $C_3A_{1-x}F_x$ - solid solutions is as described in literature [1,13,14,16,17,18]. C_3AH_6 was observed as the main phases after 72h hydration in case of gypsum-free hydration. Monosulfate phase was found in the hydration products of $C_3A_{1-x}F_x$ - solid solutions with gypsum. A correlation between the iron oxide content and the hydration heat could be detected. The hydration heat decreases with rising Fe_2O_3 -content of the $C_3A_{1-x}F_x$ - solid solutions. This dependence is higher without gypsum than for gypsum addition. This effect is probably due to the different hydration products. C_3AH_6 does not form a complete solid solution with C_3FH_6 . The substitution limit lies between 0.8 mole%, Strassen [19], and at 0.2 mole% ,Schwiete & Iwai [20] at room temperature. Whereas Ettringite and Monosulfate are forming a complete solid solution with increasing Fe_2O_3 -content [21]. Because the $Al^{3+} \rightarrow Fe^{3+}$ substitution for Monosulfate phase is higher than for Hydrogrossular ($C_3(A,F)H_6$), more $C_3A_{1-x}F_x$ phase can be hydrated with increasing iron content, which leads to higher hydration heat. Monosulfate can easily incorporate the liberated iron but in case of gypsum-free hydration probably non crystalline iron hydroxides are formed during hydration. The iron oxides are inhibiting further hydration of $C_3A_{1-x}F_x$ due to the reduction of available H_2O in the samples. Furthermore we are assuming that iron oxides are forming an gel like shell around the $C_3A_{1-x}F_x$ particles. Both effects reduce the hydration heat in the system without gypsum. When sulfate is available the hydration of $C_3A_{1-x}F_x$ is less affected by iron content.

An influence of the iron content on the time point of the transformation of Ettringite to Monosulfate could not be detected. The kinetics of this transformation seems to depend on other factors like temperature, w/c- ratio, surface area, grain spectrum, grain size distribution and the gypsum/ C_3A ratio [18].

ABSTRACT

The application of heat-flow calorimetry in qualitative and quantitative analysis of hydration reactions of hydraulic binders became vastly important during the last years. The calorimeter, which has been developed and continuously improved at the Department of Mineralogy, has proven its accuracy and reliability in academic and industrial use. The following investigations deal with synthesis and hydration of pure Alite and Belite of OPC clinker like composition and synthetic mixtures of both. The hydration reactions were measured over a period of 72 hours with different W/C-ratios at a temperature of $23^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$. Weighed amounts of deionized water were filled in single-use syringes and injected into the sample vessels through a hole in the lid. The evaluation of the hydration process resulted in a very good reproducibility for all measurements performed. It also could be shown that the hydration of Alite is retarded by the addition of Belite.

1. INTRODUCTION

Within this contribution heat-flow calorimetric studies of the synthetic OPC-phases Alite, Belite and mixtures of both will be presented.

Alite is the most important component of all common OPC clinkers with an average content of about 60 ma.% [4]. Chemically, Alite is tricalcium silicate C_3S (Ca_3SiO_5). The composition and crystal structure may vary by the incorporation of up to 3 – 4 ma.% of foreign ions [5], especially MgO , Al_2O_3 and Fe_2O_3 . Alite reacts relatively fast with water and dominates the hydraulic activity of the clinker, being the most abundant component. It determines the level of the initial and early strength during hydration.

The average content of Belite in normal OPC clinker is approximately about 15 ma.% [4]. The chemical composition of the dicalcium silicate C_2S (Ca_2SiO_4) varies by the incorporation of about 5 ma.% of foreign ions like MgO , Al_2O_3 , Fe_2O_3 , K_2O into the crystal lattice. In Portland cement clinker Belite occurs almost entirely in the β -modification [5]. Belite reacts slowly with water and contributes only little to initial and early strength in comparison to Alite, but is assumed to have influence on the final strength [4].

The hydration process of Alite, which has been examined by several authors [5,6,7,8,9,10,11,12] can be divided into four stages. These are the initial reaction, the induction period, the main reaction and the final, slow periods [5]. The mechanism of Belite hydration is similar to those of Alite but with a slower rate of reaction [3,13,14,15,16,17,18] and a lower content of produced CH (Portlandite, $\text{Ca}(\text{OH})_2$). The rates of heat liberation during the different hydration stages of both Alite and Belite can be investigated using heat-flow calorimetry.

In order to examine the hydration behaviour of synthesized Alite and Belite and their mutual interaction during hydration, an improved highly sensitive heat-flow calorimeter [1,2] has been applied.

2. EXPERIMENTAL

2.1. Preparation of synthetic Alite and Belite

The OPC clinker phases Alite and Belite have been synthesized by sintering stoichiometric amounts of their corresponding oxides, respectively CaO, SiO₂, α -Al₂O₃, MgO. All chemicals used were of “reagent grade” quality. The composition of Alite, according to Regourd [19], is shown in Table 1.

Table 1. Composition of synthetic Alite in ma.%

CaO [ma.%]	SiO ₂ [ma.%]	Al ₂ O ₃ [ma.%]	MgO [ma.%]
71.7	25.9	0.6	1.8

Synthetic Belite has been stabilized using α -Al₂O₃ as minor oxide [20]. Its composition is shown in Table 2.

Table 2. Composition of synthetic Belite in ma.%

CaO [ma.%]	SiO ₂ [ma.%]	Al ₂ O ₃ [ma.%]
65.32	32.90	1.78

The initial substances were homogenized in an agate disk mill (Retsch, Type RS1) with a speed of 700 rpm and then transferred into platinum crucibles. Sintering was carried out in a high-temperature chamber furnace (Nabertherm, Type HT 1750) three times for two hours at a temperature of 1550°C for both Alite and Belite. Between each sintering period the samples were rapidly cooled in air and ground and homogenized in an agate disk mill. After the last sintering stage, samples were ground to a defined specific surface (after Blaine) as shown in Table 3.

Table 3. Specific surface (after Blaine) with standard deviation of synthetic Alite and Belite

	Alite	Belite
Specific surface [cm ² /g] \pm SD	2851 \pm 24	2760 \pm 14

The purity of the synthesized phases was verified by qualitative X-ray powder diffraction (Siemens, Kristalloflex D5000) in combination with quantitative Rietveld-approach. In addition a particle size analysis (Malvern Instruments, MasterSizer) was carried out on both samples. The results are shown in Table 4.

Table 4. Grain size analysis of synthetic Alite and Belite

d (%)	Alite 1 min. dispersed	Belite 1 min. dispersed
10	$\leq 2.3 \mu\text{m}$	$\leq 1.9 \mu\text{m}$
50	$\leq 13.4 \mu\text{m}$	$\leq 16.7 \mu\text{m}$
97	$\leq 63.5 \mu\text{m}$	$\leq 59.1 \mu\text{m}$

The samples have been stored in polyethene bottles inside an exsiccator until further use.

2.2. Calorimetry

For the calorimetric investigations different synthetic mixtures of Alite and Belite, as shown in Table 5, have been prepared. Both synthesized phases were, according to their weight ratios, weighed in polyethene bottles and homogenized manually for about one hour. For calorimetry

single-use polystyrene vessels with lid have been used. Before being filled with the sample substance, the polystyrene vessels have been cleaned with isopropyl and deionized water and were dried at 45°C. As initial weight for Alite, Belite and the synthetic mixtures 2 has been chosen. The substances in powder form were weighed into the polystyrene vessels and were subsequently covered with a dispenser-paper which was exactly fitted to the interior dimensions of the vessels. This piece of paper prevents a spraying of the sample to the walls of the vessel during injection of the hydration liquid. After that the samples have been compressed with a press and closed with the lid which contained a closeable hole in the center of its diameter for the injection of deionized water as hydration liquid. The water has been weighed in single-use syringes with a w/s-ratios of 0.40, 0.45 and 0.50.

Table 5. Synthetic mixtures of Alite and Belite

	Mixture 1	Mixture 2	Mixture 3
Alite : Belite [ma.%]	90 : 10	75 : 25	60 : 40

For the realization of the calorimetric measurements a quadruplet-calorimeter in isothermal operation mode was used which has been developed [1] and continuously improved [2] at the Department of Mineralogy. The polystyrene vessels were coupled to heat-sensitive semi-conductors with a reproducible amount of a thermal transfer compound. To guarantee a constant temperature inside the calorimeter ($23^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$) an external liquid-thermostat was connected. After the adjustment of a thermal equilibrium inside the calorimeter, measurement was started with the data collection and device control software, followed by the immediate injection of the deionized water into the sample vessels. The hydration reactions of Alite, Belite and the synthetic mixtures were recorded over a period of 72 hours.

3. RESULTS AND DISCUSSION

3.1 Hydration of synthetic Alite

The hydration behaviour of synthetic Alite in polystyrene vessels with a w/c-ratio of 0.45 is shown in Figure 1.

Figure 1. Heat-flow diagram of Alite in polystyrene vessels with w/c=0.45

The initial reaction is characterized by a relatively high heat-flow of about 8.4 mW/g during the first 0.5 hours. This corresponds to a heat of hydration of 1.77 J/g. The proportion of this first hydration period within the totally released heat of hydration after 72 hours amounts to about 1%. This observed initial, short hydration reaction has been reported earlier by Kondo and Daimon [21] as well as by Tadros et. al. [22]. The consumed amount of Alite during this period seems to be very low. This corresponds with the results of Fujii and Kondo [23], who reported a consumption of about 0,1%. Kondo and Daimon [21] supposed that the amount of Alite consumed before the induction period is less than 2%.

The induction period from this synthesized Alite is marked very shortly. The rate of hydration during this period decreases significantly. This corresponds to a period with low heat evolution as described before from calorimetric investigations by Kondo and Daimon [21].

At the beginning of the main reaction, the induction period gets replaced by a phase of rapid hydration. The examined Alite shows maximum heat-flow with a w/c-ratio of 0.45 after about 10.5 hours. Table 6 shows the time of the maximum of main reaction (in hours), the corresponding maximum heat-flow (in mW/g) and heat of hydration (in J/g) as well as the percentage of heat of hydration until t_m in relation to the total heat of hydration after 72 hours.

Table 6. Data of the main reaction period of Alite in polystyrene vessels

	Maximum of main reaction t_m [h]	Maximum heat-flow at t_m [mW/g]	Heat of hydration until t_m [J/g]	Heat of hydration until t_m [%]
Alite, w/c =0.45 Measurement 1	10.49	4.68	70.66	34.4
Alite, w/c =0.45 Measurement 2	10.50	4.51	71.00	34.4
Alite, w/c =0.45 Measurement 3	10.55	4.65	73.09	35.6
Mean value $\bar{\varnothing}$	10.51	4.61	71.58	34.8
Standard deviation SD	± 0.03	± 0.09	± 1.32	± 0.7
Maximum deviation Δ_{max}	0.04	0.10	1.51	0.8

On closer inspection of the reproducibility of the Alite measurements shown above, a very good result can be reported as shown in Table 7. The average total heat of hydration after 72 hours of the Alite is 205.69 J/g with a standard deviation of ± 0.75 J/g or, as a total percentage, of 0.42%.

Table 7. Total heat of hydration of Alite in polystyrene vessels with w/c=0.45

	Heat of hydration [J/g]			$\bar{\varnothing}$	SD	Δ_{max} [J/g]
	Measurement 1	Measurement 2	Measurement 3			
Alite w/s = 0.45	205.37	206.55	205.16	205.69	± 0.75	0.86

To determine the influence of the w/c-ratio on the hydration behaviour of the synthetic Alite additional investigations with w/c-values of 0.40 and 0.50 have been performed. The results are shown in Figure 2, where measurements of three different w/s-ratios are compared. By comparing the main reaction periods, a possible dependence on the w/c-value may be observed. A higher w/c-value therefore accelerates this period of hydration.

This trend could be observed in all measurements performed. A relation to the maximum value of the heat-flow (t_m) could not be found. The total heat of hydration after 72 hours at a w/c-value of 0.50 is about 3.07 J/g lower than that at a w/c-value of 0.45. But there is no distinction between the w/s-values of 0.40 and 0.45 within the scope of the determined reproducibility (see Table 7).

Figure 2. Heat-flow diagram of Alite in polystyrene vessels with different w/c-values

3.2 Hydration of synthetic Belite

The hydration behaviour of synthetic Belite doped with Al_2O_3 has been studied in polystyrene vessels at a w/c-value of 0.45. The relatively high heat evolution during the initial reaction, as shown in Figure 3, is noticeable. The initial reaction of this Belite shows a maximum heat-flow of about 48 mW/g, which exceeds that of Alite with the factor six. After 0.5 hours the average heat of hydration amounts about 12.74 J/g (± 0.28 J/g). This corresponds to a proportion of 58.8% of the total heat of hydration after 72 hours, as shown in Table 8.

Table 8. Heat of hydration of synthetic Belite in polystyrene vessels with w/c=0.45

Time [h]	Heat of hydration [J/g]				SD	Δ_{\max} [J/g]
	Belite Measurement 1	Belite Measurement 2	Belite Measurement 3	\varnothing		
0.5	12.46	12.73	13.02	12.74	± 0.28	0.28
24	18.97	19.42	19.41	19.27	± 0.26	0.30
48	19.90	21.00	21.17	20.69	± 0.69	0.79
72	20.21	22.26	22.52	21.66	± 1.27	1.45

The occurrence of such a high heat-flow at the very beginning of hydration could be related to the presence of the aluminate-phase. Because of the stabilization of Belite with Al_2O_3 , the formation of aluminate-phase could be possible in the event of incomplete reaction of the educts. However, this case has been excluded by examining the synthesized phases with X-ray powder diffraction in combination with a quantitative Rietveld analysis. Because of the present results, this behaviour seems to be typical for this Belite stabilized by Al_2O_3 . Among the high heat-flow at the beginning of hydration the appearance of two more maxima is remarkable. Figure 4 shows the comparison of the hydration process of Belite and Alite.

Figure 3. Heat-flow of Belite in polystyrene vessels with $w/c=0.45$ between the first 0.5 hours

Figure 4. Comparison of hydration behaviour of synthetic Alite and Belite with $w/c=0.45$

The hydration of Belite shows similarities to that of Alite. Belite, in the same way as Alite, shows an elevated heat-flow between 9.5 and 11 hours after the initiation of hydration. However, the value of the maximum heat-flow of Alite (4.68 mW/g) during this period exceeds that of Belite (0.40 mW/g) by about 11 times. The mechanisms of these observed hydration reactions of Belite stabilized with Al_2O_3 have to be clarified in further investigations.

3.3 Hydration of synthetic mixtures of Alite and Belite

Comparing the hydration behaviour of the single phases Alite and Belite with the one of the synthetic mixtures, it could be shown that there is a correlation between the content of Belite and the hydration rate of Alite. Figure 5 shows the development of heat evolution.

Figure 5. Heat-flow diagram of Alite, Belite and synthetic mixtures with w/c=0.45

The maximum heat-flow at the main reaction period is decreasing and is getting delayed with an increasing amount of Belite, as shown in Table 9.

Table 9. Average time and value of maximum heat-flow of the main reaction of Alite, Belite and synthetic mixtures with w/c=0.45; each three measurements

	Time of maximum heat-flow t_m [h], with SD	Maximum heat-flow at the main reaction [mW/g], with SD
Alite	10.51 \pm 0.03	4.61 \pm 0.09
Mixture 1 (90:10)	11.46 \pm 0.07	4.06 \pm 0.02
Mixture 2 (75:25)	11.33 \pm 0.10	3.71 \pm 0.08
Mixture 3 (60:40)	14.94 \pm 0.13	2.77 \pm 0.02
Belite	10.01 \pm 0.77	0.31 \pm 0.09

The results also indicate that there is no significant difference in delay between mixture 1 and mixture 2. However, the delay of mixture 3 with 40 ma.% of Belite of about more than 4 hours is very high. Also, the maximum heat-flow at the main reaction shows a continuous decrease with an increasing amount of Belite. The total heat of hydration after 72 hours is shown in Table 10, where the influence of an increasing amount of Belite results in a continuous decrease.

Table 10. Heat of hydration of Alite, Belite and synthetic mixtures with w/c=0.45

	Average heat of hydration after 72 hours [J/g]	SD	Δ_{\max} [J/g]	Δ_{\max} [%]
Alite	205.69	± 0.75	0.86	0.42
Mixture 1 (90:10)	204.38	± 1.59	1.13	0.55
Mixture 2 (75:25)	189.38	± 0.26	0.30	0.16
Mixture 3 (60:40)	165.55	± 1.08	1.19	0.72
Belite	21.66	± 1.27	1.45	6.69

The qualitative development shows, in comparison to pure Alite, a slight prolongation of the initial period. The adjacent induction period, which is hardly developed for Alite, gets prolonged with an increasing amount of Belite. The development of the recorded hydration-curves in this area shows, however, a slightly increasing heat-flow until the start of the main reaction. Because of that, this period should better be assigned to the main reaction. The beginning is first of all delayed by an increasing amount of Belite and the formation of CH is inhibited. This stage of hydration is shown explicitly in Figure 6.

Figure 6. Heat-flow diagram of Alite, Belite and synthetic mixtures with w/c=0.45, closer view of the induction period from Figure 5

The above results confirmed those reported by Odler and Schüppstuhl [3] who also studied the mutual interaction of Alite and Belite during hydration process. The retardation of the hydration of Alite by an increasing amount of Belite could be shown clearly with heat-flow calorimetry. The unexpected results within the hydration process of synthetic Belite stabilized by α - Al_2O_3 have to be investigated by further studies.

Dirk Schmitt

Address: Schlossgarten 5a
91054 Erlangen, Germany

Telephone: +499131 / 8526198

Date of Birth: 18 December 1968

Nationality: German

Education:

1991 - 1992 Friedrich - Alexander - Universität Erlangen Nürnberg
Studies of Chemistry

1992 – 2000 Friedrich - Alexander - Universität Erlangen Nürnberg
Studies of Mineralogy

Since 2000 Friedrich - Alexander - Universität Erlangen Nürnberg
Scientific assistant at the Department of Mineralogy

Additional Information:

Well-grounded education and experience with analytical problems (Microscopy, REM, RFA, AAS, UV-VIS-Spectroscopy, IR-Spectroscopy and Ion-Chromatography).

Experience in Thermal Analysis (DSC, DTA, TG) and Calorimetry (DCA).

Excellent knowledge of Heat-flow Calorimetry related with hydraulic binders.

Well-grounded information in X-ray Analysis (Powder- and Single-crystal - Methods).

Well-grounded knowledge of Quantitative Rietveld Phase Analysis of cements.

Experience with MS-DOS, MS-Windows and several scientific programs (Excel, Origin, Diffrac AT, Rietveld-Software, Atoms, etc.)

A DYNAMIC MODEL AS A TOOL FOR THE DEVELOPMENT OF A SUSTAINABLE CEMENT CLINKER PROCESS

ABSTRACT

A dynamic model for the description of the cement clinker production process was developed. The model is based on the first principles of mass and energy conservation for gas, dust and solid flows in all apparatus under consideration. It comprises all relevant thermal processes that contribute to the formation of emissions. The model was adapted from a commercial plant and was validated statically and dynamically. Stationary validation of the model yields agreement with practical data within 10 % accuracy for all chemical components and key indicators. The dynamic validation shows a good similarity between model and practice for both trends and levels of all variables. The calculated and measured signals for the output variables also showed similar timescales as was proven by spectral analysis of the signals. It is now possible to investigate the effects of new control concepts and implementation of new processes, like mid-kiln firing, precalcination and pregasification of fuels, within the process. Further model improvement will be carried out in the future by using process identification experiments in practice.

1. INTRODUCTION

The production of cement clinker is an energy-intensive and raw material consuming process. By replacing the fossil fuels (coal, natural gas) with biomass and waste residues the costs can substantially be reduced. Also the raw materials can be replaced by secondary materials such as furnace slag, fly ash, etc. The use of these alternative fuels and raw materials may also contribute to the reduction of CO₂, known as an important greenhouse gas. However, the use of secondary fuels and raw materials may also result in higher emissions of harmful components, such as CO, NO_x, SO₂, HCl, heavy metals, etc. Besides increased emissions, process control can easily be disturbed using all kinds of inhomogeneous alternative fuels and raw materials. In order to investigate the consequences of application of secondary fuels and raw materials a mathematical model can be a helpful tool.

In contrast to many other industrial processes, such as drying technologies and waste and coal combustion, the development of numerical tools for the cement industry is relatively scarce. A possible explanation for this phenomenon lies in the complexity of the chemical and thermal processes that occur within the production process of cement clinker. Another important factor is the difficulty or (mostly) impossibility of measuring the key process indicators. However, as a result of increased knowledge of the different parts of the clinker production process the possibilities of a descriptive dynamic model which covers the entire process are increasing, with the emphasis laid on the rotary kiln. The modeling of rotary kilns started with the development of empirical relations for heat transfer [1-3]. More extensive modeling of rotary kilns comprised chemical reactions and different types of heat transfer [4,5]. Modern research focused on the development of dynamic and

static tools for cement production plant engineering and design [1,6-8]. Although research has led to an increased understanding of the various parts of the clinker production process a general purpose model that simulates process dynamics related to input of primary and secondary fuels and raw materials has not been presented in literature yet.

In this paper a dynamic mathematical model is presented that can be used as a tool in the development of a sustainable cement clinker process with a maximum use of sustainable fuels and raw materials, a minimum of emissions and an optimal process control.

Figure 1. Overview of the modeled parts of the clinker production process.

2. MODEL DESCRIPTION

The core of the mathematical model includes a clinker cement kiln, a preheater section, a dryer and a satellite cooler as depicted in Figure 1. The model is completed with a model for an E-filter and meal mill to provide necessary material in- and outputs serving recycle calculations. The layout is adapted to the clinker production process of ENCI Maastricht, The Netherlands. Due to the modular structure of the computer code the configuration of the process scheme can easily be changed to alternative layouts and can be extended with other types of equipment. Therefore, each piece of equipment has distinct, predefined in- and output of heat and mass. The model is based on the principles of mass and energy conservation and supplemented with experimental and empirical relationships for heat and mass transfer as well as for reaction kinetics. Each part of the process is modeled in a different manner dictated by the type of operation performed in the corresponding equipment.

Table 1. Thermal relevant reactions, that are incorporated in the model.

Reaction	Ref.	Kiln	Cooler	Preheater	Dryer
Calcination	[9,10]	+	-	+	-
Sulphate (de-) composition	[11,12]	+	-	+	-
Sintering	[13]	+	-	-	-
Drying	[14,15]	+	+	+	+
Solid phase transition	[13]	+	+	-	-
Evaporation and condensation	[16]	+	+	+	+
Fuel decomposition	[16-18]	+	-	-	+
Gas phase kinetics	[19-22]	+	-	+	-

The overall process is governed mainly by thermal processes. It is therefore presumed that only the phenomena that have significant thermal effect are taken into account in the model. An overview of relevant chemical reactions as well as the different process components is shown in Table 1.

2.1 The rotary kiln

The actual burning of the clinker takes place in a rotary kiln in which gas and solid material are transported in a countercurrent fashion. The fuels are burned at the hot side of the kiln with preheated secondary air from the clinker cooler. The secondary airflow contains a substantial amount of dust, that originates from the cooler. To describe the conservation of mass for the gas, solid material and dust the following balances were used:

$$\frac{\partial \rho_g}{\partial t} = \frac{\partial (V_g \rho_g)}{\partial z} + \Phi_{\text{sec}} \frac{\partial R_g}{\partial z} + \sum_{i=1}^{nc} \Psi_i + \sum_{j=1}^{nf} F_{g,j} \quad (1)$$

$$\frac{\partial M_s}{\partial t} = \frac{\partial (V_s M_s)}{\partial z} + \frac{\partial}{\partial z} \left(D_s \frac{\partial M_s}{\partial z} \right) - \sum_{i=1}^{nc} \Psi_i + \Gamma_s + \sum_{j=1}^{nf} F_{g,j} \quad (2)$$

$$\frac{\partial M_d}{\partial t} = \frac{\partial (V_g M_d)}{\partial z} - \Gamma_s + \sum_{j=1}^{nf} F_{d,j} \quad (3)$$

The nomenclature used above is defined in Section 5 of this paper. The mass balance for the gas phase only contains convective transport, since the effects of diffusion can be neglected. Furthermore, it can be proven that the plug flow approach is justified based on the large Reynolds and Péclet numbers for the gas phase, indicating large radial mixing. In order to account for the transversel mixing of solids, a diffusion term arises in Equation (2). The diffusion coefficient and the solid axial convective velocity can be estimated from previous experimental work [23-25]. The opposite signs for summation terms on the right-hand-side of Equations (1) and (2) denote the exchange of mass between gasphase and solids, that arise from decompositions in the solid phase as well as from condensation and evaporation of volatile chemical components. The transport of dust is determined by the convective velocity of the gasphase because of the high level of acceleration of the fine dust particles and small relaxation times. The local degree of mixing with the solid phase is implemented empirically based on experimental values for the solid kiln feed and the cooled clinker. The decomposition of fuels has a contribution to all three mass balances via gaseous reaction products and fuel ashes.

Since the formation of gaseous emissions is related to temperature and local concentrations of reactants like oxygen and nitrogen it was decided to apply a semi two-dimensional flame approach that enables the staged mixing of secondary air with the kiln gasphase [26,27]. The actual shape of the flame is determined by the cross-sectional area for flow, A_g . With the application of different types of fuels several fuel decomposition models that contribute to the mass balances by the term F were incorporated. In Table 2 an overview of fuel models is given. The fuels are injected into the kiln for which motion balances are incorporated. For large fuel particles the burn-out is allowed to take place in the clinkerbed. The products of the fuel decomposition models are added to the kiln gasphase, which comprises extensive kinetic mechanisms for the formation of various chemical components, such as NO_x , CO , CO_2 and SO_2 [19-22].

Table 2. Overview of applied fuel decomposition models.

Fuel	Model	Ref.	Applied to
Gas	Mixing	-	Natural gas, producer gas
Liquids	Evaporation	[16]	Spent-glycol
Volatile solid	Pyrolysis	[18]	Paper residue, sludge, scrap tires
Heavy solid	Coal combustion	[17]	Bedcokes, finecoke, slate, lignite

The heat balance contains equations for the gasphase and the solid phase. The dust contribution to the heat balances of the kiln is taken into account in the gasphase balance:

$$\frac{\partial(\rho_g C_{p,g} T_g)}{\partial t} + \frac{\partial(X_d C_{p,s} T_g)}{\partial t} = \frac{\partial(\rho_g C_{p,g} V_g T_g)}{\partial z} + \frac{\partial(X_d C_{p,s} V_g T_g)}{\partial z} + \sum_{i=1}^{nr} H_{g,i} + \Omega_{g,w} + \Omega_{g,s} + \sum_{j=1}^{nf} H_{f,j} \quad (4)$$

$$\frac{\partial(\rho_s C_{p,s} T_s)}{\partial t} = \frac{\partial(\rho_s C_{p,s} V_s T_s)}{\partial z} + \frac{\partial}{\partial z} \left(\lambda_s \frac{\partial T_s}{\partial z} \right) - \sum_{i=1}^{nr} H_{s,i} + \Omega_{s,w} + \Omega_{g,s} \quad (5)$$

The transfer of heat is given by Ω and represents direct and indirect exchange as well as radiation and heat loss to the surroundings via the kiln wall. The external heat loss is modeled by conduction through the kiln lining and wall and forced convection, radiation and natural convection at the outside of the kiln. The change in chemical enthalpy due to decomposition of fuels is added to the gasphase balance. The density of the gasphase is calculated by the ideal gas approach. Heat capacities for both gas and solids are mean, concentration-based values of the single component values.

2.2 Preheater

The cyclone preheater is a combination of cyclones and risers that operate at different temperature levels. The hot kiln exhaust gas is cooled as the dried raw meal is preheated for feeding into the kiln. The cyclones separate dust leaving the kiln, and hot kiln gas. In the configuration shown in Figure 2. the raw meal is heated in a two-stage preheater, containing three cyclones and two risers. Heating up the meal up to 750 °C can cause various emissions, such as CO and C_xH_y , that add to the emissions from the kiln.

Figure 2. Setup of the two-stage cyclonepreheater

The cyclones are modeled using the CSTR-approach with an infinite heat transfer, while the risers contain an axial temperature gradient with radial temperature equivalence between the two phases. Mass transfer between the two phases is limited by heat or mass transfer to the meal particles. Sulphur capture and condensation of volatile components like alkali halogenes are the main

reactions that occur in the preheater. The cyclones operate at separation efficiencies that are calculated by semi-empirical modeling [28,29].

A new experimental method has been developed to get insight in the release of CO and C_xH_y from the raw material in the preheater cyclones [30]. For this purpose a so-called entrained flow reactor is used, resulting in different experimental relationships for the different emissions, process conditions and raw materials. New experimental results with the entrained flow reactor can easily be integrated in the model. The detailed results of this new experimental method will be published elsewhere.

2.3 Cooler

The cooler is used to cool down the clinker from the kiln and to preheat the secondary air. The modeling of the cooler was adapted from the kiln approach (see Paragraph 2.1). Parts of this model that were deleted for the description of the cooler are secondary air mixing, fuel decomposition and several reactions. The cooler contains extensive dust exchange between solid material and gasphase as well as water injection at the cooler exit to cool down the clinker material. An important process in the satellite coolers is the solidification of the partly melted clinker material. The configuration cooler is built up with nine satellites.

2.4 Dryer

In contrast to the clinker cooler and the cement kiln, the solid material and the gas move concurrently in the dryer. In literature many mathematical models are described to calculate the drying process. Our mathematical model consists of heat and mass balances [31], solid transport and flying of dust [32,33], completed with combined mass and heat transfer for the release of water from the particles. As implemented in the clinker process the dryer is equipped with water injection and burners to compensate for fluctuations in entering gas temperatures and water content of the wet meal. The configuration of the dryer is shown in Figure 3.

Figure 3. Setup of the dryer, including water injection and additional preheating of exhaust gases from the cyclone preheater.

2.5 Numerical methods

The balances that were set in the building of the model were discretized according to a finite difference scheme with an upwind approach for the convective contributions. Up to 50 grid points were used per apparatus. The complete set of linear equations is then solved with fifth order Runge-Kutta method with variable stepsize in time. For the convenience of the user the mathematical model is supplied by a graphical user interface. On a standard 1 Ghz pentium machine the model calculation speed is 8 times faster than real-time.

3. MODEL RESULTS

In order to validate the model practical data of the plant of ENCI Maastricht are used. The model is validated stationary and dynamically. The stationary validation was performed using mean annual practical data as input for the model. The model was calculated to a stationary situation, after which the outcome of the model was compared to the data of ENCI Maastricht. The dynamic validation of the model was conducted by usage of realtime practical data on a ten-second basis, that served as input for the model.

3.1 Stationary validation

The stationary validation of the model is used to investigate the magnitude of the chemical and physical operations that are comprised by the model. If any of these operations are not in order with practice, then stationary values are not predicted correctly. In Table 3. the results of the validation are shown. In this table model calculations are presented with the corresponding practical data. For the practical data standard deviations for the process output are given as well as deviations of the model results from practical data.

Table 3. Results of the stationary validation of the model, using mean practical data for all inputs of the year 1999. Concentrations are calculated for dry conditions and 10% O₂.

Process variable	Unit	Model	ENCI	s.d. ENCI	Model vs. ENCI
Clinker production	t/h	114	122	7.6	-7.9
T kiln inlet	°C	876	876	21.0	0
T after preheater	°C	495	493	6.0	2.0
CO ₂ kiln inlet	vol%	25.8	28.0	1.1	-2.2
NO _x kiln inlet	ppm	978	965	149	13
O ₂ kiln inlet	vol%	1.58	1.60	0.3	-0.02
Max. melt fraction	%	23.2	23.1	0.4	0.1
SO ₂ at stack	mg/Nm ³	37.8	36.0	30.0	1.8
NO _x at stack	mg/Nm ³	824	797	156	27
CO at stack	mg/Nm ³	120	119	11	1

It shows that all calculated values, except the clinker production, are well within the range of the practical data. Since the model was focused on the gasphase, good agreement for temperatures and concentrations is obtained for the stationary situation. The results for the prediction of gasphase concentrations at kiln inlet are somewhat better than at the stack because of slight underestimation of air leakage into the system downstream of the kiln, as can be seen in both concentrations for NO_x. The model predicts NO_x at the stack with a relatively small error of 4%. The model prediction for the clinker production is less then the value from practice. The reason for this could be found in the accuracy of the input data, since errors in raw meal composition and fuel ash fractions add up to errors in the clinker production. Also, overestimated dust release from the kiln and clinker cooler have large impact on the accuracy of the calculated clinker production. However, measured dust concentration in the exhaust gas of the cyclone preheater and calculated values match up to 2 tonnes per hour, indicating that the deviation is caused by erroneous input.

3.2 Dynamic validation

The dynamic validation is used to investigate the dynamic responses of the model to the required input. For a period of 24 hours practical data of ENCI Maastricht were gathered and were used as input for the mathematical model. In order to reflect the results of these calculations the NO_x signal at the kiln inlet is compared to the measured signal. This signal is affected by all thermal processes that take place within the cement clinker production process. The results are shown in Figure 4.

The match between calculations and practical data is reasonable. The magnitude of the signals are comparable, as was already proven in the stationary validation. The figure also shows that the clinker production process is very dynamic and contains various cycles in the low and high frequency domain. However, in contrast to the results of the static validation, where the signal for both calculation and measurement for NO_x were integrated over a long period of time, the model predictions deviate from measurements.

Figure 4. Result of the dynamic validation of the model, represented by the NO_x concentration at the stack. Practical data were obtained from ENCI, Maastricht.

The possible causes can be found in the long-term dynamics of the process. Historic trends that are present in the process are not covered by the model and can only be calculated on a long-term basis. Induced by this historic trend, the deviations in the stationary situation from which the model starts its calculation are reflected for long period. Another reason for the differences in both signals can be found in the input data. In Figure 5, the fuel input in the kiln and the O_2 concentration at the kiln inlet show that there exist large errors in fuel composition, which has direct influence on the NO_x and O_2 signals. Further refinement of the model input should have a positive influence on the accuracy of the model calculations.

Figure 5. Result of the dynamic validation of the model, represented by the NO_x concentration at the stack. Practical data were obtained from ENCI, Maastricht.

The dynamic responses of the model can be investigated furthermore by looking at the emission spectra of the signal. Since the cement clinker production process contains several interactions in and between process apparatus the spectrum can be useful. In Figure 6. the Bode plot for the calculated and the measured NO_x signal are presented. At time scales of 500 to 5000 seconds the dynamics of both are comparable. The high frequency domain is ruled by aliasing of the signal and is not representative. Low frequency domains cannot be compared because of the short calculation period of 24 hours.

The most important cycles in the process at time scales 3600 and 7200 seconds, representing kiln interactions with clinker cooler and cyclone preheater, correlate well indicating correct residence time distribution for the solid phase.

Further research is needed on the dynamic of the process concentrates on dynamic process identification. By application of process identification, better understanding of the interactions in the kiln and between kiln, clinker cooler and cyclone preheater will be obtained, which can be used in the model. Especially flow behavior of the melted material and influences of the dust on the heat transfer from gasphase to solid phase must be demonstrated more thoroughly. Also the cycles of chlorine and sulphur as a direct result of thermal processes within the clinker production process will be investigated further.

Figure 6. Bode plot of the measured and calculated NO_x emission spectra.

Because of the modular approach in the modeling process it is possible to incorporate several new processes. At this moment optional implementation of mid-kiln firing, precalcining and gasification of biomass are modeled and the effects of implementation on the process emissions and stability are calculated with the mathematical model.

4. CONCLUSIONS

A dynamic model for the description of the cement clinker production process was developed. The model contains all relevant apparatus and processes for the prediction of exhaust gas and clinker emissions for the main components like NO_x , CO and SO_x resulting from the deployment of primary and secondary raw materials and fuels.

ABSTRACT

There is a great interest in the Quantitative Phase Analysis (QPA) of complex crystalline mixtures such as clinkers or cements. Final performances of these materials mainly depend on their mineralogical compositions and textures and not on the elemental compositions, as determined by x-ray fluorescence, XRF. X-ray Powder Diffraction (XRPD) combined with the Rietveld method is the most powerful tool to obtain the QPA of the cement samples. Here, we present mineralogical analyses for white Portland clinkers, gray Portland clinkers and gray Portland cements, using laboratory XRPD and the Rietveld method. The complexity of the systems is variable with the easiest mixture having three crystalline phases. Nevertheless, the toughest case can contain up to nine phases. Some effects such as good/poor particle statistics, preferred orientation or microabsorption have to be borne in mind in order to get accurate results. So, data collection strategy is very important. Moreover, it is possible to quantify the amorphous/non-diffracting content of the building materials by adding a suitable standard, for example Al_2O_3 . Some results and guidelines to carry out the refinements of these mixtures will be given.

1. INTRODUCTION

The mineralogical phase analysis of materials of world importance such as cements is necessary to predict and understand their final performances. In the cement industry, Bogue calculations [1] are used to estimate the mineralogical composition by means of the elemental analysis obtained by XRF. This method is used worldwide to know the main phase fractions as quality control. However, it has well known problems [2] mainly due to the lack thermodynamical equilibrium in the kiln. Mineralogical composition of simple systems can be straightforwardly measured by Laboratory X-Ray Powder Diffraction (LXRPD) combined with the Rietveld method [3]. This methodology is the most powerful tool to obtain the Quantitative Phase Analysis, QPA [4]. This method is standardless but the crystal structures of all the phases must be known as the process consists in the comparison of the measured and calculated patterns. It has even adapted to follow online the cement samples in the factory [5,6]. QPA using the Rietveld method has been successfully used to analyze simple crystalline mixtures [7,8] and recently applied to gray Portland clinkers of different complexities [9-12], aluminous cements [13], calcium sulpho-aluminate cements [14] and mineralized white Portland clinkers [15]. To set up a contrasted technology to carry out fast and robust mineralogical quantitative analyses of these systems is a step forward for both the use of the Rietveld method and the Portland cement quality controls.

On the other hand, building materials contain amorphous/non-diffracting phases in variable amounts that may have an important role in the hydration processes. The quantification of an amorphous component in a crystalline sample by adding a suitable standard is being established [16,17]. In order to carry out a good quantitative analysis of the amorphous content, it is necessary

to minimized all systematic errors in the powder diffraction data that causes deviations in the results, such as the choice of an adequate standard, preferred orientation, microabsorption, etc. [17].

2. EXPERIMENTAL SECTION

Three industrial samples have been analyzed: A white Portland clinker (W), a gray Portland clinker (G) and a gray Portland cement type I 42.5 R (C). The LXRPD patterns were recorded on a Siemens D5000 $\theta/2\theta$ diffractometer (flat reflection mode) by using $\text{CuK}_{\alpha_{1,2}}$ radiation (1.542 Å) with a secondary curved graphite monochromator at room temperature. The samples were loaded in a methacrylate holder by sample-front pressing and they were spun during data collection at 15 rpm. The scanned 2θ range was 10° to 70° in all cases, in 0.03° steps, counting by 15s per step. The optics of the diffractometer was: two sets of Soller slits in the incident and diffracted paths, and three slits of 2, 2 and 0.2 mm (divergence, antivergence, and receiving, respectively). The X-ray tube worked at 40 kV and 30 mA.

A high resolution powder diffraction pattern for a gray Portland clinker mixed with standard Al_2O_3 was recorded on a Stoe/Stadi-P powder diffractometer with Ge(111) monochromatized CuK_{α_1} radiation (1.540589 Å). The sample was loaded in a borosilicate glass capillary (0.3mm of diameter) and rotated during data collection. A position sensitive detector, PSD, was used in the angular range $10\text{--}70^\circ$ [step 0.1° counting for 60s], with data transformed to 0.02° steps. The X-ray tube worked at 40 kV and 25 mA.

The elemental compositions were determined by XRF on a Philips PW 1660 spectrometer using the borate glass bead sample preparation method which minimizes matrix effects. Na and K chemical analyses were carried out by atomic emission spectroscopy. The sulfate content was determined gravimetrically as BaSO_4 .

3. RESULTS AND DISCUSSION

3.1 Common features in the refinements

The powder patterns were analyzed by the Rietveld method with the GSAS suite of programs [18] by using the pseudo-Voigt peak shape function for all phases [19] corrected for axial divergency [20]. To fit the peakshape of the phases we have refined GW (the Gaussian part) and LY (the Lorentzian part) for most phases. For phases that showed anisotropic peak broadening, i.e. sharper and wider peaks depending upon the (hkl) indexes, a third parameter STEC (the anisotropic correction of the Lorentzian width) was refined along the adequate axis. The background was fitted by linear interpolation function. The goniometer zero was also optimized. Lattice parameters were refined for all phases.

The complexity of building materials is variable, the easiest mixture having three phases. Nevertheless, the toughest case can contain up to nine phases. Sample **W** had three phases, Ca_3SiO_5 or C_3S , Ca_2SiO_4 or C_2S and $\text{Ca}_3\text{Al}_2\text{O}_6$ or C_3A . Sample **G** contained five phases C_3S , C_2S , C_3A , $\text{Ca}_2(\text{AlFe})_2\text{O}_5$ or C_4AF and aphtthalite $\text{NaK}_3(\text{SO}_4)_2$ or $\text{K}_3\text{N}\bar{\text{S}}_4$. Sample **C** was the most complex, it contained nine crystalline phases C_3S , C_2S , C_3A , C_4AF , $\text{K}_3\text{N}\bar{\text{S}}_4$, gypsum $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ or $\text{C}\bar{\text{S}}\text{H}_2$, bassanite, $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ or $\text{C}_2\bar{\text{S}}_2\text{H}$, calcite CaCO_3 and MgO or M. Table 1 shows some crystallographic information about these phases.

All mixtures contained C_3S as the main phase. Stoichiometric Ca_3SiO_5 presents polymorphism but the presence of foreign ions in the samples stabilizes high temperature MIII polymorph. It was suggested [2] that the monoclinic MIII form, called alite, is the one contained in the clinkers. We could unambiguously confirm this using ultra-high resolution synchrotron powder diffraction data

[9]. Alite crystallizes as pseudohexagonal multitwinned plaquets with large dimensions. Because of these large particle sizes, it usually presents strong preferred orientation when working in reflection geometry, i.e $\theta/2\theta$. This behavior is exacerbated if the sample is processed as pellets prior to the LXRPD experiment. Preferred orientation has been taken into account in all samples by using the spherical-harmonic correction [21]. This method yields much better fits than the March-Dollase algorithm [22]. Cylindrical symmetry was used with an order for the spherical harmonics of 8. The final texture indexes were 4.79, 2.79 and 2.50 for W, G and C samples, respectively. A value of 1 for the texture index represents an ideal random powder whereas ∞ stands for a single crystal. Hence, higher values of this index indicate more oriented samples. Clinker pellets usually give even higher texture indexes. On the other hand, if the LXRPD experiments are carried out in Debye-Scherrer geometry (transmission, with the sample contained in a rotating capillary), then the texture index is much smaller and sometimes negligible.

In addition to the preferred orientation, alite also presents anisotropic peak broadening. The broadening of the diffraction peaks slightly depends on the (hkl) indexes. This was taken into account using the ellipsoidal correction implemented in GSAS with the STEC parameter and the anisotropic axis running along the [1 0 0] direction.

Table 1. Crystallographic information of the phases in the analyzed samples.

Phase	Nomenclature	Space group	μ/cm^{-1} *	References
Ca_3SiO_5	C_3S	Monoclinic, C m	314	[23]

3.2 Refinement for a white Portland clinker

The Rietveld plot for a white Portland clinker is given in Figure 1. This sample contains only three crystalline phases, C_3S , C_2S and C_3A . The inset of Figure 1 displays the most informative peaks of the sample. It should be noted that the diffraction peaks due to C_3S and C_2S are very overlapped and the peak of C_2S at $31^\circ 2\theta$ is essential to de-correlate the scale factors for these phases, and so, the phase fractions.

Due to the strong peak overlapping and the limited information present in the powder pattern for low concentration phases, it is not advisable to refine the peak shape parameters for low content phases. So, the peak shape function for phases at concentration lower than 10% w/w were kept fixed to previously established values [9]. The final disagreement factors, as defined in references [3, 18] were $R_{\text{WP}}=10.7\%$ and $R_{\text{P}}=7.8\%$. Removing the background contribution to these factors led to $R_{\text{WP}}=8.5\%$ and $R_{\text{P}}=6.8\%$. The fit is remarkably good as the difference between the observed pattern (red crosses) and the calculated one (green line) is the very flat, pink bottom line in Figure 1.

The mineralogical composition for sample **W** obtained from the Rietveld analysis of the LXRPD data is given in Table 2. The elemental analysis, measured as reported in the experimental section, is also given in Table 2. In order to compare the mineralogical composition (Rietveld study) with the elemental composition from the XRF analysis, the phase analysis is also expressed as oxides

crystalline particles. We have annealed the white Portland clinkers at high temperatures and the C_3A phase fraction increases notably.

Table 2. Mineralogical composition for a white Portland clinker obtained by the Rietveld method. Derived elemental composition from Rietveld results and elemental composition measured by XRF expressed as oxide content.

Phases/elements	LXRPD-Rietveld /% w/w	XRF * /% w/w
C_3S	77.3(2)	-
C_2S	19.8(4)	-
C_3A	2.9(1)	-
CaO	71.66	68.90
SiO_2	27.25	22.98
Al_2O_3	1.09	5.08
Fe_2O_3	-	0.24
SO_3	-	0.9
MgO	-	0.58

* Na_2O and K_2O contents not determined

3.3 Refinement for a gray Portland clinker

The Rietveld plot for a gray Portland clinker is given in Figure 2. This sample contains five crystalline phases, C_3S , C_2S , C_4AF , C_3A and K_3NS_4 . The inset of Figure 2 displays the most informative peaks of the sample. Due to the real nature of the phases, the crystallinity and so the peak shape of the different phases is not the same. This has to be taken into account to correctly describe the peak profiles. For instance, alkaline sulfates are the last crystallizing fraction from the melt in the kiln and it has the broadest diffraction peaks. So, K_3NS_4 is poorly crystalline and their peaks were described with a Lorentzian. C_4AF peaks are also quite wide and present anisotropic broadening which was corrected refining STEC along $[1\ 2\ 0]$.

Figure 2. LXRPD Rietveld plot for a gray Portland clinker as in Figure 1. Phases from bottom to top: C_3S (black), C_2S (red), C_4AF (blue), C_3A (green) and K_3NS_4 (yellow). The inset shows the most representative region ($29-35^\circ 2\theta$) with some peaks labeled

The mineralogical composition for the gray Portland clinker is given in Table 3. The final disagreement factors were $R_{WP}=11.4\%$ and $R_P=8.7\%$. Without the background contribution, these values were $R_{WP}=10.4\%$ and $R_P=8.5\%$. The good quality of the fit is evidenced in Figure 2 by the relatively flatness of the pink difference curve.

Consistently with the results shown above for sample W, both Ca and Si contents are also overestimated for this sample. However, the difference in the Al_2O_3 percentages is much smaller. This is likely due to the lower content of sub-cooled fraction in the gray Portland clinkers. A detailed diffraction study which includes the comparison between the amorphous contents of the white and gray Portland clinkers is in progress but it is out of the scope of the present work.

Table 3. Mineralogical composition for a gray Portland clinker obtained by the Rietveld method. Derived elemental composition from Rietveld results and elemental composition measured by XRF expressed as oxide content.

Phases/elements	LXRPD-Rietveld /% w/w	XRF /% w/w
C_3S	68.1(3)	-
C_2S	12.1(5)	-
C_4AF	11.6(2)	-
C_3A	6.8(2)	-
$K_3N\bar{S}_4$	1.4(1)	-
CaO	67.71	64.83
SiO ₂	22.14	20.52
Al_2O_3	5.04	5.55
Fe ₂ O ₃	3.81	3.28
Na ₂ O	0.13	0.26
K ₂ O	0.60	0.93
SO ₃	0.67	1.35
MgO	-	1.30

3.4 Refinement for a gray Portland clinker with standard Al_2O_3

A high resolution pattern, strictly monochromatic $CuK\alpha_1$ radiation, was collected for a gray Portland clinker mixed with Al_2O_3 . The Rietveld plot for this sample is given in Figure 3. This sample contains six crystalline phases, C_3S , C_2S , C_4AF , C_3A , $K_3N\bar{S}_4$ and Al_2O_3 . The inset of this Figure displays again the most informative peaks of the sample.

The final disagreement factors for this refinement were $R_{WP}=5.7\%$ and $R_P=5.4\%$. Without the background contribution, these values were $R_{WP}=5.4\%$ and $R_P=4.4\%$. The good quality of the fit is again evidenced in Figure 3 by the flat pink difference curve. It must be noted that working in transmission with a rotating capillary the phases should not show strong preferred orientation. In fact, we tested the spherical-harmonic correction and the texture index of C_3S converged to 1.07. So, it was not applied as the improvement in the refinement was negligible. The fit showed in Figure 3 was obtained with our structural model for C_3S [23] and without correcting the diffraction peak intensities.

From the overestimation in the Rietveld refined Al_2O_3 ratio with respect to the weighted fraction, we can estimate the non-diffracting content. However, this type of study has to be carried out with extreme care as microabsorption can lead to erroneous results. This work is in progress and it will be reported elsewhere.

Figure 3. High-resolution LXRPD Rietveld plot for a gray Portland clinker as in Figure 1. Phases from bottom to top: C_3S (black), C_2S (red), C_4AF (blue), C_3A (green), K_3NS_4 (yellow) and Al_2O_3 (pink). The inset shows the most representative region ($29-35^\circ 2\theta$) with some peaks labeled

3.5 Refinement for a gray Portland cement

The Rietveld plot for a gray Portland cement is given in Figure 4. This sample contains nine crystalline phases, C_3S , C_2S , C_4AF , C_3A , K_3NS_4 , $CaSO_4 \cdot \frac{1}{2}H_2O$, $CaSO_4 \cdot 2H_2O$, $CaCO_3$ and MgO . The inset of Figure 4 displays the low angle region of the pattern where the peaks due to the set-retarder agents, gypsum and bassanite, are evident.

The mineralogical composition for this sample is given in Table 4. $CaSO_4 \cdot 2H_2O$ and $CaSO_4 \cdot \frac{1}{2}H_2O$ showed strong preferred orientation due to their layered structures that yield plaquets for the microparticle shapes. This was corrected using March-Dollase algorithm [22] along $[0\ 1\ 0]$ axis. Due to their low phase contents, the peak shape function was not refined and the values were kept fixed to those obtained in previous studies. The final disagreement factors were $R_{WP}=11.7\%$ and $R_P=8.8\%$. Without the background contribution, these values were $R_{WP}=10.1\%$ and $R_P=8.1\%$. Again, the pink difference curve is quite flat.

These studies show that mineralogical analyses of Portland cements with up to nine phases are feasible. Furthermore, the results are consistent, if $CaSO_4 \cdot 2H_2O$ was detected, then a lower content of $CaSO_4 \cdot \frac{1}{2}H_2O$ was measured. We systematically detect bassanite in higher contents than gypsum in the analyzed Portland cements. Therefore, quantitative mineralogical analyses allow even to follow the dehydration reactions of gypsum in the cement ball mills. The content range for all phases in the studied cements were within the expected limits.

Figure 4. LXRPD Rietveld plot for a gray Portland cement as in Figure 1. Phases from bottom to top: C_3S (black), C_2S (red), C_4AF (blue), C_3A (green), K_3NS_4 (yellow), $CaSO_4 \cdot \frac{1}{2}H_2O$ (pink), $CaSO_4 \cdot 2H_2O$ (light blue), $CaCO_3$ (black) and MgO (red). The inset shows the low angle region ($10-18^\circ 2\theta$) with the conspicuous peaks for gypsum and bassanite also labeled

Table 4. Mineralogical composition for a gray Portland cement obtained by the Rietveld method.

Phases	LXRPD-Rietveld /% w/w
C_3S	58.7(3)
C_2S	16.7(5)
C_3A	5.1(2)
C_4AF	11.3(3)
K_3NS_4	0.8(1)
$CaSO_4 \cdot 2H_2O$	0.9(1)
$CaSO_4 \cdot \frac{1}{2}H_2O$	4.3(2)
$CaCO_3$	1.6(2)
MgO	0.6(1)

3.6 Errors in the mineralogical analysis by the Rietveld method

The errors in the analyses are variable and mainly due to poor particle statistics. So, rotation of the sample is essential in order to get accurate results for point quality control analysis. However, for on-line systems where many analyses are carried out, the results can be averaged and the particle statistics is not the main concern. Another important issue is microabsorption. A correction for this effect cannot be easily implemented in an on-line system. The preferred orientation and the overlapping of the peaks are other error sources.

It should be noted that the errors stated in Tables 2-4 are those only arising from the counting statistics in the patterns. The other sources of errors should increase the reported values by approximately 3-4. Taking all together, relative precision of 1% can be obtained for C_3S . For low

content phases, the relative errors are higher. Finally, it should be noted that the crystalline C_3S content can be measured with an overall error lower than 2% w/w.

4. CONCLUSIONS

Rietveld mineralogical analyses of building materials are shown to be feasible. As an example, we have presented three cases of different complexities: white Portland clinker, gray Portland clinker, gray Portland cement. The complexity increases in the series as the samples contained three, five and nine crystalline phases, respectively. The fits to the powder pattern are good as evidenced by flat difference curves. The disagreement factors are low indicating a suitable modeling. Subtle features such as the partial dehydration process in the cement ball mill can be investigated. With LXRPD data and the Rietveld method it is possible to quantify the bassanite and gypsum content in the cement and it can be satisfactorily related to the dosage.

ACKNOWLEDGEMENTS

We thank Dr. S. Bruque (Universidad de Málaga) and Dr. M.T. Blanco-Varela (CSIC-Madrid) for their fruitful discussions. We thank Dr. Zuñiga (Universidad del País Vasco) for collecting the high resolution X-ray pattern. This work has been supported by the FEDER 1FD97-0894 research grant. A. G. De la Torre acknowledges a studentship from Junta de Andalucía (Spain).

Short CURRICULUM VITAE for Dr. Miguel Angel García Aranda

Dr. Miguel Angel García Aranda
Departamento de Química Inorgánica, Cristalografía y Mineralogía
Universidad de Málaga
29071-MÁLAGA
Spain
Phone: Int- 34-952131874
Fax: Int- 34-952132000
e-mail: g_aranda@uma.es
www: <http://webdeptos.uma.es/qicm/maga.htm>

Dr. Aranda obtained his D. Phil. at the University of Málaga, Spain, in 1992 with a complementary doctoral training at the Chemical Crystallography Laboratory, University of Oxford, UK. His postdoctoral stay (1992-1993) was carried out in the "Interdisciplinary Research Centre in Superconductivity", University of Cambridge, UK. In 1994 he came back to the University of Málaga as an Assistant Lecturer and became Lecturer in Inorganic Chemistry on 1999.

He has interest in the structural elucidation of compounds from powder diffraction as well as quantitative phase analyses of industrial materials. These tools include laboratory and synchrotron X-rays and neutrons with the Rietveld method. His primary interests are in the synthesis and properties transition metal oxides such as manganites and novel open-framework systems, especially phosphonates.

He organizes a Summer school devoted of the Rietveld method and participates in the design, construction and commissioning of the powder diffraction facility of the Spanish-CRG at ESRF (European Synchrotron Research Facility), SPLINE. He belongs to the International Centre for Diffraction Data, ICDD, since 1997 and Real Sociedad Española de Química, RSEQ, since 1997.

He is co-author of more than 80 research articles in international Journals.

STUDY OF MAGNESIUM ION ATTACK IN PORTLAND CEMENT MORTARS

ABSTRACT

Portland cement mortars prepared in accordance with ASTM C109 were subjected to immersion in magnesium sulfate and magnesium chloride solutions. Periodic monitoring of the physical properties, such as length, mass, compressive strength and dynamic modulus, was performed. The amounts of the primary reaction products formed were detected by thermal analysis, while microstructural observations were conducted by scanning electron microscopy.

Results from the studies indicate that the primary effect of Magnesium ions is the formation of magnesium hydroxide, or brucite, on the surface of the mortar specimens, soon after immersion. The mechanism of attack is then dictated by the nature of the solution. In the case of magnesium sulfate solution, the consumption of calcium hydroxide (for brucite formation) is matched by the deposition of gypsum. Expansion gradually increases and compressive strength drops with the increased formation of gypsum and ettringite. On the other hand, in the case of magnesium chloride solution, there are no secondary products formed. Thus, the removal of calcium hydroxide causes an increase in the porosity of the mortar, leading to a rapid drop in strength. At advanced stages of the attack, decalcification of calcium silicate hydrate (C-S-H) and its conversion to magnesium silicate hydrate (M-S-H) is observed for both the attacking solutions.

1. INTRODUCTION

The reactions involved in sulfate and chloride attack are well understood by researchers [1,2]. Magnesium sulfate (MgSO₄) and magnesium chloride (MgCl₂) solutions react with the hydrated cement paste to form gypsum (CaSO₄.2H₂O), ettringite (6CaO.Al₂O₃.3SO₃.32H₂O), brucite (Mg(OH)₂), and chloroaluminate salts, according to the following approximate equations:

The gypsum that forms in reaction (1) can further combine with aluminates and their hydration products in cement paste to form ettringite. The formation of ettringite causes expansion [3, 4], although the mechanism of expansion is still debated by researchers. In the case of magnesium

chloride solution, the chloride ions can combine with the aluminates in the paste to form chloroaluminate compounds such as Friedel's salt, which are similar in structure to ettringite, but do not cause any expansion [5].

The brucite layer that forms on the surface has a very low solubility. Thus, the formation of brucite according to equations (1) and (2) will continue until the Ca(OH)_2 is depleted. With the consumption of Ca(OH)_2 , a gradual decrease of pH occurs. This renders the calcium silicate hydrate (C-S-H) gel unstable, and causes it to liberate some Ca(OH)_2 into the surrounding solution to increase the pH. This can once again go into reaction with the attacking solutions. Thus, a progressive reduction of the CaO to SiO_2 ratio occurs in the C-S-H. At advanced stages of the attack, the Mg^{2+} ion can replace Ca^{2+} in the C-S-H to form magnesium silicate hydrate (M-S-H), which is reported to be non-cementitious [6]. The formation of M-S-H is the last stage of magnesium ion attack. A direct attack of the C-S-H by MgSO_4 can also cause the formation of M-S-H and secondary gypsum [7]. The M-S-H and gypsum are precipitated in bands parallel to the surface of the specimen [7, 8, 9].

Bonen and Cohen [7] investigated the effect of magnesium sulfate solutions on Portland cement pastes. They suggested that the attack by magnesium ions primarily leads to the formation of a brucite layer at the surface. A layer of gypsum underneath the brucite layer is also formed, by a two-way diffusion of ions. The SO_4 ions from the solution diffuse inwards, while the OH ions from the cement paste move outwards. Because of the low solubility of brucite, the penetration of Mg^{2+} beneath the brucite layer into the interior of the paste specimen is restricted.

A comparative study of attack of Portland cement mortars by magnesium sulfate and magnesium chloride solutions was conducted by Moukwa [10]. Pore structure analysis by Mercury Intrusion Porosimetry (MIP) showed that the attack by magnesium sulfate actually led to a densification of the pore structure at early ages, and a corresponding increase in strength. On the other hand, attack by magnesium chloride caused an increase in the porosity of the mortar, as well as in the threshold diameter.

This study described in this paper is an attempt to analyze Mg ion attack by combining physical, chemical, and microstructural studies.

2. EXPERIMENTAL MEHODS AND MATERIALS

Portland cement mortars were prepared using ASTM Type I cement in accordance with ASTM C109 [11]. The types of specimens cast are listed in Table 1. The specimens were stored within the molds in a moist condition for 24 hours. The molds were then removed, and the specimens transferred to a container with saturated limewater solution. At the age of 14 days after casting, the initial measurements for length, mass, compressive strength, and dynamic modulus were performed. Subsequently, the mortar specimens were stored in three different solutions at a temperature of 21 °C: (1) LW - saturated limewater solution (control), (2) MS - 3.8 mass percent MgSO_4 solution ($\text{Mg}^{2+} = 7600$ ppm, $\text{SO}_3 = 25000$ ppm), and (3) MC - 3.0 mass percent MgCl_2 solution ($\text{Mg}^{2+} = 7600$ ppm, $\text{Cl}^- = 22200$ ppm).

Table 1. Details of mortar specimens

Type	Dimensions	Test
1	Cube - 25 mm side	Compressive strength
2	Prism – 4 mm x 14 mm x 60 mm	DSC
3	Prism – 6 mm x 15 mm x 80 mm with plastic end pieces (described in Figure 1)	Length
4	Cylinder – 23 mm diameter, 80 mm height	Mass, Dynamic modulus, SEM

Measurements of physical properties were performed periodically. For all the physical measurements, the mortar specimens were dried using a cloth to bring them to a saturated surface dry (SSD) condition. The length of the prismatic specimens was measured using a comparator. Compressive strength was measured using a 60,000 lb. capacity universal testing machine. Dynamic modulus was calculated from measurements of the velocity of ultrasonic pulse transmitted through concrete, in accordance with ASTM C 597 [12].

Thermal analyses by differential scanning calorimetry (DSC) and microstructural studies by scanning electron microscopy (SEM) were performed after 32 weeks of immersion. The mortar specimens were removed from the solution and stored in acetone for one day in order to stop the hydration. The specimens for DSC were then ground using mortar and pestle and the fraction passing the 75 μm sieve was used for testing. For SEM studies, a 10 mm thick section was cut from the cylindrical specimens using a saw, and this section was then dried at 70 °C for at least 12 hours. This dried specimen was then impregnated by a low modulus epoxy, inside a cylindrical plastic mold, by evacuating to a low vacuum for two to three hours. The epoxy was then cured in an oven at 70 °C for at least eight hours. The hardened epoxy polymer was then cut with a fine diamond-tipped saw to expose the cross-section of the specimen. This was followed by grinding of the exposed surface on progressively fine grids. The adequacy of polishing was confirmed after each step using an optical microscope. After polishing, the surface was coated with a layer of gold-palladium. The prepared specimens were then stored in desiccators until testing.

3. RESULTS

3.1. Physical properties

The results of the tests for physical properties are shown in Figures 2 to 5. Each point in the plots represents an average of three measurements. According to the data in Figure 2, the mortar specimens in LW and MC exhibit a small amount of shrinkage, while the specimens in MS show a gradually increasing expansion.

As shown in Figure 3, the specimens in MS exhibit a steady increase in mass with time. On the other hand, the specimens in MC show a rapid increase in mass in the early stage, followed by a slower rate of mass gain. The control specimens in LW also show a slight gain in mass, presumably due to absorption. Compressive strength data, plotted in Figure 4, indicate that the specimens in MS undergo a steady decline in strength with immersion, while the specimens in MC show a rapid drop in strength at the early stages. Dynamic modulus of specimens in MS shows an increase in the early stages, followed by a sharp decline. The behaviour is similar in the case of MC; however, the drop in modulus is not as high as in MS. The control specimens exhibit an increase in modulus at the early stages, and then maintain a steady value.

Figure 3. Change in mass of mortar specimens

Figure 4. Compressive strength of mortar cubes

Figure 5. Dynamic modulus by pulse velocity of mortar specimens

3.2. Thermal analysis by DSC

Figures 6 and 7 show the results of the thermal analyses by DSC. The quantities of brucite formed are greater in MgCl_2 compared to MgSO_4 . The high degree of brucite formation in MgCl_2 could be a possible explanation for the high initial mass increase observed in these mortars. The quantity of brucite increases steadily, although by a very small degree, in MgSO_4 . In MgCl_2 , there is an initial increase followed by a steady decline in the quantity of brucite.

At early ages, the depletion of CH in MgSO_4 matches the increase in the quantity of gypsum formed. The quantity of ettringite formed first increases and then decreases with age. The decrease in ettringite could possibly occur as a result of an unfavorable environment (low pH) for ettringite to be stable. The unstable ettringite could also decompose to form secondary gypsum. The high amounts of gypsum forming at later ages (32 weeks) seem to support this argument. Another reason

for the detection of large quantities of gypsum could be the direct attack of the C-S-H by the MgSO_4 solution.

Rapid consumption of calcium hydroxide occurs with MgCl_2 , and no CH is left after 6 weeks of immersion. In MgSO_4 , the CH becomes depleted only after 32 weeks of immersion.

Figure 6. DSC results for PC mortar in magnesium sulfate solution

Figure 7. DSC results for PC mortar in magnesium chloride solution

3.3. Microstructural investigations by SEM

The micrographs for PC mortars attacked by MgSO_4 and MgCl_2 are shown in Figures 8 through 18. Figure 8 shows the micrograph of the PC mortar in MgSO_4 after 12 weeks of immersion. From the low magnification image on the left, the mortar does not appear to be damaged except in the near surface regions. The magnified view of a deteriorated surface region on the right side shows the presence of a brucite-gypsum double layer, and the formation of M-S-H. In Figure 9, a micrograph

of the PC mortar immersed for 32 weeks in MgSO_4 is shown. The high magnification image on the right represents a region about 500 μm from the surface of the mortar specimen, as shown by the highlighted area on the low magnification image on the left. Gypsum deposits around an aggregate can be observed, and small inclusions of thaumasite (corresponding X-ray spectrum shown at the bottom) are also found.

Figure 10 depicts a region near the surface of the mortar where the C-S-H has been completely transformed to M-S-H. Bands of gypsum are also observed. Thick layers of gypsum and brucite have precipitated underneath this surface region, presumably due to the penetration of the solution through the cracked region. Another region of the paste showing complete conversion to M-S-H has been shown in Figure 11. Figure 12 shows an overview of the mortar attacked by magnesium sulfate. The paste within this near-surface region appears dense, with abundant deposits of gypsum around aggregates and in air voids. Some cracks are also observed around aggregates and in the paste. Figure 13 is a high magnification image of the mortar in MgSO_4 showing a dense but cracked microstructure of the paste.

In Figure 14, the surface region of the mortar attacked by magnesium chloride is shown. From the low magnification image on the left, the brucite layer appears more than 100 μm thick. In the high magnification image on the right, a deposit of Friedel's salt can be observed. The paste in this surface region has a porous appearance. An intimate mixture of C-S-H and Friedel's salt is seen in Figure 15. Formation of M-S-H was also detected for the PC mortars in MgCl_2 , as shown in Figure 16. Figure 17 shows an overview of the surface zone in the PC mortar attacked by MgCl_2 . The paste in this region appears porous, although there are fewer cracks compared to the mortar in MgSO_4 . A high magnification image shown in Figure 18 shows the nature of the paste in MgCl_2 . This paste is marked by the presence of numerous voids resembling Hadley grains, which are the main cause of the porous appearance.

4. DISCUSSION

The primary difference in the pattern of attack by magnesium sulfate and magnesium chloride is seen in the rates of deterioration. The attack by MgSO_4 starts slowly, owing to the limited penetration of the sulfate ions into the mortar because of the formation of a surface layer of brucite. The reaction at this stage becomes diffusion controlled. The sulfate ions diffusing through the brucite layer react with the hydrated cement products to produce gypsum and ettringite. The reduction in pH due to the consumption of calcium hydroxide (CH) can ultimately lead to the decalcification of the C-S-H. The formation of M-S-H occurs when the C-S-H is directly attacked by the magnesium sulfate solution. The brucite layer tends to break down leading to an increased penetration at later ages. This is reflected in the increased rate of attack as seen from the sudden jump in mass, and a sudden drop in the compressive strength seen at later ages with MgSO_4 attack. The presence of M-S-H is primarily in those areas within the specimen where the brucite layer is cracked. This implies that the damaging effects of the attack can be delayed considerably if a thick brucite layer is formed.

Cementitious systems having large replacement levels of pozzolans have been reported to perform poorly during magnesium sulfate attack [1, 14]. This can be attributed to the consumption of calcium hydroxide by the pozzolanic reaction. Thus, only small amounts of brucite can form in such systems. This can lead to a quicker direct attack on C-S-H. However, at optimal dosages, the reduced permeability and pore refinement that is obtained by pozzolanic replacement can effectively offset the negative effects of the pozzolanic reaction during magnesium sulfate attack [14].

MgCl_2 attack occurs very rapidly at first, but then slows down ultimately. The high quantity of brucite formed in MgCl_2 attack, along with the rapid consumption of CH indicates that the primary effect of the Mg ion is to drive the reaction towards brucite formation. The rate of attack, as seen from the mass change and compressive strength measurements, slows down at later ages, possibly because of a decreased formation of brucite. MgCl_2 attack depletes the CH very fast to form brucite, and triggers the decalcification of C-S-H, thus rendering the paste porous. Due to the absence of sulfate ions, the only secondary product that forms as a result of decalcification is M-S-H. Because no other secondary products are deposited, the structure is rendered porous, causing a rapid drop in strength at early ages. The chlorides enter into reaction with C_3A to produce chloroaluminate compounds such as Friedel's salt. These chloroaluminate compounds are reported to be similar in appearance to ettringite but do not cause any expansion [5]. Chlorides also get incorporated within the C-S-H. The CaCl_2 that is formed as a result of the reaction between MgCl_2 and CH is highly soluble and does not precipitate.

5. CONCLUSIONS

Magnesium ion attack of PC mortars was studied by monitoring physical, chemical, and microstructural properties of mortar specimens immersed in magnesium sulfate and magnesium chloride solutions.

The presence of the Mg ion is responsible for the following:

- (1) Formation of an insoluble surface layer of brucite on the surface of the mortar specimens that temporarily prevents further ingress of the attacking solution. However, the formation of brucite leads to a rapid consumption of calcium hydroxide. When no secondary products (such as gypsum) are precipitated, the consumption of calcium hydroxide can render the structure porous leading to a rapid drop in strength.
- (2) Direct or indirect attack of C-S-H and its subsequent conversion to M-S-H (reported to be non-cementitious) that causes the ultimate degradation of the mortars. In the case of a direct

attack, such as that happening in case of magnesium sulfate solution, the C-S-H is transformed progressively into silica hydrate and M-S-H through reactions with the attacking solution. On the other hand, indirect attack pertains to the situation where decalcification of C-S-H occurs as a result of the prevalent low pH levels (created by the consumption of calcium hydroxide). Subsequent conversion of decalcified C-S-H to M-S-H causes the ultimate failure.

ABSTRACT

Alkaline activation of fly ash yields materials whose strength exceeds that of standard Portland cements. Alkaline activation (AA) of fly ash in aqueous medium at $\text{pH} > 12$, when the material sets and hardens, is a process differing from hydration of inorganic binders such as Portland cement. In the former process (mostly taking place by the “through solution” mechanism) the atoms of Al (and probably also those of Ca) penetrate the originally silicate lattice of fly ash, producing a 2D-3D inorganic hydrated polymer (geopolymer) having the general formula $M_n[-(\text{Si}-\text{O})_z-\text{Al}-\text{O}]_n \cdot w\text{H}_2\text{O}$. The hydration products of alkali-activated fly ash are amorphous in character, with prevailing $\text{Q}^4(2\text{Al})$ arrangement and minority crystalline phases. The properties of alkali-activated fly ash depend on the way of preparing the mix, in particular on the concentration of the alkaline activator and on ambient moisture conditions. The optimum conditions were attained by curing at $60 - 90^\circ\text{C}$ in open atmosphere. Additions of blast-furnace slag to alkali-activated mixes bring about significant increases in strength (more than 150 MPa in compression) under hydrothermal conditions at $60 - 90^\circ\text{C}$ when also the C-S-H phase is formed apart from the geopolymeric one. Materials based on AA fly ash can be characterized as “chemically bonded ceramics”, or as geopolymers, or as low-temperature hydrated aluminosilicate glasses.

Key words: Fly ash, geopolymer, high strength, new materials

1. INTRODUCTION

Slag-alkali cements [1,2], alkali-activated gypsum-free cement [3], cements of the Pyrament [4] type or geopolymeric binders [5,6,7] are new types of inorganic binding agents whose common feature is alkaline activation of clinker or substances with latent hydraulic properties, such as slag or fly ash. The effect of solutions of alkaline compounds (such as NaOH, Na_2CO_3 or Na_2SiO_3) on hydraulically active substances consists of disrupting the Si-O-Si bonds and producing hydrates of alkali-lime aluminosilicates similar to zeolites, and hydrates of the type C-S-H phase, gehlenite hydrate and hydrogarnates. Alkali-activated binders provide the possibility of utilizing waste materials, because the properties of materials based on alkali-activated binders are often superior to those of concrete and mortar prepared from standard Portland cement. The presence of zeolite-type substances is responsible for modifying the properties of the alkali-activated binders, for instance by increasing their resistance to acids [8] or improving their ability to immobilise heavy metals [9,10].

The literature presents relatively little information on binders based on alkali-activated fly ash. However, the results published recently [11,12,13] show that alkaline activation is also applicable to materials such as fly ash, similarly to the case of blast-furnace slag.

The Czech Republic produces annually more than 10 million tons of fly ash. Some of it is utilized as an additive to cements and concrete, but the majority is disposed of on dumps (for instance in a mixture with waste gypsum). For this reason we have been dealing with other possibilities of using waste power station fly ash, and with the development of new materials based on alkali-activated fly ash.

The present study is concerned with the effect of alkaline activators of the type NaOH and Na₂SiO₃ on aqueous suspensions of fly ash, also in the presence of ground granulated blast-furnace slag.

2. EXPERIMENTAL

The raw materials employed in the study were power station fly ash and granulated blast-furnace slag. Their chemical compositions are given in Table 1.

Table 1.

wt. %	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	K ₂ O	Na ₂ O	TiO ₂	P ₂ O ₅	Combustible substances
Slag	40.46	7.31	0.25	41.93	6.82	0.95	0.63	0.41	0.19		
Fly ash	53.79	32.97	5.51	1.84	0.92	0.46	1.76	0.37	2.1	0.15	0.74

In the experiments, use was made of non-ground fly ash with a specific surface area of 210 m²/kg (Blaine), and of fly ash samples ground to a specific surface area of 450 - 600 m²/kg. The slag was ground to a surface area of 350 m²/kg and 520 m²/kg respectively. The binder was prepared by mixing the fly ash and the slag in proportions over the range from 100 to 5 wt.% fly ash and from 0 to 95 wt.% slag. The alkaline activator was added in the form of solution to the dry mixture of fly ash and slag. The SiO₂/Na₂O ratio (module M_S) of the alkaline activator was adjusted by adding NaOH to water glass having the module M_S = 1.68 so as to obtain values over the range of M_S = 0.6 - 1.6. The water glass employed had the composition 25.98% SiO₂, 15.49% Na₂O and 58.53% H₂O. The total concentration of the alkaline activator was varied over the range of 4 to 10% Na₂O of the binder weight. The pastes prepared in the experiments had mostly a w of 0.30 (w = weight of H₂O / weight of fly ash + slag).

The binder pastes were moulded into specimens 20x20x20 mm in size, which were kept for 24 hours in an environment of 95% relative humidity and then unmoulded. The subsequent curing was carried out under various conditions of temperature and relative humidity. The “moisture cured” specimens were kept in an environment of 95% R.H. up to the time of compressive strength testing. Some specimens were subjected to “hydrothermal curing”, namely after the 24 hours of curing at 95% R.H. they were heated up to 60°C during 1 hour, up to 40 – 90°C during 2 hours and kept at the respective temperatures for an additional 4 hours. In the course of the hydrothermal curing process the specimens were kept in an enclosed space where the water vapour pressure corresponded to the respective temperature. Following this hydrothermal treatment the specimens were kept at 20°C and 40-50% R.H. up to the term of strength testing. The remaining part of the specimens were exposed to “dry curing”, when following their preparation they were placed in a drying oven at a temperature of 60 – 90°C (in open atmosphere) for 4 to 24 hours and then kept in air at 40 – 50% R.H. up to the time of testing. The compressive strength was tested after 2, 7 and 28 days. The fragments from the compressive strength tests were studied by X-ray diffraction, FTIR and thermal analysis and by high-pressure mercury porosimetry. The NMR MAS spectra (²⁹Si, ²⁷Al) were also measured. The microstructure was studied on fracture surfaces by the scanning electron microscope, and ED spectrometric analysis was carried out at selected points.

2.1 Results and Discussion

It may be generally said that the strength of alkali-activated (hereinafter AA) fly ash is influenced by the M_s modulus and the concentration of Na_2O in the alkaline activator, where the optimum performance was achieved at Na_2O concentration of 7 to 10% and at M_s of 0.6 to 1. The curing conditions are the dominant factor controlling the strength of AA fly ash. The initial strength of the AA fly ash system (for “moist curing” at 25°C) is very low and essentially independent of Na_2O concentration and the M_s module. The 28-day strength of the systems after curing at 20°C is also relatively low. A considerable increase in strength of the AA fly ash system was due to hydrothermal curing. The “dry curing” brought about a significant increase in strength (Figure 1) when the 24-hour strength exceeded the 28-day strength of standard Portland cement.

Figure 1. Compressive strength of alkali activated fly ash.

A very rapid increase in strength was found with mixes containing 50 – 70% fly ash and 50 – 30% slag, cured under hydrothermal conditions (Figure 2). However, relatively low strengths were achieved with systems of AA fly ash and slag under “dry curing conditions”. Under “hydrothermal conditions of curing” the effect of grinding fineness of slag and fly ash was significant. With the system composed of 50% fly ash and 50% slag, 28-day strengths of up to 170 MPa were achieved by hydrothermal curing. These strengths are comparable to those of the new bonding materials (DSP materials 120 to 130 MPa, MDF materials 100 – 300 MPa).

Figure 2. Compressive strength of alkali activated fly ash with slag.

The information obtained on the properties of the systems being studied indicates that the principle of alkaline activation is likewise applicable to power station fly ash. However, the formation of hydrates by alkaline activation of mixes comprising 100% fly ash is distinctly slower under both moisture and hydrothermal curing conditions than in the case of slag. Under the conditions of alkaline activation, the higher content of CaO in slag compared to fly ash obviously contributes to faster formation of bonding hydrates, particularly zeolite-like substances.

The basic hydration products in alkali-activated materials were identified in specimens hydrated at 20°C, in those cured under hydrothermal conditions, and in specimens first treated by “dry curing” and subsequently moisture-cured for additional 28 days.

The X-ray diffraction patterns (Figure 3) show that the hydration products are mostly of X-ray amorphous character, where the sole diffraction (apart from that of mullite and quartz from the original material) is that of $d = 0.304$ nm, and that only in the systems with a high content of slag. This line obviously corresponds to the C-S-H phase formed. The results of thermal analysis (Figure 4) likewise indicate the presence of hydrated amorphous (gel-like) products, showing a continuous loss of H₂O in terms of temperature. The loss in weight of the products is listed in Table 2.

Table 2.

Curing conditions	Δm (%)	
	20-200 °C	200-600 °C
Dry conditions	8.21	2.53
Hydrothermal curing	8.56	2.68

The TA data show that the H₂O content in the products is virtually identical regardless of the conditions of curing.

Regardless of the curing conditions, the basic matter of the hydrates is positively of amorphous glassy character, only rarely containing acicular minority formations (Figures 5, 6). The results of ED spectrometer analyses of the fracture surfaces show that most of the hydrates are sodium

aluminosilicate ones. The minority of hydrates are probably composed of polymerized water glass in which Al was partially substituted for Ca.

The hydrates contain residues of the original fly ash particles on which the effects of gradual dissolution are apparent. The AA fly ash was found to exhibit a relatively high porosity (of up to 50%) regardless of the curing conditions. The material contains closed spherical pores formed by dissolution of the original ash particles and possibly by air entrapped during the preparation. A distinctly lower porosity is shown by the AA fly ash–slag mixes, where the total porosity amounted to 2-10% and there was a shift towards smaller pore sizes (Figure 7 vs. Figure 8).

On FTIR spectra (Figure 9) one can find the differences due to different conditions of alkaline activation. The band corresponding to Si-O and Al-O vibrations [14,15] of the original fly ash at $1080\text{--}1090\text{ cm}^{-1}$ is shifted towards lower values by alkaline activation. This shift is explained as a result of incorporation of aluminium into the original structure of the Si-O-Si lattice, similarly as has been found in the case of zeolites [18]. The more distinct the shift, the higher degree of aluminium penetration from the original mullite into the $[\text{SiO}_4]^{4-}$ lattice.

Analogous results have been obtained by NMR measurements of AA fly ash in solid phase. Table 3 presents evaluation ^{29}Si MAS NMR spectra (deconvulence of the spectra obtained).

Figure 7. Pore size distribution of alkali activated fly ash.

Figure 8. Pore size distribution of alkali activated fly ash with slag.

Figure 9. Infrared spectrum of alkali activated materials.

Table 3. Evaluation of ^{29}Si MAS NMR spectra

Co-ordination Si,Al [16,17]	Si(4Al)	Si(3Al,1Si)	Si(2Al,2Si)	Si(0Al)	shift (ppm) % in spectrum
Raw fly ash	-79.1 8%	-87.6 23%	-95.8 8%	-107.4 61%	
AA fly ash hydrothermal curing		-88.5 40%	-96.2 23%	-107.3 32%	
AA fly ash dry curing		-90.1 52%	-98.7 17%	-106.0 28%	
AA fly ash + slag	-81.2 6%	-90.4 51%	-98.9 16%	-104.9 25%	

The deconvolution yielded signals with a very close value of the shift and with various representations in percent. The majority signal of the original fly ash was attributed to tetrahedral $[\text{SiO}_4]^{4-}$ (Si(0Al)); the co-ordination Si(2-3Al), also established for this spectrum, probably corresponds to the mullitic phase. A sample of AA fly ash that underwent hydrothermal curing exhibited a quite different structure. The Si(0Al) was eliminated down to 5% (in contrast to 61% in the fly ash), new formations appear in the structure, co-ordination Si(4Al) has a representation of 40% and the content of Si(4Al) was more than 50%. This shift is still more distinct with the sample of AA fly ash cured under “dry conditions”. In this case more than 50% of the bonds show Si(4Al) co-ordination and the rest the Si(2-3Al) co-ordination. The ^{27}Al spectra are almost identical, which confirms the similarity of the two materials, where the only difference arises in the signal intensity of about 10 ppm (beyond the framework of the experimental error).

Alkaline activation of fly ash in an aqueous medium at $\text{pH} > 12$, which causes the material to set and harden, differs from the processes of hydration of inorganic binders, for example of Portland cement. The former process obviously proceeds by the “through solution” mechanism where the fly

ash particles (SiO_2 and mullite) first dissolve in the strongly alkaline medium and a new geopolymeric structure is formed from the solution. A 2D-3D inorganic hydrated polymer (geopolymer) having the general formula $M_n[-(\text{Si}-\text{O})_z-\text{Al}-\text{O}]_n \cdot w\text{H}_2\text{O}$ is produced. An elevated temperature of 40 to 95°C is necessary for establishing an adequately interconnected lattice of bonds in the geopolymer. A significant part is played by the moisture conditions, where “hydrothermal curing” yields lower strengths than the “dry curing” conditions. According to the FTIR and NMR results, the “dry curing” causes more Al atoms to become incorporated in the originally silicate lattice of fly ash and to create a more interconnected lattice structure of the geopolymer. According to the results of TA the water content is virtually the same after heating up in open atmosphere and after hydrothermal curing. However, it is possible that the small loss of H_2O due to heating in open atmosphere (“dry curing” conditions) affects positively the process of incorporation of Al atoms and the degree of higher interconnection of the structure.

On the other hand, the hydrothermal curing conditions are optimal in the presence of another hydraulically active substance, namely the slag. In that case the strengths achieved by “dry curing” conditions are distinctly lower (by 30-50%). Under hydrothermal curing and alkaline activation conditions, blast-furnace slag is even capable of forming additional hydrates of type CSH and CAH phases that can contribute to higher strength.

The materials based on alkali-activated substances exhibiting latent hydraulic properties (fly ash, slag) obviously belong among the materials which, due to their high strengths and prevalingly amorphous structure, constitute a transition between the classical inorganic binders and ceramics, and can be affiliated to the group called “chemically bonded ceramics”. The materials based on AA fly ash can be characterized as an inorganic polymer similar to zeolitic precursors. The materials can also be described as low-temperature hydrated aluminosilicate glasses.

It should be emphasized that the materials of the type of “chemically bonded ceramics”, such as the MDF or DSP modifications, are frequently prepared by special methods such as isostatic pressing, vacuum compaction, etc. In contrast to this, in our experiments the materials based on chemically activated substances with latent hydraulic properties were prepared by standard methods, have acceptable rheological properties and acceptable times of early set.

3. CONCLUSIONS

The products of hydration of alkali-activated fly ash are of amorphous character and contain minority crystalline phases. The FTIR demonstrates the difference between the non-hydrated and the alkali-activated fly ash, where the main band corresponding to SiO and AlO vibrations is shifted towards the lower values. In the Si^{29} MAS NMR spectrum, the hydration products of alkali-activated fly ash exhibit a three-dimensional glassy structure with prevailing $\text{Q}^4(2\text{Al})$ arrangement. Alkaline activation brings about penetration of Al atoms into the original silicate network of fly ash.

The properties of alkali-activated fly ash depend on the way the mix has been prepared and treated, particularly on the concentration of the alkaline activator and on moisture conditions. The optimum results were obtained under the “dry curing conditions”.

Considerable increases in strength were obtained when blast-furnace slag was added to mixes of alkali-activated slag. “Hydrothermal curing” has proved as being the optimum one for these mixes, as apart from the geopolymeric phase, also C-S-H phases are formed under these conditions, with the resulting compressive strength of more than 150 MPa.

The alkali-activated binders provide the possibility of utilizing waste inorganic materials, and the properties of the resulting binders often surpass those of standard Portland cement. The materials

based on AA fly ash can be characterized as “chemically bonded ceramics”, or as geopolymers, or as low-temperature hydrated aluminosilicate glasses.

ABSTRACT

The effect of temperature over the range 20–80°C on the heat output of a number of Portland-blastfurnace slag blended cements has been studied by isothermal conduction calorimetry (ICC). The materials used were 100% ordinary Portland cement (OPC), 1:1, BFS:OPC, 9:1 BFS:OPC and, as a preliminary study, 100% ground granulated blast furnace slag (BFS). A superplasticiser was incorporated, allowing a very low water:powder ratio of 0.31 to be used. Results indicate that the setting of the cement was accelerated both with increasing temperature and decreasing slag content, although even 100% BFS at 20°C set within 48 hours. The presence of a peak ‘S’ was not observed at 60°C or 80°C. It was also noted that, as the curing temperature was increased, the contribution of the slag fraction to the total heat evolved increased.

1. INTRODUCTION

The use of composite cements based on the partial replacement of Portland cement by waste materials has become commonplace because they offer cost reduction, energy saving and, often, superior longer term products. These replacement materials fall into two nominal groups, pozzolanic and latently hydraulic. The first group includes pulverised fuel ash (PFA), rice husk ash, volcanic ash and silica fume. Ground granulated blast furnace slag (BFS) is the most notable material from the second group and the one used for this study. Cements containing up to about 65% BFS are well established and characterised in the literature [1-2]. However, cements with higher levels of replacement are less well documented [3] as they are more likely to be used for specific applications, for example, when low heat evolution is important, rather than in general construction.

The safe and cost effective storage and disposal of radioactive waste is a major problem facing all countries with nuclear power generating capacity. While the high level waste is likely to be vitrified prior to final disposal, cementation is the favoured method in the U.K. for disposal of low and intermediate level waste. It is essential to have a full and fundamental understanding of the effects that these waste materials have on the hydration behaviour and microstructural development of cement pastes, in order that reasonable predictions can be made concerning the long term storage of these products.

Due to the exothermic nature of cement hydration it is desirable, for the prediction of the long-term performance of packaged immobilised radioactive waste, to measure the exotherm produced. Many nuclear waste encapsulation processes use composite cements with high

replacement levels in part because of the reduced amount of heat generation of these systems. However, due to the scale of the encapsulation, temperatures within a package can rise significantly above ambient. It is also known that blast furnace slag can contribute to the total heat generation, especially at higher temperatures [4-8].

Isothermal conduction calorimetry (ICC) can provide valuable information on the early hydration of cements as well as the heat evolution during this hydration. The heat evolution plots obtained are not only affected by the composition of the cement but also by the presence of replacement materials and are strongly dependent on the temperature of hydration. Previously reported calorimetric studies [4-9] have examined the effect of temperature up to 60°C, but in this study, curing temperatures up to 80°C have been used to establish the contribution to the evolution of heat from the BFS. The data will be used in modelling studies to predict the temperature rise after various curing times in composite cements based on high levels of replacement of OPC by BFS, and to validate models being developed to predict thermal characteristics of cemented mixed waste products.

2. EXPERIMENTAL

Four cement systems were studied during this investigation. These were 100% ground granulated blast furnace slag (BFS), 100% ordinary Portland cement (OPC), 1:1 BFS:OPC and 9:1 BFS:OPC. The OPC was supplied by Castle Cement with the coarse ground BFS being sourced at Redcar Steelworks. All powders were prepared to comply with the specification of BNFL plc. The typical chemical analyses for these materials are given in Table I, and correspond to a potential phase composition for the OPC, based on the Bogue calculation, of C₃S, 53.5%; C₂S, 19.1%; C₃A, 7.7%; and C₄AF, 9.4%.

Table 1. Typical chemical analyses of materials used during the investigation

Component	OPC	BFS
CaO	64.4	42.1
SiO ₂	20.7	32.3
Al ₂ O ₃	4.9	13.1
Fe ₂ O ₃	3.1	0.5
MgO	2.2	6.5
SO ₃	2.9	—
K ₂ O	0.5	0.4
Na ₂ O	0.2	0.3
Chloride	0.02	0.03
Sulphide	-	0.9
Loss on ignition	0.9	0.8
Free lime	1.4	—

The powders were hydrated with deionised water containing a naphthalene sodium sulphonate admixture. A constant liquid:powder ratio of 0.31 was chosen. The admixture was added to the deionised water in such a quantity that the concentration of admixture in the paste was 0.65 ± 0.01 ml per 100 g of powder. Since the amount of cement in each system was different, and since the liquid used for hydration contained water and the plasticiser, the w:c ratio was not constant at 0.31. The true w:c ratios are presented in Table 2

Table 2. True w:c ratios for the cements studied

System	w:c ratio
100 % BFS	-
100 % OPC	0.3035
1:1 BFS/OPC	0.607
9:1 BFS/OPC	3.035

Two JAF calorimeters, supplied by Wexham Developments, were used and external mixing employed throughout. Internal mixing was not used as the design of this equipment only allows for very small samples (2g of powder) which resulted in very weak outputs, especially for samples with high levels of cement replacement. At temperatures up to and including 60°C a water-filled bath and perspex cells were used and maintained at a constant temperature $\pm 0.1^\circ\text{C}$. A diagram of a typical cell can be seen in Figure 1. At higher temperatures a silicone-oil filled bath and stainless steel cells were used. The stability of the temperature of this bath at 80°C was $\pm 0.5^\circ\text{C}$. Using this apparatus it was possible to observe the rate of heat evolution and the cumulative heat of hydration for treatments lasting either 72 hours (for temperatures 40°C and below) or 48 hours (for temperatures 60°C and above).

Figure 1. Calorimeter cell

Pastes consisting of 15 ± 0.001 g of powder and 4.65 ± 0.002 g of the water/admixture solution were mixed in polythene bags until homogeneous (approximately 2 minutes). The bags were then closed using adhesive tape, placed into sample cans containing transformer oil, and sealed inside the calorimeter cells. The cells were then immersed in the water/oil bath within 10 minutes of mixing having taken place. Prior to sample insertion, the cells were placed in the baths for a sufficient period of time to allow acclimatisation to the bath temperature. However, for experiments taking place at elevated temperatures, the cells cooled as the specimens were introduced, resulting in an initial endothermic response as the

relatively cooler cell re-heated to the bath temperature. The period of reheating lasted up to 2 hours and completely obscured the exothermic heat of wetting. This ‘reheating endotherm’, which has been removed from the results, affected the runs carried out at higher temperatures (60°C and 80°C) more than those at the lower temperatures. However, the reproducibility of the results at these temperatures was good, although there was increased noise on the trace, believed to be a consequence of the need to use stainless steel calorimeter cells rather than perspex. The rate of heat flux for a given temperature difference is a function of the heat transfer coefficient of the fluid and the thermal conductivity of the barrier. The thermal conductivity of stainless steel is two hundred times higher than that of perspex and, therefore, fluctuations in the temperature of the water bath are more strongly relayed to the thermopiles inside the cells, imparting greater noise.

3. RESULTS

Isothermal conduction calorimetry results are presented in Figures 2-9 for all the cement systems used. There were distinct differences in the rate of heat output of the individual cements at the different temperatures and also between the different cement systems at the same temperature (Table 3).

The effect of temperature on the rate of heat output of ordinary Portland cement can be seen in Figure 2. The sharpness of the peak and the amount of heat generated when considering the values of Q_m , the value of the maximum rate of heat output, (Table 3) increased with increasing temperature. However, t_m , the time at which Q_m occurred, decreased with increasing temperature. This demonstrates that increasing the temperature caused a classic acceleration of the set of the cement. When considering the total heat output (Figure 3) it can be seen that the shape of the curves at 40 and 60°C were similar but displaced, with the sample cured at the higher temperature generating more heat. At 20°C, there was a delay in the initial heat output followed by an acceleration in heat generation, so that, by around 35 hours, this sample had generated more heat than that at 40°C. At 80°C there was rapid initial heat evolution to 8 hours followed by a dropping off of the curve possibly due to evaporation of transformer oil and/or degradation of the sample bag and, therefore, mixing of the oil with the cement. After 60 hours hydration the sample cured at 60°C had generated more heat than at 80°C. This is a similar trend to the one seen between the 20°C and 40°C results. This is illustrated clearly in Table 3 and Figure 3.

Figure 2. 100% OPC

Figure 3. 100% OPC

Replacing 50% of the OPC with BFS (Figures 4 and 5) had the effect of decreasing the value of Q_m by just over half (Table 3). Again, it can be seen that the effect of decreasing temperature was to retard the set of the cement. However, unlike the neat Portland cement, there was no overlap in the total heat outputs of the slag cements but there was a longer initial delay at 20°C than at either 40, 60 or 80°C. If the slag fraction of the cement did not contribute to the cement hydration it would be expected that the total amount of heat generated would be half that of the OPC. At 20°C, the amount of heat generated by the slag cement was less than half that of the OPC. As the temperature was increased, however, the total amount of heat generated by the slag-containing cement also increased, so that, after 40 hours hydration at 80°C, the amount of heat generated was not dissimilar; 262 kJ kg⁻¹ compared with 255 kJ kg⁻¹ (Table 3).

Figure 4. 1:1 BFS:OPC

Figure 5. 1:1 BFS:OPC

The addition of 90% BFS to the cement (Figures 6 and 7) also had the effect of reducing the rate of heat generated (Q_m values decreased when compared to both OPC and 1:1 BFS:OPC) and reducing the total amount of heat generated at all temperatures (Table 3). Applying the same assumption that the slag acted merely as an inert diluent, there should have been only one tenth of the amount of heat generated when compared to 100% OPC. It can be seen from Table 3 that this was not the case at any of the temperatures studied. The heat generated from the 9:1 BFS:OPC system was consistently higher than one tenth. It can be concluded from the results of the 1:1 and 9:1 BFS:OPC systems that the slag fraction of the cement did contribute to the overall heat generated and, at higher hydration temperatures, this contribution was greater than at ambient temperature. Another interesting feature of these systems incorporating BFS was that the evidence for a peak 'S' (as reported elsewhere, e.g. [5-8,10,12], and discussed below) was not very strong, even at the 90% replacement level, although there was a broadening of the peaks at lower temperatures. The total heat output curves (Figure 7) followed the same trend as that observed for the 1:1 BFS:OPC cements.

Figure 6. 9:1 BFS:OPC

Figure 7. 9:1 BFS:OPC

The results of the hydration of the 100% BFS sample are shown in Figures 8 and 9. Although data for hydration at 80°C have been obtained they are not shown because they are not felt to be as reliable as the other data presented in this paper due to problems with the sensitivity of the stainless steel cells and the sensitive nature of the heat output. Further experimentation is continuing to obtain more reliable quantitative data. It can be seen that even at 20°C a definite peak was observed (Figure 8) but with a very low rate of heat output. This would be expected for a slag that was not being strongly activated by calcium hydroxide. The total heat of hydration was also low but, even at 20°C, it can be seen that heat was still generated and, therefore, that some hydration was taking place. The Q_m values (Table 3) at all temperatures were very similar to those of the 9:1 BFS:OPC system. However, the t_m values changed with temperature. At 20°C, the value for the 9:1 BFS:OPC cement was less than that for the pure BFS system. At 40°C and 60°C the opposite is true, which suggests that the increase in temperature has a greater effect on the hydration of BFS than that of the OPC.

Figure 8. 100% BFS

Figure 9. 100% BFS

The general trend between the different cement systems (Table 3) is that the maximum amount of heat generated decreased and the time taken to reach this maximum increased with increasing slag content. The opposite trend was observed as the curing temperature increased. All data need to be interpreted with care because in a number of systems (especially at lower curing temperatures) heat evolution was continuing beyond 72 hours, so the total heat recorded in Table 3 is incomplete. This, however, has no bearing on the general trends of the results.

Table 3. Values of Q_m (value of maximum rate of heat output), t_m (time at which Q_m occurs) and total heat evolved

Temp (°C)	Cement	t_m (hours)	Q_m (Wkg ⁻¹)	@ Q_m	Total heat evolved (kJkg ⁻¹)		
					24 hours	40 hours	60 hours
20	100% OPC	10.8	3.7	62.5	177.3	225.8	247.3
	1:1 BFS:OPC	11.9	1.3	16.7	57.3	77.6	91.3
	9:1 BFS:OPC	29.5	0.7	25.7	13.0	46.9	72.3
	100% BFS	33.3	0.6	16.3	6.3	27.8	43.5
40	100% OPC	4.7	9.8	59.8	206.3	217.1	223.5
	1:1 BFS:OPC	6.2	5.3	40.4	152.9	175.2	185.1
	9:1 BFS:OPC	10.7	1.5	19.3	69.1	89.6	98.1
	100% BFS	8.1	1.7	11.8	40.1	44.1	45.4

80	100% OPC	1.8	44.7	48.1	266.9	261.6	256.1
	1:1 BFS:OPC	3.5	20.7	258.6	257.5	255.1	-
	9:1 BFS:OPC	5.6	6.3	51.3	119.2	121.7	122.9

4. DISCUSSION

Isothermal conduction calorimetry provides valuable quantitative information about the hydration reactions that occur during the early stages of hydration of cements. The most obvious information given is the amount of heat released. Additionally, the shape of the curves and other features in the plot can also provide information about the relative rates of hydration and the occurrence of other reactions (such as slag hydration). There is some disagreement as to the reactions associated with each peak but generally they are as follows. Peak I is due to the initial interaction and wetting of the cement powder with water and early stage reactions (not seen in this study because of the use of external mixing). After this initial peak there is the dormant period (also known as the induction period) during which little heat is evolved and the stiffness of the paste increases, followed by acceleration in heat evolution during which setting occurs [11]. The main peak, known as peak II, occurs after this acceleratory period and is generally believed to be due to the hydration of C_3S and generation of C-S-H gel and CH. In composite cements incorporating significant amounts of blast furnace slag, a peak 'S' occurring after peak II has been attributed to the hydration of the slag fraction [2,11] because this requires activation by the alkali which, in this case, is the calcium hydroxide liberated during the hydration of the C_3S [2,11]. It has also been reported, however, that, as the curing temperature increases, the occurrence of peak 'S' disappears as the slag hydration becomes increasingly thermally activated until peaks II and 'S' merge [4-8].

Perhaps the two most relevant previous studies of the heat evolution from OPC-BFS composite cements at elevated temperatures are those by Ma et al. [4], who studied a cement with 65% replacement by BFS in the temperature range from 10 to 55°C, and Escalante and Sharp [5], who studied a cement with 60% replacement by BFS in the temperature range from 10 to 60°C. There are, therefore, two novel features to this investigation. The first is the application of ICC at the very high curing temperature of 80°C, while the second relates to the high replacement level (90%) of OPC by BFS, previously studied by Richardson et al [7] and Hill and Sharp [3,10]. The results were obtained to provide reliable quantitative data for theoretical models to be developed to predict the temperature variations in composite cement systems incorporating radioactive wastes. There is concern that if the heat of hydration is excessive and that the thermal profile within a package results in high thermal stresses, the integrity of the package may be adversely affected.

The results obtained are an extension of, and mostly similar to, those reported in previous studies [4-8,10,12]. It is confirmed that:

- the time to reach t_m , corresponding to the maximum in the heat evolution curve, for OPC, for the composite cements containing BFS, and indeed for ground, granulated BFS itself, decreases with increasing temperature
- the intensity of the main peak (often referred to as peak II and attributed to the hydration of alite to form C-S-H gel and calcium hydroxide) increases substantially with increasing curing temperature
- peak II is rather broad and shallow at 20°C, becoming stronger and sharper at higher temperatures (as can be seen in Figures 2, 4 and 6)
- the induction, acceleratory and decay periods in the hydration of cement can be clearly distinguished.
- the BFS is hydraulic and its reactivity increases markedly with increase in curing temperature (see Figure 8)

Although a pronounced asymmetry of the endothermic peaks is evident in Figure 6, and to a lesser extent in Figure 4, especially at 40 and 60°C, the presence of a definite peak 'S' attributed to the hydration of the BFS after activation by calcium hydroxide formed in the reaction occurring at peak II, is not as apparent as in previous studies. For example, using similar equipment and experimental procedures (except for the use of internal mixing), Ma et al. [4], Bland and Sharp [12], and Escalante and Sharp [5] had obtained a second peak or shoulder in OPC-BFS composite cements, especially in the temperature range from 30 to 55°C. In addition, Hill and Sharp [10], using external mixing and one of the calorimeters used in the present investigation, and a similar 9:1 BFS:OPC composite cement with a w:s ratio of 0.35 reported a clear peak 'S' at 35°C. There are three factors that may contribute to this observation, namely the mixing procedure adopted, the coarse nature of the BFS used, and the incorporation of the naphthalene-sulfonate admixture, allowing the use of a very low liquid:powder ratio (0.31). When the superplasticiser was omitted from the 1:1 BFS:OPC system at 60°C, t_m and Q_m were both reduced, while peak 'S' was evident as a shoulder followed by a tail for several hours on the right-hand side of peak II. The presence of the admixture resulted in very strong retardation in the 9:1 BFS:OPC mix, which was particularly evident at 40 and 60°C, because the relative amount of superplasticiser to Portland cement was very high in this composite cement.

If blast furnace slag were an inert diluent, it would be expected that, as Portland cement were replaced by slag, the heat generated would decrease accordingly. Therefore, in a 1:1 BFS:OPC cement, it would be expected that the total amount of heat generated at a given temperature would be half that of the Portland cement. However, it can be seen from Table 3 that this was not observed at any replacement level. The total amount of heat generated by the composite cement systems was generally greater than that which would have been predicted. Also, this effect became more pronounced as the curing temperature increased. This indicates that an increase in temperature has a greater effect on the slag fraction than on Portland cement. This has been observed in the literature [6-8] where activation energies have been calculated and been found to be higher for blast furnace slag than for Portland cement. This has implications for predicting the thermal characteristics of composite cement systems incorporating blast furnace slag. From the results presented here, it can be seen that simple adaptation of a model for Portland cement hydration would not be sufficient for predicting the thermal events of blast furnace slag cement. The continuing study into the neat blast furnace slag hydration will provide valuable data for validation of predictive models.

5. CONCLUSIONS

1. This study has shown that it is possible to obtain reliable quantitative data at elevated temperatures up to 80°C.
2. Thermal activation of the cements especially those incorporating BFS, increases with increasing temperature.

ACKNOWLEDGEMENTS

The authors would like to acknowledge BNFL plc for the financial support for this work and the supply of materials used. We are grateful to Mr E Miller for many helpful discussions.

ABSTRACT

The paper deals with ultrasonic investigation of the structure formation process in cement grout prepared on the basis of water and 8 % CaCl_2 and NaCl solutions at a water-to-cement ratio of 0.5. The comparison of curves of structure formation, with and without additives, shows that the increase in frequency of ultrasonic signal from 100 kHz to 1.2 MHz leads to a sufficient increase of sonic speed (by 2 – 10 times). At the same time this increase demonstrates more distinctly the minimums that correspond to the periods of cement grout setting. If for the initial setting period the increase of ultrasonic frequency does not have any sufficient effect, then the period of final set reduces (approximately by 2 hours). This fact confirms once more that any impact on the process of cementing agent hydration at the initial stage has a sufficient effect on the further flow of cementing system structure formation process.

1. INTRODUCTION

Ultrasonic methods have found extensive application for studying the structure formation process in mineral cementing agents [1,2] and non-destructive testing strength properties of artificial stone taking into consideration the size of internal defects of the structure [3,4]. However, this method is rarely used for studying the kinetics of structure formation, especially at the initial stage of the cementing agent's hydration. This is due to the fact that a measurement of propagation speed of sonic waves and signal amplitude is a difficult experimental task, especially for systems with a high rate of structure formation of e.g. cement grout with hardeners.

The purpose of this work is ultrasonic investigation of the structure formation process in cement grout prepared on the basis of water and 8 % CaCl_2 and NaCl solutions at a water-to-cement ratio of 0.5.

2. ULTRASONIC STUDY OF STRUCTURE FORMATION PROCESS IN CEMENT GROUT

The ultrasonic measuring chamber is a 200 cm³ Plexiglas cylinder mounted on microscope support. To avoid measurement errors arising due to volumetric changes of the cement grout during hardening, the receiver was fastened at the bottom of the acoustic chamber while the emitter was allowed to move freely along the height of the cylinder with the help of a microcrew. A clock-type indicator and IZV-2 unit measured the distance between acoustic delays, taking into account linear

deformations of the object concerned, with accuracy up to 0.001 mm. The principle of the test stand's operation is as follows. A reference pulse of the G5-4B generator starts horizontal scanning of the C1-54 oscilloscope. A pulse of negative polarity from one of the channels of the generator is fed to a radio pulse generator input. Then the pulse with basic frequency corresponding to a resonance frequency of the transducer is fed to a piezoelectric cell. The cell after having been excited by electric pulse forms an elastic pulse which, after passing the medium investigated, is transformed again into an electric pulse by the other piezoelectric cell. Then the signal amplified in the receiver is fed simultaneously to the B4-1A pulse millivoltmeter and the C1-54 oscilloscope and then analyzed.

The method of measuring ultrasonic wave parameters is as follows. Amplitude and speed of wave propagation in the grouting liquid (water or CaCl_2 and NaCl solutions) are measured in the acoustic chamber at $22 \pm 2^\circ\text{C}$ followed by Portland cement addition and mixing for 1 minute to a homogenous grout. The measurements are carried out at frequencies of 1.2 MHz and 100 kHz (for the purpose of comparison). Due to the problem of determination of the leading edge of the pulse because of considerable attenuation of the sonic wave at the early stage of hydration, the maximum of 2d and 3d half waves are taken as a reference. The following equation can be used for estimating the speed of acoustic vibration propagation:

$$c = L/(\tau_1 - \tau_2)$$

where L is the length of acoustic path in the medium considered; τ_1 is a total delay time of signal along the whole path; and τ_2 is the propagation time in acoustic delays. A maximum error of sonic propagation and signal amplitude measurement is respectively 1% and 5 %.

The first section on time vs. sonic speed graphs (Figure 1) characterized by sonic speed increase is the result of intensive wetting, dissolution and interaction of particles of cementing agent on the surface with the formation of external hydrates. The results of phase analysis show that the main hydrate phases having a high level of anisometricity during this period are ettringite (in water) and CSH (I) and ettringite (in chloride solutions).

Figure 1. Amplitude (1) and speed (2) of ultrasound ($f = 1.2$ MHz) in cement grout without additive (a) and with sodium (b) and calcium (c) chloride vs. hardening time

Figure 2. Sonic speed ($f = 100$ kHz) in cement grout without additive (1) and with calcium chloride (2) vs. hardening time

The next period is characterized by the formation of hydrosulfoaluminate (partially hydrosilicate) coatings. During this period the process of hydration slows down sharply, as reflected by the decrease in ultrasonic speed. Following the destruction of the blocking coating by crystalline pressure of the internal hydrates has the dominant effect on the decrease of sonic speed (due to a constant loss of contact between solid phase particles) as compared to the intensification of hydration. The latter is a result of more free diffusion of water to the unhydrated grains and the formation of periodic colloidal structures (PCS) with typical forces of molecular attraction and forces of interaction related to a polarization effect under the condition of restricted volume of the system [5]. The sonic speed slows down until the formation of a more or less stable spatial skeleton of coagulation structure from hydrate new formations including those growing on the surface of hydrating particles.

As the coagulation structure strengthens and phase contacts appear, sonic speed again increases. The first minimum on the curve corresponds to the initial setting of cement grout by Vical needle. Under the conditions of gradual increase in the number of phase contacts, filling voids with new formations and their interlinkage, the sonic speed increases as well. However, with time and with continued increase of plastic strength, caused by the transition of the coagulated structure into crystalline structure, sonic speed drops sharply. The comparison of data obtained with the results of the thermokinetic investigation shows that the minimum on the sonic speed curve, that approximately corresponds to the final set of cement grout by the Vical needle, coinciding with the maximum on the temperature vs. setting time curve. In this case the drop of sonic speed is caused, in our opinion, by a sharp increase of cement grout temperature. This, in turn, enhances thermal motion of particles of solid and liquid phases preventing the sonic pulse passing through the medium investigated. However, some researchers [4] think that temperature does not have a pronounced effect on this process.

After reaching the highest exothermal effect (during temperature drop) the thermal motion slows down and sonic speed increases again with the formation of rigid crystalline bonds. It should be noted that if the increase in ultrasonic signal amplitude during the formation of the coagulated structure of the cement grout results from a prevailing influence of new formations dispersion and a large quantity of free water, then, after commencing a final set, this is a result of the crystalline skeleton formation leading to the decrease of fluctuation absorption together with the decrease of transit time of the leading front of sonic wave. Besides, the decrease of free moisture and the increase of adsorbed moisture density (in pores and capillaries), as well as fibrous (or laminar) form

of new formations as compared to rounded grains of initial cementing agent at the initial stage of hydration lead to the decrease of sonic energy absorption. The introduction of sodium and calcium chloride into a cement grout leads to the increase in ultrasonic signal amplitude and reduction of specific periods on the curves of structure formation in accordance with the classical mechanism of accelerating action of the additives.

The comparison of structure formation curves, Figures 1 and 2, shows that the increase in frequency of the ultrasonic signal from 100 kHz to 1.2 MHz leads to a sufficient increase of sonic speed (by 2 – 10 times) and more distinct demonstration of minimums corresponding to the periods of cement grout setting. If for the initial setting period the increase of ultrasonic frequency does not have any significant effect, then the period of final set reduces (approximately by 2 hours). Data on sonic speed increase with the increase in signal frequency in cement grout obtained in these experiments agree with the opinion of the majority of experts [3]. The mechanism of the above phenomenon can be explained from the position of physical and chemical mechanics of dispersion. The increase in ultrasonic impact frequency in cement grout being kinetically active system as compared to inert one intensifies the process of hydration and hardening. As a result, we observe the increase of supersaturation with CaO and the formation of a large number of nuclei followed by crystallization of a large number of highly dispersed crystals of new formations in a unit of the system's volume. This results in the formation of amore dense structure with a large number of coalescence contacts.

3. CONCLUSION

The structure formation kinetics investigated with the help of the ultrasonic method reflects the main periods of cement grout hydration and hardening.

The introduction of chlorides into a cementing grout promotes a decrease in ultrasound absorption at the expense of intensive nucleus-formation and formation of more crystallized structure of the stone.

The increase of ultrasonic signal frequency from 100 kHz to 1.2 MHz leads to a significant increase of sonic speed and reduction of cement grout setting time.

ABSTRACT

The kinetics of metakaolin - calcium hydroxide reactions, effects of portlandite/metakaolin ratio on compressive strength and microstructural development were investigated. Portlandite - metakaolin pastes containing 25%, 50%, 65%, 80%, 90% and 95% of metakaolin were prepared at water/solid ratios of 1. The reaction kinetics was investigated using differential thermal analysis. The nature and quantity of hydration products were determined. In an additional series the hydration process of metakaolin - Portland cement pastes was studied by examining the hydration products. The replacement percentage of metakaolin was 8.4% and 15% by weight, respectively. The water to binder ratio was 0.33 in all the pastes. The relationship between the content of hydration products and strength development was obtained and discussed.

1. INTRODUCTION

In recent years the use of high-performance concrete (HPC) in structures has been greatly increased. Pozzolanic admixtures such as silica fume, fly ash, and metakaolin are used for the production of HPC [1 - 5]. In practice, a pozzolanic admixture can be introduced into concrete in one of two ways: as a partial replacement of cement and/or fine sand. It is known that the content of pozzolanic admixture influences properties of fresh concrete, mechanical properties and durability of hardened concrete. One of the engineering problems facing the technological engineer centers on the rational use of pozzolanic admixtures (i.e. choosing the optimal content of pozzolanic admixture) in the preparation of concrete and mortars. The pozzolanic admixtures such as silica fume and metakaolin are expensive materials. The non-rational use of pozzolanic admixtures will increase the cost of the mixture and/or reflect negatively on physical and mechanical properties of the concrete. It is known that pozzolanic admixture acts as chemically reactive material (able to react with portlandite) on the one hand and as microfiller, on the other hand. Quality and quantity of the active phases, the type of treatment, Si/Al molar ratio, the lime/pozzolana ratio in the mix, water to binder ratio, curing conditions, shape and size of particles, particle size distribution and specific surface area influence the activity of the admixture.

It is also well known that properties of concrete or paste are closely related to its microstructure and products of hydration. Of late, numerous studies have been reported related to the hydration of fly ash - cement, fly ash - lime, silica fume - cement and metakaolin - cement pastes [6 - 10].

Formation of calcium hydroxide (portlandite) and non-evaporated water in the system are usually the main criteria for estimating hydration process. Some researchers have also investigated the fraction of reacted fly ash and the alkalinity of pore solution in fly ash - cement pastes. However, the influence of quality and quantity of hydration products on compressive strength development has not been studied adequately yet.

The main objectives of this research were to investigate the influence of metakaolin/portlandite molar ratio on the kinetics of the hydration process, to determine the optimal molar ratio from the viewpoint of chemical activity and to find out the relationships between the content of hydration products and compressive strength. This information will facilitate the rational use of metakaolinite for designing concrete mixes.

2. EXPERIMENTAL WORK

2.1 Materials and properties

An ordinary Portland cement (ASTM Type 1) was used throughout this work. A commercial metakaolin (MK1) produced by Engelhard Corporation (USA) and heat-treated local kaolin clay (MK2) were used in this study. The chemical composition, amorphous phase content (A.P.C.) and specific surface area (S.A.) of admixtures and cement are given in Table 1. The portlandite was analytical grade $\text{Ca}(\text{OH})_2$.

Table 1. Chemical compositions of cement and additives (% wt.) and specific surface area (m^2/g)

	Portland cement	MK1	MK2
SiO_2	19.38	52.18	59.34
Al_2O_3	4.30	43.36	37.68
Fe_2O_3	1.95	0.25	1.86
TiO_2	0.38	4.21	1.12
CaO	64.8	0	0
MgO	1.09	0	0
Na_2O	0.19	0	0
K_2O	0.25	0	0
SO_3+Cl	1.92	0	0
P_2O_5	0	0	0
S.A.	0.35	11.4	18.3
A.P.C.		85	75

2.2 Chemical activity

Chemical activity, i.e. the ability to react with portlandite, $\text{Ca}(\text{OH})_2$, in the presence of an excess of water, was determined indirectly – using the results of the compressive test of the paste. Six compositions with different portlandite/metakaolin ratios were prepared (Table 2). Metakaolin (MK1) and portlandite were dry-mixed for 5 min in the pan mixer. Later water was added to the metakaolin - portlandite mixture and mixed for 5 min. The water to solid ratio (W/S) in the paste specimens was 1.

The pastes mixed with a pan mixer were cast as cube samples of 25-mm size and cured in air ($\text{RH}=65\%$, at 20°C) until demolding. The samples were demolded after 6 days and then cured in humidity room ($\text{RH}=100\%$, at 20°C) until testing at 3, 7, 14, 21, 28 and 90 days.

Three cubes were tested in compression at every testing age and the average strength was determined, with the individual values varying within $\pm 5\%$ of the mean.

Table 2. Mix compositions

Content of Admixture (% wt.)	Content of Meta-kaolinite (%)	Content of Portlandite (% wt)	CaO/(Al ₂ O ₃ ·2SiO ₂) Molar Ratio
25	21	75	12.3
50	42.5	50	4.1
65	55	35	2.2
80	68	20	1.0
90	76.5	10	0.5
95	81	5	0.2

2.3 Compressive strength of cement - metakaolin pastes

The water to binder ratio was 0.33 in the paste specimens. Heat-treated kaolin clay was used as admixture. The replacement ratio of admixture was 20% by weight; the content of amorphous phase was 8.4% and 15%.

The pastes mixed with a pan mixer were cast as cube samples of 25-mm size. The samples containing heat-treated kaolin clay (MK2) and the reference sample were demolded after 24 hours and cured in lime-saturated water at 20°C until the day of testing at 1, 3, 7, 14, 28 and 360 days.

2.4 Sample characterization

The weight change, energetic transformations and a gas evolution under elevated temperature were performed by simultaneous Differential Thermal and Thermogravimetric Analysis (DTA/TGA - Setaram TG 92-16.12, France). During DTA/TGA analysis the samples were heated at the rate of 5°C min⁻¹ to a maximum temperature of 1000°C in airflow of 30 cm³/min.

2.5 Hydration products

DTA/TGA analysis was used to study the nature of the reaction products, their content and the kinetics of the hydration process.

To investigate the effect of CaO/Al₂O₃·2SiO₂ molar ratio on the kinetics of reaction portlandite and metakaolinite, DTA/ TGA analysis was performed at age of 90 days for different mixtures and at age of 14, 28 and 90 days for the mixture that was found optimal from the viewpoint of chemical activity.

3. RESULTS AND DISCUSSION

3.1 Effect of CaO/(Al₂O₃·2SiO₂) molar ratio on chemical activity

The compressive strength development of the pastes with different CaO/(Al₂O₃·2SiO₂) molar ratio [MR] is presented in Figure 1.

Figure 1. Compressive strength vs. $\text{CaO}/(\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2)$ molar ratio

As can be seen, the molar ratio influences compressive strength development. There is a parabolic dependence between compressive strength and [MR]. The $\text{CaO}/\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$ molar ratio of 2.2÷4.1 is optimal from the viewpoint of compressive strength or chemical activity. In the range of 0.2 to 4.1 of [MR] a drastic increase in compressive strength was observed. However at $\text{MR} > 4.1$ a severe decrease in compressive strength occurred. As can be seen from Figure 1, such intensive strength growth was observed within a very short aging time.

3.2 Effect of portlandite/metakaolin ratio on phase formation

The DTA - curves for portlandite-metakaolin paste with different molar ratios at age 90 days are shown in Figure 2. Content of hydration products was calculated from the TG curves. Figure 3 shows the weight loss associated with the disintegration of hydration products as a function of the portlandite/metakaolin molar ratio [MR].

As can be seen from Figure 2, the main phases formed at hydration are C_2ASH_8 (gehlenite hydrate) and C-S-H. In the range of $[\text{MR}] = 0.45 \dots 4.1$ an increase in the weight loss and, respectively, in the content of hydration products, such as C_2ASH_8 and C-S-H is observed (see Figure 3).

Figure 2. DTA-curves for portlandite - metakaolin paste with different $\text{CaO}/(\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2)$ molar ratios

Figure 3. Influence of $\text{CaO}/(\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2)$ molar ratio on weight loss and compressive strength (age of 90 days)

3.3 Kinetics of hydration process of portlandite–metakaolin system

The DTA and TG-curves for portlandite - metakaolin paste with $\text{MR}=4.1$ at age 14, 28, and 90 days are shown in Figures 4 and 5. Kinetics of hydration process (the rate of the change of the weight loss), and the rate of strength development and content of hydration products are presented in Figures 6 and 7, respectively. The relationship between compressive strength and hydration products (gehlenite hydrate and calcium – silicate hydrate is shown in Figure 8.

As can be seen from Figure 6, the hydration process was very intensive at early ages. The rate of both strength development and hydration products formation was maximal at 14 days. According to Figure 6, the development of compressive strength is associated with the increase in C_2ASH_8 and C-S-H content, and the decrease in CH content, respectively. It was found (see Figure 8) that compressive strength of metakaolin - portlandite pastes with $\text{W/S}=1$ could be expressed as a linear function of the gehlenite hydrate and calcium silicate content. C-S-H and C_2ASH_8 are interdependent parameters. At the present stage of research it is not possible to determine the leading role of either of them.

Figure 4. DTA-curves of CH/MK mixture with $\text{MR}=4.1$ at different hydration time

Figure 5. TG-curves of CH/MK mixture with MR=4.1 at different hydration time

Figure 6. Kinetics of hydration process (MR=4.1)

Figure 7. Influence of time on content of hydration products and compressive strength (MR=4.1)

Figure 8. Relationship between compressive strength and gehlenite hydrate content and calcium silicate hydrate

3.4 Influence of metakaolin content on the mechanism of hydration in cement system

Figure 9 shows the evolution in the DTA curves at age of 28 days as a function of metakaolin content. The content of hydration products, such as gehlenite hydrate and portlandite, vs. metakaolin content at age of 28 and 360 days is shown in Figure 10. Compressive strength development for cement pastes with different content of metakaolin is shown in Figure 11.

As observed in Figure 9, the main phases present in the system are CSH and CH (portlandite). In MK- cement system gehlenite hydrate is also present, in addition to CSH and CH. It can be also seen that the content of metakaolin influences phase composition of the hydrating system. The increase in metakaolin content results in the decrease of CH content and the formation of gehlenite hydrate. There is a linear correlation between CH and C_2ASH_8 phase contents on the one hand, and metakaolin content on the other hand (see Figure 10). As in the case of metakaolin/portlandite systems, the increase in content of hydration products such as C_2ASH_8 and C-S-H corresponds to the increase of compressive strength. The compressive strength of pastes incorporating heat-treated kaolin is somewhat lower than that of reference pastes (see Figure 11). This phenomenon seems to be related to the amount of amorphous phase.

As can be found earlier, the $CaO/Al_2O_3 \cdot 2SiO_2$ molar ratio of $2.2 \div 4.1$ is optimal from the viewpoint of compressive strength for metakaolin-portlandite systems. Analogical phenomenon was observed for metakaolin – cement systems. For example: the compressive strength of the paste with MK=8.4% (MR=7.4) was significantly lower than the compressive strength of the paste with MK=15% (MR=4.1).

Figure 9. DTA-curves of paste with different content of metakaolin (Age: 28 days)

Figure 10. Influence of metakaolin content on the hydration products content (age of 28 and 360 days)

Figure 11. Strength development of cement pastes with different content of metakaolin

4. CONCLUSIONS

- The main phases that form in the hydrated MK-portlandite system are C₂ASH₈ and C-S-H.
- The hydration process is very intensive at early age. The rate of both strength development and hydration products formation was maximal at 14 days.
- Portlandite/metakaolin molar ratio influences the hydration rate, the content of hydration phases and strength development.

- In MK–cement systems an increase in C_2ASH_8 and C-S-H content corresponds to the growth of compressive strength, as in the case of MK-portlandite systems. An increase of metakaolin content leads to the growth of gehlenite hydrate and reduction of portlandite content.
- The $CaO/Al_2O_3 \cdot 2SiO_2$ molar ratio of $2.2 \div 4.1$ is optimal from the viewpoint of compressive strength for both metakaolin-portlandite systems and cement-metakaolin system.

ABSTRACT

It is possible to make reduced density autoclaved aerated concrete (AAC) - like materials without foaming by adding fly ash derived cenospheres to the formulation. The cenospheres are robust enough to allow all types of mixing including shear mixing associated with macro defect free processing (MDF). Work has demonstrated that fly ash derived AAC can be produced with and without alkali activation. Sodium hydroxide activated samples produced various zeolites within the matrix whereas conventional lime based AAC produced tobermorite and katoite. Strengths of the samples are related to the nature of the precuring conditions, which ultimately affect microstructure and strength development during final autoclave processing.

Keywords: autoclaved aerated concrete, AAC, alkali activated, fly ash, cenospheres

1. INTRODUCTION

Autoclaved aerated concrete (AAC) is a popular building material in use all over the world. It has a 50-year history of successful use in all environments for all types of buildings (Wittmann, 1983, 1992). Two types of AAC are commonly being manufactured. Both use combinations of lime and Portland cement mixed with either ground quartz sand or Class F fly ash. AAC offers a wide array of positive attributes vis à vis concrete block and insulated wood frame construction for residents of North America. However, the final decision to use AAC instead of more conventional building materials will ultimately hinge on the cost of making, transporting and assembling AAC at its point of use. To date, even after intensive lobbying by the AAC industry, the North American consumer has not made the switch. In fact two of the original German manufacturers have pulled up stakes and gone home.

Environmentally speaking, AAC is less material and energy consumptive than many construction materials. It is estimated that the total amount of energy consumed during production (including energy invested in making Portland cement, lime and aluminum powder) is on the order of 1000 MJ/m³ (Aroni et al., 1993). It achieves this status because some AAC manufacturers already use fly ash and other industrial waste in their formulations coupled with the traditional low energy processing in an autoclave at ~12 bars and 180°C. The introduction of a cellular structure during initial formation of the AAC allows one to produce 3-4 m³ of AAC from 1 m³ starting materials (Aroni et al., 1993). When making lime-silica AAC, ground quartz flour is mixed with lime (CaO), Portland cement and water to make thin slurry. At the last moment, aluminum powder is added to the mixture. The mixture is then transferred to a massive steel mold wherein the slurry begins to foam. The foaming causes it to rise in the mold much like a cake leavened with baking powder will rise in an oven. After 45 minutes or so, the AAC “cake” occupies approximately 3-4 times as much space as it did when it was first poured. It has also developed enough green strength to be

demolded, cut with wire saws to a variety of shapes (blocks and/or panels), and placed in a steam-heated autoclave. After treating at 180°C for 10-18 hours the block or panel is removed and ready for use. Densities are on the order of 400-600 kg/m³ and compressive strengths range from 2 to 5 MPa (Aroni et al, 1993). AAC can also be made from Class F fly ash. The use of fly ash in this manner saves the AAC manufacturer the time and cost of ball milling quartz sand and also keeps the fly ash out of the World's landfills. However due to the Al₂O₃ content of the fly ash, using it instead of quartz does introduce a second phase in the final product, in addition to tobermorite fly ash based AAC contains aluminum substituted hydrogarnet (katoite).

In light of the above, the promotion of fly ash-based AAC as an environmentally friendly “green material” is reasonable. In addition to fly ash, AAC formulations can also include other by-product materials such as silica rich mine tailings and recycled glass cullet as well as alternate sources of lime and Portland cement including ground granulated blast furnace slag and cement kiln dust. In fact, it is possible to produce AAC entirely from these by-products. The latter substitutions are environmentally desirable in as much as the manufacture of Portland cement and lime require a great deal of energy and produce a great deal of carbon dioxide gas.

Given the many advantages of AAC, the issue at hand at this point in time in North America is customer appeal, which is ultimately linked to cost. The outward appearance and livability of an AAC and conventional house are nearly identical, but the similarity ends there. An AAC house is self-insulating, fireproof, and insect and mildew resistant, while not containing known allergens such as VOCs or fiberglass. The current building industry is well established and much of the cost of a wood framed house is labor. In contrast, AAC walls (exterior and interior) can be assembled with thin-set mortar in a week or less. Window and door openings as well as channels for interior wiring and plumbing can be cut after the fact using carbide tipped woodworking equipment: hand saws, routers and the like. Outer wall finishes can be stucco or brick. Interior finishes can be conventional dry wall or plaster. A motivated “do-it-your selfer” could assemble an AAC house from a kit, much like a Sears house kit of the 1930s. AAC could make affordable housing a reality.

The overall objective of the currently funded work is to find a means of toughening AAC in order to make it less prone to breakage and edge damage that often takes place during handling and placing. The damage problem is costly, but even more important is the fact that the builder/customer is left with a negative impression that is hard to overcome. Adoption of a new building material in North America will take time as first impressions are replaced by more favorable ones. If the proposed work is successful, it will provide a deeper understanding of the underlying chemistry of AAC and the feasibility of the proposed toughening process. If implemented by the industry, the proposed technology could provide builders with a more robust AAC resulting in greater user satisfaction and possibly new market penetration, e.g. using AAC to adsorb energy under extraordinary circumstances (runaway trucks and/or blast protection).

The work described below examines the feasibility of using alkali activation of fly ash based AAC to bring about a phase change, and alternate methods of introducing cellular structure to the material. It is known that micrometer-sized wollastonite and xonotlite particles can be used to toughen cement pastes (Low and Beaudoin, 1993a and b). Thus it was hypothesized that insitu growth of well dispersed micrometer sized zeolites in place of larger katoite crystals normally present in the matrix could serve a similar purpose. Sodium hydroxide (NaOH) was used to supply the needed alkali. At first all formulations contained only Class F fly ash and small amounts of either a concentrated NaOH solution or a molar equivalent Ca(OH)₂ slurry. These samples were precured and then autoclaved. The data were used to contrast behavior of materials resulting from a conventional pozzolanic reaction compared with those resulting from an alkali activated reaction. Due to the difficulty of foaming alkali containing mixtures with aluminum powder, cenospheres derived from Class F fly ash were used in a second series of samples to lower the density of the

final product. The cenospheres imparted voids as well as a degree of robustness to the mixtures, which made it possible to use shear mixing to prepare a reduced density material. Finally Portland cement was added to the alkali containing mixtures. It was anticipated that phase behavior would parallel those in a traditionally foamed AAC and that findings would be directly applicable to conventional AAC manufacturing. It was also anticipated that the new processing techniques employed to make reduced density AAC-like materials might possibly lead to the development of a new technology and new markets.

2. EXPERIMENTAL METHOD AND RESULTS

2.1 100% Fly Ash and Cenosphere Samples

100% Class F fly ash (Ft. Martin-Allegheny Power-Table 1) was mixed with just enough 12 M NaOH containing a few drops of superplasticizer (Mighty RD-1) to make a thick (modeling clay-like consistency) paste. The paste was manually kneaded, much like bread dough, on a counter top until smooth and then it was compacted into a 2-inch mineral oil coated brass cube mold.

Table 1. Composition and Characteristics of Starting Materials (wt %)

Component	Ft. Martin Fly Ash	Bruce Mansfield Cenospheres

Strength at 28 days (%)	79.75	-nd-

-nd- not determined

The sample was troweled off and then covered with a glass plate. The mold was placed in a 38°C walk-in curing chamber overnight. After precuring, it was demolded and then autoclaved at 180°C for an additional 16 hours. The compressive strength of the sample was 59 MPa, which is similar to the strength reported by Palomo et al. (1999) for a similar material. The X-ray diffraction pattern of the alkali activated fly ash sample (see Figure 1a) indicates that it contains residual glass (amorphous hump centered at $\approx 22^\circ 2\theta$), residual quartz and mullite, crystalline zeolites (Na-P1, hydroxysodalite and Na-chabazite), and X-ray amorphous tectosilicates (amorphous hump centered at $\approx 29^\circ 2\theta$).

Figure 1. X-ray diffraction patterns of samples made from fly ash and cenospheres cured as a function of temperature. (M = Mullite, Q = Quartz, NaP1 = Na-P1, HS = Hydroxysodalite, G = Gmelinite, C=Na-Chabazite, A=Analcime.)

The accompanying microstructure for this sample is given in Figure 2. The matrix is dense and exhibits very little evidence of crystal growth at both levels of magnification (Photos 2A and 2B). The matrix seems more “gel-like” than crystalline, a characteristic in keeping with its strength and X-ray diffraction pattern.

Figure 2. Microstructure of autoclaved 100% Class F fly ash sample made with 12M NaOH. Original magnifications: (A) 2000X and (B) 10000X

Due to the high specific gravity of the sample ($\sim 1700 \text{ kg/m}^3$), a second sample was made using 100% cenospheres derived from a Class F fly ash. These are commercially available from First Energy’s Bruce Mansfield plant available through US Natural Resources, Inc. (Table 1). The cenospheres were mixed with the same 12M NaOH (containing Mighty RD-1) used previously and again kneaded by hand with the caveat that a few extra grams of NaOH solution were necessary to attain a similar “play dough” consistency. The mix, which now occupied about twice as much volume, was packed into two 2-inch mineral oil coated brass molds rather than one, and again

precured at 38°C overnight. After precuring, the two cubes were demolded. One was autoclaved for an additional 16 hours at 180°C and the other was placed on a platform in a desiccator containing water and cured at 90°C over night (~16 hours). Interestingly, the 90°C sample was twice as strong (2 MPa) as the 180°C autoclaved sample (1 MPa). X-ray diffraction data for these two samples are given in Figures 1b and 1c. The 90°C sample (Figure 1b) is generally devoid of secondary crystalline zeolites, save a trace of hydroxysodalite. Instead the pattern is dominated by a large X-ray amorphous hump with superimposed peaks representing residual quartz and mullite found in the Class F fly ash starting material. More salient is the shift of the maximum of the amorphous hump from $\approx 22^\circ 2\theta$ to one centered near $\approx 29^\circ 2\theta$. This shift is a result of the development of a sodium-modified hydroxylated tectosilicate network structure (zeolite-like) in the sample during the curing process. These precursors represent nanoscale structures that will ultimately crystallize at higher temperatures. The X-ray diffraction pattern for the 180°C sample (Figure 1c) contains significantly more crystalline material than its 90°C counterpart. Autoclaving at 180°C caused most of the glass in the cenospheres to react (dissolve) and nucleate and grow into crystalline zeolites: Na-P1, hydroxysodalite, gmelinite, Na-chabazite and analcime. The phase development is similar to that observed for the 100% fly ash sample (Figure 1a), but it is better developed and the sample as a whole contains less residual glass. It is worth noting however that the sample cured at 90°C was stronger than the autoclaved sample. These differences are reflected in their microstructures (see Figure 3).

Figure 3. Micrographs of a 100% cenosphere sample cured at different temperatures. (samples A and B) were precured at 38°C and cured at 90°C, and (samples C and D) were precured at 38°C and autoclaved at 180°. Original magnifications: (A,C) 250X and (B,D) 2000X.

Photos A and B represent a sample precured at 38°C followed by curing at 90°C overnight. The cenospheres show varying amounts of dissolution due to the high alkaline mixing solution, but significant amounts of residual glass still remain (note cross section of cenospheres in Photo A).

The cenospheres are covered with a continuous “gel-like” coating. It is suggested that this coating is holding the cenospheres together. Photos C and D are micrographs of a 100% cenosphere sample precured at 38°C followed by autoclaving at 180°C overnight. The dissolution and subsequent reaction of the cenospheres is much more evident in this sample. The shells now consist entirely of zeolite crystals. Massive crystals are also evident in Photo D. The formation of zeolite crystals seems to have a negative impact on the compressive strength of the autoclaved sample.

Apparently the glassy cenospheres are better held together by the precursor gel that formed at 90°C, the lower reactivity at 90°C provides more continuous coverage and more strength than the nearly completely zeolitized sample. The 180°C cured samples are almost totally crystalline and have a very porous, almost lacy structure that seems to impart weakness rather than strength. The specific gravity of the 90°C cured sample was 618 kg/m³; a conventional AAC sample would have been much stronger. As a result of the very low compressive strength, it was decided to examine a 50:50 blend of fly ash and cenospheres as a mean of providing strength and a more moderate density.

2.2 50:50 Cenosphere:Fly Ash Samples

A 50:50 by weight fly ash/cenosphere sample was again mixed and kneaded by hand as described above. In this instance, overnight precuring took place in the brass mold at 90°C instead of 38°C. Two samples were prepared. One was tested after curing at 90°C overnight, whereas the other sample was autoclaved at 180°C for an additional 16 hours. Unlike the earlier samples, analysis of these X-ray diffraction patterns indicated that curing temperature had made a significant difference in the phase development of the two samples, see Figure 4.

Figure 4. X-ray diffraction patterns of 50:50 samples of fly ash and cenospheres cured under different conditions. (M = Mullite, Q = Quartz, NaP1 = Na-P1, HS = Hydroxysodalite)

The 90°C sample contains residual glass and residual quartz and mullite. The pattern is dominated by a large X-ray amorphous hump centered at $\approx 27\text{--}28^\circ 2\theta$. Only trace amounts of hydroxysodalite can be detected. See Figure 4a. The 90°C plus 180°C autoclaving sample was radically different. Although it still contains a trace of mullite and hydroxysodalite, the quartz peak and most if not all of the amorphous background are gone. The pattern is more crystalline. See Figure 4b. The

sample consists of nearly pure Na-P1 zeolite with small amounts hydroxysodalite and residual quartz and mullite.

Micrographs for the two 50:50 samples are given in Figure 5. The difference in density of the samples is quite obvious from the micrographs. The appearance of the samples at 250x magnification closely resembles that of AAC. At higher magnifications (2000x and 1000x) however, the not so obvious differences become quite apparent. The 90°C sample (Figure 5A and 5B) contains a significant amount of residual glass and open porosity. The 90°/180°C cured sample (Figure 5C and 5D) is considerably more crystalline. Crystals are part of the matrix and fill once open pores. Using a blend of fly ash and cenospheres could provide an alternate method of developing a cellular structure on the microscale.

The interesting outcome, which may be due to a phase change, is the radical difference in compressive strength of these samples. Although specific gravities were nearly the same (924 kg/m³ (90°C) versus 976 kg/m³ (90°/180°C), the strength fell from 21 MPa for the 90°C sample to 9 MPa when the 90°C sample was subsequently autoclaved at 180°C.

Figure 5. Comparison of microstructure of a 50:50 fly ash:cenosphere sample cured at various temperatures.

It is suggested that the 90°C cure caused the sample to develop initial strength and X-ray amorphous precursor phases that subsequently crystallized at 180°C. The crystallization process disrupted the continuity of the structure resulting in the lower strength of the 180°C sample. Although the 9 MPa value is still in keeping with the expected values for a 900 kg/m³ sample (Aroni et al., 1993), the possibility of manufacturing a stronger material at 90°C seems attractive because an autoclave would not be needed to cure the material.

2.3 40:40:100 Portland Cement:Cenospheres:Fly Ash Mixtures

In conventional lime based AAC, tobermorite is the phase responsible for strength. Due to the complete lack of crystalline tobermorite in the above mixtures, it was decided to add Portland cement to the mixture in order to increase the calcium oxide content enough to produce tobermorite along with the zeolite. The recipe chosen contained the following materials:

- 40g Portland cement (Type III) Southdown Plant, Wampum, PA.
- 40g First Energy - Bruce Mansfield cenospheres (US Natural Resources)
- 100g Ft. Martin fly ash (Allegheny Power)

The dry ingredients were pre-blended and then mixed with 20g NaOH mixed in 40g H₂O containing a few drops of Mighty RD-1 (~12 M NaOH). A few extra drops of the ~12 M NaOH solution was added during the mixing and kneading process to obtain the same workability as above. For the sake of comparison, a duplicate sample was made in which the NaOH was replaced by a molar equivalent of CaO. In this instance 14g CaO was added to 40 g of DI water (containing a few drops of Mighty RD-1) in order to slake the lime prior to mixing. The dry ingredients were then mixed with the liquid and the resulting paste kneaded as before. A few grams of extra water were added to make a workable clay-like paste. Both mixtures were placed in glass covered 2-inch brass cube molds and precured overnight at 90°C. Both samples were already extremely hard on de-molding. Both 90°C cured samples were then autoclaved at 180°C overnight (approximately 16 hours).

Figure 6. X-ray diffraction patterns of Portland cement containing mixtures (40:40:100) cured at various temperatures. (T=Tobermorite, K = Katoite, A = Analcime, Q = Quartz)

The specific gravity before and after autoclaving did not change significantly: Final values were approximately the same as their initial ones, i.e. 1526 kg/m³ (NaOH sample) vs. 1335 kg/m³ (CaO sample), suggesting that water vapor from the autoclave did not contribute water to the hydration reaction to any great extent. The X-ray diffraction patterns for the NaOH autoclaved sample are dominated by analcime while the CaO autoclaved sample consists primarily of tobermorite and partially silica substituted hydrogarnet (katoite). Both samples contain residual mullite and quartz. See Figure 6 above.

Microstructure of the samples are given in Figure 7. At low magnifications the samples look alike (A and C), but at higher magnifications the NaOH sample (B) appears massive and tends to contain zeolites growing inside of cenosphere cavities. The CaO sample (D) ends to consist of a lower porosity matrix that contains less cenosphere casts and little if any zeolites. Instead it is dominated by abundant tobermorite crystals filling space and leaving little porosity. Strength behavior was as follows: the NaOH-containing sample maxed out at 14 MPa. The companion lime-containing sample reached 32 MPa. If correct, the lower strength of the 90°C precured NaOH sample might be attributed to the development of precursor phases at 90°C that subsequently changed to analcime on curing to 180°C. The phase change could cause matrix weakness if there is a volume change associated with it. Conversely, the CaO containing sample developed tobermorite at 90°C and continued to improve its crystallinity and strength at 180°C, no phase change occurred. In this instance, the tobermorite sample is about twice as strong as one might expect for an AAC sample having a similar density (Aroni et al., 1993).

Figure 7. Comparison of microstructure of 40-40-100 samples made with NaOH and $\text{Ca}(\text{OH})_2$. (A,C) 200X and (B,D) 2000X

In order to test this hypothesis, the same two samples were prepared again, but this time they were precured overnight at 38°C instead of 90°C prior to autoclaving. X-ray diffraction traces are given in Figure 8. Phase development for the lime-containing sample (Figure 8b) is identical to that for the 90°C precured sample depicted in Figure 6b.

They are significantly different from their counterparts given in Figure 7. Cenospheres and most of the fly ash particles in the NaOH containing sample (Figure 8A and 8B) have reacted and been replaced by a large quantity of irregular crystalline masses. The lime-containing sample consists of less well defined tobermorite crystals (Figure 8C and 8D) compared to its 90°C precured counterpart presented earlier. The NaOH cured sample is rather interesting. All traces of cenospheres are gone and only a few fly ash spheres remain.

The matrix is dominated by small irregular crystalline masses that must interlock on the microscale and provide the increased strength noted for this sample. It is suggested that precuring at 38°C allowed significant dissolution and gel formation and that the gel subsequently nucleated and crystallized when heated to 180°C. Crystallization normally does not occur at 38°C, but, when the sample was precured at 90°C rather than 38°C, the nucleation and growth process occurred directly without the formation of a large amount of gel phase. This apparently reduced the degree of reactivity and the total amount of zeolite that formed. The sample still contains glassy material and an AAC like structure, which is not as strong. The CaO sample appears much like its Figure 7 counterpart except it was harder to find distinct tobermorite crystals. In addition, once they were identified, they did not exhibit the same degree of crystallinity as the sample precured at 90°C (compare Figures 7D and 9D). Unexpectedly, the 38°C cured CaO-cured sample was half as strong as its 90°C counterpart. It is suggested that a lime rich sorosilicate C-S-H formed initially at 38°C and then subsequently crystallized to tobermorite when it was heated to 180°C (Sato and Grutzeck, 1992). C-S-H is the normal precursor phase for tobermorite, but in this instance the sample had already developed enough strength that the conversion process disrupted the matrix. Normally AAC is autoclaved within a few hours of demolding while it is still relatively soft. This sample had cured overnight at 38°C and was already quite hard prior to autoclaving. The specific gravity of the 38°C sample (1500 kg/m³) was slightly lower than the sample precured at 90°C (1526 kg/m³). This is not really significant, and a priori one would not anticipate the drop in compressive strength from 32 MPa to 16 MPa unless some other mechanism were operative. It is suggested that the 38°C precure had locked in some other phase, which changed on further heating; it is suggested that C-S-H was this phase. The increase in strength of the NaOH sample seems justified, in light of our previously discussed hypothesis. Analcime formed directly from a well-developed gel having little strength, therefore the matrix was not disrupted.

3. CONCLUSIONS

Autoclaving shear mixed samples containing fly ash and/or cenospheres mixed with concentrated sodium hydroxide solution provides a means of producing a range of materials having varying densities and strengths that are based upon the development of zeolites as the binder phase. Although the objective of the work was to produce both tobermorite and zeolites at the same time, this has not yet been achieved. Further experiments are in progress. However, it was shown that shear mixing a paste formulated with Class F cenospheres, Class F fly ash, Portland cement and either concentrated lime water or sodium hydroxide solution allows one to make an extrudable AAC - like material without a foaming step. The material contains voids similar to those found in AAC that result from the added cenospheres, but the voids occur at the micrometer scale. Density is reduced even though MDF mixing technology is employed. Although precuring conditions did not affect phase development, it did affect microstructure and strength. When NaOH is used, precuring at 38°C prior to autoclaving allows for maximum aluminosilicate gel formation prior to crystallization. Nearly all of the cenospheres and fly ash particles are consumed during this process. If the sample is activated with CaO, an initial precure at 90°C seems to provide greater strength.

The following explanation for the observed behavior of the CaO system is based upon a new model for the hydration process (Grutzeck, 1999). When a lime-rich sample is precured at 38°C, the lime

will react with the fly ash and form a predominantly dimeric sorosilicate C-S-H on the surfaces of the fly ash. At 90°C, the situation is similar, but because of the lowered solubility of $\text{Ca}(\text{OH})_2$ at elevated temperatures and the fact that sorosilicate C-S-H is not stable at temperatures above 80°C, dreierkette chains found in tobermorite form directly without the sorosilicate intermediary that forms at 38°C. Upon autoclaving, the 90°C precured sample will continue to build crystallinity of the already existing phase (tobermorite). The situation at 38°C is slightly different in as much as autoclaving necessitates the change of the original sorosilicate C-S-H into one dominated by chains (tobermorite).

In the case of the NaOH sample, precuring tends to allow the solution phase to dissolve significant quantities of alumina and silica from the fly ash and at the same time depress the Ca^{2+} ion solubility. Once in solution, the solvated sodium aluminosilicates ions tend to combine and form insoluble gels. When heated the gel tends to crystallize as zeolites. Both samples formed precursor gels, but in the case of the 38°C sample, the process was nearly complete. The gel occupied formally open spaces and, once it crystallized, became a rather continuous fine-grained matrix. The sample precured at 90°C crystallized almost immediately without significant gel formation. This caused much of the sodium to enter the zeolite structure at early times while much of the glassy phase still remained. The zeolites tend to form coatings on the surfaces of cenospheres and fly ash grains rather than consume them.

It is concluded that the precuring step plays a significant role in determining early micro-structural development of these materials, which in turn ultimately impacts the performance of the final product. In a lime-based AAC, it is suggested that a 90°C precure could in fact increase the strength of the final product by a factor of two. Likewise in an alkali activated zeolite-containing system a 38°C precure leads to similar two-fold increase in strength versus a precure at 90°C.

ABSTRACT

Concrete and mortars are porous composite materials resulting from a mix of cement, aggregates and water. Addition of an organic additive, currently used as grinding aid (Triisopropanolamine named TIPA), generates a mechanical strength increase of concrete and mortars with respect to samples hydrated without additive. The physico-chemical study we have carried out in order to explain this macroscopic observation has led us to dismiss the assumption of a possible increase of the cement paste hydration degree despite a soluble complex formation between TIPA and iron hydroxide. A change of the cement paste microstructure has been emphasised in presence of TIPA but this modification involves no effect on the mechanical properties of cement pastes.

A modification of the cement paste - aggregate interface in presence of TIPA has to be taken into account as a result of mechanical compressive tests made on pure cement pastes and mortars.

1. INTRODUCTION

Concrete is a resistant material obtained by mixing cement, aggregates and water. This composite material is composed by a cement matrix where hydrated phases form from anhydrous cement grains hydration. The hydration reactions take place following a dissolution-precipitation mechanism. Calcium silicate hydrate (C-S-H) and Portlandite (Ca(OH)_2) precipitate from the dissolution of the silicate phases (C_3S and C_2S) which are the main component of a Portland cement with respect to the aluminate phase (C_3A et C_4AF). This is the C-S-H formation on anhydrous grains which mainly leads to the cohesive structure⁽¹⁾. The higher the hydration degree at a given time, the higher the mechanical properties^{(2) (3)}.

For a cement paste blended with aggregates, a part of the contact hydrates – hydrates will be replaced by new contacts hydrates - aggregates. This substitution could be at the origin of the lower mechanical strength of mortars because of the weak link of the hydrate – aggregate bond where cracks can initiate and propagate⁽⁴⁾.

Moreover, cement manufacturers add grinding aids such as Triisopropanolamine (TIPA) in small amounts to increase grinder productivity. Besides this effect, TIPA is also particularly known to enhance mechanical strength of mortars at 7 and 28 days⁽⁵⁾. A mechanism based on a soluble iron-TIPA complex formation which could increase the hydration degree of the cement paste has been proposed^{(6) (7)}. Iron hydroxide (Fe(OH)_3) is able to form in the C_4AF hydration process according to the mechanism proposed in (6). This precipitation could limit water and ionic species diffusion

and this could limit the hydration degree of a cement paste. TIPA, according to a facilitated transport model could solubilise iron hydroxide because of a soluble complex formation. Therefore, the aluminoferrite phase hydration degree could increase as well as the cement paste hydration degree and could lead to an enhancement of the mechanical properties of mortars.

But some basic questions can be expressed as follow:

- Can we link the mechanical strength enhancement to the only increase of the aluminoferrite phase hydration degree knowing that the mechanical properties are directly join up to the quantity of the C-S-H formed?
- Or, is the hydration degree increase of the silicate phases with TIPA a result to explain this macroscopic effect?
- Is the evolution of these mechanical properties observed on mortars samples identical on pure cement paste?
- Clear answers have not been yet proposed, so the aim of this work is to verify these assumptions in order to lead to a better understanding on the actual effect of TIPA on the mechanical properties of concrete and mortars.

First, the physico-chemical evolution of a cement diluted suspension with and without additive were studied by isothermal calorimetry and measurements of ionic concentration in solution.

Then, the microstructure of pure cement pastes was characterised by mercury intrusion porosimetry experiments. The hydration degree of cement paste was also determined by XRD analysis and calorimetry coupled with thermogravimetry measurements.

At last, mechanical compressive tests were carried out in the same way on both pure cement pastes and on mortars.

2. EXPERIMENTAL

2.1 Materials

A model clinker (synthesised by Lafarge) composed solely by the four principal phases with gypsum added (1.63% SO₃ by weight) was used for the physico-chemical experiments and for the hydration and porosimetry determination. An industrial clinker (Lafarge) with gypsum added (2.33% SO₃ by weight) was used for the mechanical tests because of the great quantities required. The chemical and mineralogical composition of both materials are given in the table 1.

Table 1. Chemical and mineralogical composition (% mass)

	CaO	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	Na ₂ O	K ₂ O
Model clinker	68	23	5	4	0.05	0.1
clinker	65	20	5	3	0.1	0.8

	C ₃ S	C ₂ S	C ₃ A	C ₄ AF
Model clinker	62.7	18.7	6.5	12.1
clinker	67.5	6.5	8	8

The Blaine fineness of both clinkers are respectively 3500 cm²/g (model clinker) and 2500 cm²/g. TIPA solutions were obtained by dissolving trialkanolamine (Fluka) in deionized water.

2.2 Experimental methods

2.2.1 Cement diluted suspensions

The model clinker - gypsum mix was hydrated at 25°C with a w/c ratio equal to 5 under N₂ atmosphere to avoid carbonation. The chemical evolution was followed by isothermal calorimetry (Tian-Calvet Setaram). Furthermore, iron concentrations in solution were followed after 0.3 µm filtration using an atomic absorption spectrophotometer (Perkin-Elmer 3030).

2.2.2 Pure cement pastes and mortars

Two kinds of samples have been prepared, on the one hand, for hydration degree measurements and porosimetry experiments, and on the other hand, for mechanical compressive tests.

Cement pastes were mixed by hand for two minutes respectively with a saturated solution with respect to Portlandite and with the same solution containing TIPA ([TIPA] = 4.2 mmol/l). The water to cement ratio w/c is equal to 0.4. Pastes were then cast in Teflon moulds, kept at a relative humidity of 100% before demoulding and cured in a saturated solution of Portlandite at 25°C. Hydration was stopped and pastes were dried (alcohol-water and alcohol) at 7, 14 and 28 days. The pore size distribution of hardened cement pastes was determined using a mercury intrusion porosimeter (Micrometrics Autopore III). Samples were ground before diffractometry analysis (Inel XRG 3000) and thermal analysis (TG-DSC 111 Setaram).

For mechanical tests, cylindrical micro-samples (pure cement pastes and mortars) were hydrated in the same conditions but with a higher additive concentration ([TIPA]=17 mmol/l). The water to cement ratio was fixed at 0.35 and 0.6 for pure cement pastes and mortars respectively. For mortars, limestone aggregates have been used with a 50-50 cement – aggregate proportion ($0 < D_{\text{aggregates}} < 315 \mu\text{m}$). At the appropriate time, samples were polished to obtain parallel sides before the compressive tests were carried out at a constant load rate (0.25 MPa/sec). For each time, 7 samples were crushed and the average was calculated.

3. RESULTS AND DISCUSSION

3.1 Chemical evolution of a cement suspension

The influence of TIPA (17 mmol/l) on the calorimetric and iron concentrations evolution is depicted respectively on Figures 1 and 2. The Figure 3 shows the cumulated flux for both hydrations.

Figure 1. Heat evolution rate versus time for a cement hydration without (1) and with TIPA (2), w/c = 5 at 25°C.

Figure 2. Iron concentrations evolution versus time for a cement hydration without (1) and with TIPA (2), $w/c = 5$ at 25°C .

The calorimetric curve (Figure 1) obtained for an hydration in a solution saturated with respect to Portlandite is described by three peaks which can be ascribed to the following different reaction steps. First, the initial peak corresponds to the different anhydrous phases dissolution followed by hydrates precipitation such as ettringite and C-S-H. Then, the second peak is ascribed to the acceleration of the silicate phases hydration and, at last the total sulphate ions consumption leads to the third multi-component peak corresponding to the aluminate phases hydration without gypsum. This last reaction leads to calcium hydroaluminate precipitation and to the ettringite dissolution following by the calcium monosulphoaluminate precipitation.

TIPA influences the kinetic evolution of cement hydration since the initial peak is more exothermic with the additive (Figure 3). Then, the acceleration of the silicate phase hydration starts at the same time and the hydration degree of these silicate phases seems to be similar for an hydration with TIPA than without additive (cumulated heat curves superposition). Moreover, the aluminate phases hydration is strongly modified. The third peak ($[\text{SO}_4^{2-}] = 0$) arises earlier but even if a strong acceleration of the aluminate phase hydration degree is underscored in the presence of TIPA at a given time ($t = 600$ min) (Figure 3), later the hydration degree of the cement suspension became similar.

Figure 3. Heat evolution versus time for a cement hydration without (1) and with TIPA (2), $w/c = 5$ at 25°C .

Figure 2 represents the evolution of iron concentration in solution. Without TIPA, iron concentration is very low (10 $\mu\text{mol/l}$) and corresponds to the solubility of iron hydroxide $\text{Fe}(\text{OH})_3$ which precipitates during cement hydration. This iron concentration remains constant during the whole hydration. TIPA addition leads to higher iron concentration in solution due to the formation of a soluble complex (Eq(1)) as predicted by Gartner et al⁽⁶⁾. However, the iron concentration in solution does not remain constant and evolves during the cement hydration. Two domains should also be considered, the first one when sulphate ions are present in solution, and the second one, after the total sulphate ions consumption. In the first domain, ettringite, as well as $\text{Fe}(\text{OH})_3$, precipitates from the C_3A and C_4AF phases hydration and ettringite is able to incorporate iron in its structure⁽⁸⁾.

Two oversimplified equilibria Eq(1) and Eq(2) should also be taken into account:

and

In presence of sulphate ions, the fact that iron concentration remains low, but higher than that observed for a hydration without additive, means the iron affinity for the ettringite structure (Eq(2)) is stronger than that of the soluble complex (Eq(1)). When sulphate ions are completely consumed (ettringite does not precipitate any more), iron concentration increases quickly in solution as a result of the C_4AF hydration continuation characterised by the third peak on the calorimetric curves (Figure 1). Iron concentration in solution became high (approximately 2 mmol/l), evidence at this time of the important C_4AF phase hydration. Then, the weak iron concentration decrease can be ascribed to a slight incorporation of iron in the calcium hydroaluminate or calcium monosulphoaluminate structure as for ettringite. At last, iron concentration remains constant until 28 days close to 1.5 mmol/l.

So, a soluble complex is able to form but what happens to the microstructure and the hydration degree of a cement paste, and more particularly that of the silicate phases responsible of the mechanical properties, in presence of TIPA and its complex?

3.2 Pore size distribution of pure cement pastes

The microstructure of pure cement pastes hydrated respectively without additive and with TIPA at 14 and 28 days was followed by mercury intrusion porosimetry (2 bars to 4000 bars intrusion pressure) to determine the pore size distribution. Figures 4 and 5 describe the cumulative pore volume versus the pores diameter. Well-defined threshold pore width was evident from 0.1 μm to approximately 5 nm. This pore size can be ascribed to the hydrates porosity and particularly to that of C-S-H, numerous hydrates in a cement paste. It also clearly appears that a modification of the pore distribution occurs for a cement paste hydrated in presence of TIPA with respect to a paste hydrated without additive. A largest pores distribution is characterised in presence of TIPA. This can be explained by a modification of the microstructure of the hydrated paste in presence of TIPA.

3.3 Hydration degree measurements of pure cement pastes

The hydration degree of pure cement pastes hydrated respectively without additive and with TIPA at 7 and 28 days was followed by X-ray diffractometry ($\lambda_{\text{CuK}\alpha_1} = 1.54056 \text{ \AA}$) to characterise solid phases and by thermal analysis (ATG-DSC) to follow the dehydration of different hydrates precipitated.

Figure 4. Cumulative pore volume versus pores diameter for cement pastes hydrated 14 days without (1) and with TIPA (2), w/c = 0.4 at 25°C.

Figure 5. Cumulative pore volume versus pores diameter for cement pastes hydrated 28 days without (1) and with TIPA (2), w/c = 0.4 at 25°C.

In Figures 6 and 7, four diffraction peaks, in 2 theta increasing order, can be ascribed respectively to ettringite ($2\theta = 9.1$ degree), calcium monosulphoaluminate ($2\theta = 10$ degree), C_4AF ($2\theta = 12.2$ degree) and Portlandite ($2\theta = 18.3$ degree). No clear information can be extracted from the Portlandite peak. Otherwise, the C_4AF peak intensity is lower in presence of TIPA than with water whatever the hydration time (7 or 28 days) that means that C_4AF hydration is increased by TIPA certainly due to the complex formation. Similar conclusions have been reached by Schwarz⁽⁹⁾ for a specific study of the citrate action on the ferrite phase hydration, because of a soluble complex formation between iron and citrate. Moreover, TIPA promotes the calcium monosulphoaluminate formation with respect to ettringite as has already been noted by Ichikawa⁽¹⁰⁾ since calcium monosulphoaluminate peak intensity is higher and the ettringite peak is lower for hydration with TIPA than one with water.

Figure 6. XRD patterns obtained for pure cement pastes hydrated 7 days respectively without (1) and with TIPA (2), w/c = 0.4 at 25°C.

Figure 7. XRD patterns obtained for pure cement pastes hydrated 28 days respectively without (1) and with TIPA (2), w/c = 0.4 at 25°C.

Thermal analysis, Figures 8 and 9 represent the heat evolution and the weight loss associated with the heat release for 7 and 28 days hydration time. Taken as a whole, the dehydration heats and the associated weight losses are quasi similar between both samples since the total weight loss is the same, at any hydration time, for samples hydrated with TIPA and with water. On these thermal patterns, two peaks can be identified, the first one corresponding to the dehydration of C-S-H and the aluminate hydration products and the second one to the dehydration of the Portlandite which occurs in a 450°C - 550°C range of temperature. If many contributions should be considered in the first peak, a shoulder for hydration carried out with TIPA can be emphasised in a 180°C - 220°C range of temperature. This peak corresponds to the calcium monosulphoaluminate dehydration which confirms the results obtained by XRD analysis.

Figure 8. Thermograms obtained for pure cement pastes hydrated 7 days respectively without (1) and with TIPA (2) (10°C/min temperature ramp under N₂), w/c = 0.4 at 25°C.

Figure 9. Thermograms obtained for pure cement pastes hydrated 28 days respectively without (1) and with TIPA (2) (10°C/min temperature ramp under N₂), w/c = 0.4 at 25°C.

Since Portlandite is one of the silicate phase hydration product, the heat and the weight loss associated with its dehydration are directly proportional to the hydration degree of these silicates phases. Whatever the hydration time, the second peak area and the weight loss are identical for an hydration carried out with TIPA or with water. So, it means that the hydration degree of the silicate phases, which are responsible for the mechanical strength development, is similar and therefore can not explain the mechanical strength enhancement observed in presence of TIPA.

3.4 Compressive tests on pure cement pastes and mortars

All compressive tests are carried out on mortars and no studies were made on pure cement pastes. Because of the strong exothermicity hydration reactions, micro-cracks are able to be generated in pure cement samples because of the sample size used for standard tests (4 x 4 x 16 cm³). In this way, specific micro-samples of pure cement (cylinders $\phi = 6$ mm) and mortars (cylinders $\phi = 8$ mm) have been prepared in order to obtain a good dissipation of the hydration reaction heats.

Figures 10 and 11 depict the breaking strain evolution versus hydration time for pure cement pastes and mortars.

Figure 10. Breaking stress evolution versus time on pure cement paste micro-samples hydrated without (1) and with TIPA (2), $w/c = 0.35$ at 25°C .

Figure 11. Breaking stress evolution versus time on mortars micro-samples hydrated without (1) and with TIPA (2) (50% cement – 50% limestone), $w/c = 0.6$ at 25°C .

Results obtained on pure cement pastes are very interesting because breaking strain remains similar during the whole hydration period for both samples series despite the soluble complex formation during the cement hydration in presence of TIPA. These results confirm that the silicate phase hydration degree is not modified by TIPA addition at any time, and that the complex formation has no effect on the mechanical properties of cement pastes. On the other hand, the change of the paste microstructure determined by mercury intrusion porosimetry has no effect on the mechanical properties of pure cement pastes.

But, compared to hydration with water, TIPA strongly increases the mechanical properties of mortars (limestone aggregates), from the beginning of hydration. The mechanical strength gap increases until 14 days and then remains constant until 3 months where the cement paste hydration degree approaches 100%. The gap which remains constant between mortars hydrated with TIPA

and those hydrated with water after 14 days of hydration is in agreement with precedent results which dismiss the assumption of an increase of the hydration degree in presence of TIPA since an increase of the hydration degree had to lead to convergence of mechanical properties.

So, it appears clearly the aggregate insertion in the cement matrix is at the origin of the mechanical strength enhancement implying probably a modification of the Interfacial Transition Zone (ITZ) due to the complex formation of the mortar hydrated with TIPA.

4. CONCLUSIONS

A soluble complex is able to form during the C_4AF hydration with TIPA. Even if this complex formation generates an increase of the alumino-ferrite phase hydration degree, it does not influence the hydration degree of the silicate phases which are responsible for the mechanical properties of the cement paste. Moreover, TIPA promotes the calcium monosulphoaluminate formation with respect to ettringite. A change of the microstructure of the hydrates of the cement paste hydrated in presence of TIPA has been emphasised but this modification involves no effect on the mechanical properties of pure cement paste hydrated without or with TIPA which remain similar during the whole hydration.

On the other hand, TIPA addition leads to an increase of the mechanical properties of mortars with respect to mortars hydrated without additive.

So, a modification of the interfacial properties, probably due to the complex presence in the interfacial zone, between the paste and the aggregate must be considered in order to explain the mechanical strength enhancement of mortars in presence of TIPA.

UTILIZATION OF FLUORSPAR, CaSO_4 AND CaCl_2 FOR THE PRODUCTION OF LOW ENERGY CEMENT

H.U.Shah (Dr)¹, Arif Bashir (Dr)² and Zaka-ud-Din³

ABSTRACT

In this paper test results are presented from investigations conducted at laboratory level to utilize about 4% of SO_3 present in lime bearing component of an industrial white cement mix for producing white cements at lower burning temperature. Fluorspar and the composite mineralizer, fluorspar + CaCl_2 were added in varying proportions to the mix and their effect on the burnability, initial melt formation and mineral formation of the resulting low energy clinkers was evaluated. The performance of low energy white cements produced in the laboratory was studied in respect of physical properties and whiteness indices vis-à-vis plant cement.

1. INTRODUCTION

The use of CaSO_4 and fluorspar as fluxes and/or mineralizers in cement production for the sake of energy conservation is well established. In the literature is reported the production of Portland cement at a temperature of 1300°C which contained maximum alite phase together with $\beta\text{-C}_2\text{S}$, $\text{C}_4\text{A}_3\text{S}$, C_3A and CaSO_4 (1). High quality white mineralized clinker, with 10% less energy consumption than the traditional process was synthesized on an industrial scale by using CaF_2 and $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ fluxing and mineralizing pair (2). The good reactivity and burnability of special white cement mixes, possessing a silica modulus as high as 14, was achieved at the low temperature of 1350°C which is about 200°C less than the clinkering temperature of traditional white cement raw mixes (3). Portland cement clinkers containing alite as main phase were obtained in a laboratory rotary kiln at 1300°C by adding 5% CaCl_2 and chlorine was combined entirely in $\text{C}_{11}\text{A}_7\text{CaCl}_2$ phase. (4)

The new energy white cement prepared by us at laboratory level at 1300°C by adding fluorspar and fluorspar + CaCl_2 to the industrial mix, showed better mechanical properties and whiteness indices. DTA/TGA, XRD and SEM were used to study the clinkerization process.

2. MATERIALS AND EXPERIMENTAL PROCEDURE

The materials used were industrial white cement raw mix, laboratory mix, fluorspar (88% pure and prepared to a residue of less than 5% on 172 mesh) and commercial grade calcium chloride. The composition of raw mixes was determined by chemical analysis and is given in Table 1.

Table 1. Chemical Composition of White Cement Mixes

Composition of Oxides (weight %)										
Raw Mixes	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	SO ₃	Chloride	LOI
Industrial Mix	14.8	2.98	0.30	42.42	1.92	0.16	0.10	4.00	0.00	33.40
Laboratory Mix	14.82	3.70	0.40	42.80	2.00	0.52	0.24	0.12	0.00	35.40

The nodules of raw mixes containing varying proportions of fluorspar and fluorspar/CaCl₂ composite mineralizers were prepared and fired separately in platinum dishes in an electronic furnace of high precision at a heating rate of 10°C/minute and retained at a final temperature of 1300°C for 30 minutes. The resulting clinkers were allowed to cool initially within the furnace up to 1280°C and then were rapidly quenched. The level of the uncombined lime was determined by the hot ethylene glycol extraction method. The burning behavior and mineralogical composition of the clinkers was followed by XRD and DTA/TGA studies. Physical-mechanical and other hydration properties of new white cements were studied and compared with reference white cement from the plant.

3. RESULTS AND DISCUSSION

3.1 Influence of mineralizers on burnability of raw mixes

The results of burnability studies of the plant and laboratory mixes with and without fluorspar and fluorspar/CaCl₂ are summarized in Table 2.

Table 2. Influence of Mineralizers on combinability of Industrial & Laboratory mixes

Mineralizer Added Weight (%)	Free Lime (%)	Heating rate °C/minute	Residence time at 1300°C temperature minute
Industrial Mix	4.26	10	30
0.25% fluorspar	3.00	10	30
0.50% fluorspar	0.92	10	30
1.0% fluorspar	0.80	10	30
0.25% fluorspar + 1.00 CaCl ₂	1.29	10	30
0.50% fluorspar + 2.00 CaCl ₂	0.70	10	30
1.00% fluorspar + 2.00 CaCl ₂	Nil	10	30
Laboratory mix *	11	10	30

* Raw Mix prepared by adding limestone in place of lime sludge in the industrial mix.

It is apparent from the results that the addition of 0.25% of fluorspar to the industrial mix reduces the free lime content of the burnt mass from 4.26% to 3.0%. By increasing the fluorspar addition to 0.5% and 1.0 % the corresponding decrease in free lime content of the burnt masses is observed as 0.92% and 0.80% respectively.

The addition of composite mineralizer fluorspar/CaCl₂ to the mix in the range 0.25% fluorspar and 1.0% CaCl₂ reduces the free lime contents to 1.29%. Increasing the addition of fluorspar to 0.50% and CaCl₂ to 2% in the mix decreases the free lime of the clinker to 0.70%. Free lime in the clinker completely disappeared when 1% fluorspar with 2% CaCl₂ is added to the mix. In contrast, maximum free lime contents of 11% were observed in the clinker made under the same burning conditions from the laboratory mix where lime sludge in the industrial mix is replaced with pure

limestone containing 0.12% SO_3 . The results obtained for free lime contents of burnt masses in the presence of mineralizers; CaSO_4 , fluorspar and CaCl_2 confirm the previous studies carried out by Balanco (5), Klemm (6) and Wei (7). The order of effectiveness for the investigated fluxes and mineralizers pertaining to burnability of white cement mixes at 1300°C is found in the descending order, $\text{CaCl}_2 + \text{Fluorspar} > \text{Fluorspar} > \text{CaSO}_4$

4. THE EFFECT OF MINERALIZERS ON MELT AND MINERAL FORMATION PROPERTIES

The first formation of liquid, marking the start of clinkering, occurs in Ordinary Portland Cement at much lower temperatures than white cement. The absence of fluxes in white cement accentuates the need to add to the mix certain fluxes, which could reduce the clinkering temperature. The burning behavior of investigated fluxes and mineralizers on an industrial white cement mix was studied with the help of Differential Thermal (DTA) and Thermo-gravimetric Analyzer (TGA). The effect of these mineralizers on de-carbonation, melt formation and mineral formation of the mixes studied is depicted in the thermograms shown in Figure 1.

Figure 1. Thermograms of cement raw mixes (a) Laboratory mix, (b) Industrial raw mix (c) Industrial raw mix + 0.50% Fluorspar (d) Industrial mix + 0.50% Fluorspar + 2% CaCl_2

The parameters selected for DTA/TGA studies of these mixes are described in Table 3.

Table 3. Instrumental Condition for DTA/TGA

Atmosphere	Air
Reference Crucible	Al_2O_3
Sample Crucible	Al_2O_3
DTA Range	50.0 μV
TG Range	100.0 mg
Heating Rate	$10^\circ\text{C}/\text{min.}$

The laboratory mix (a) Figure 1 prepared by replacing lime sludge in the industrial mix with pure limestone, shows peak de-carbonation temperature at 878°C. The initial melt formation temperature of the laboratory mix is completed at about 1312°C. The strong exothermic peak indicating the formation of C₃S is observed at the temperature of 1360°C.

The de-carbonation temperature in industrial white cement mix (b) Figure 1, is observed at 780°C. In this case the initial melt formation temperature appears at 1140°C, which is 172°C less than the laboratory mix. There is seen an exothermic peak corresponding to C₃S formation at temperature of 1234°C. The 126°C drop in C₃S formation temperature as compared with laboratory mix, is the result of SO₃ present in the industrial mix. CaSO₄ being an effective flux and mineralizer, lowers liquid phase temperature by over 100°C, decreases its viscosity and surface tension and increases the mobility of Ca²⁺, Si_xO_y²⁻, Fe³⁺ ions (8). Thus it helps initiate C₃S formation at earlier temperatures than is usually observed in the case of normal cement mixes.

The addition of 0.5% fluorspar to the industrial mix (c) Figure 1, reduces the peak de-carbonation temperature to 863°C and initial melt formation temperature of the mix to 1136°C. The strong exothermic peak appearing at 1168°C confirms the early studies (9) where addition of fluorides to sulphate containing mixes, is found to speed up the formation of alite through formation of the transition phase. It restrains the unfavorable effect of SO₃ while strengthening its favorable effects in clinkering process. The addition of fluorspar and CaCl₂ to the industrial mix is found most effective in reducing de-carbonation temperature of the mix (d) Figure 1. The intensification of the clinkering process in the presence of fluorides (F) is further augmented because of the addition of Cl to the mix.

The mineralogical composition of low energy white cement clinkers, burnt with investigated fluxes and mineralizers, is given in Table 4 and the corresponding X-ray diffractograms of clinkers are shown in Figure 2.

Table 4. Minerals formed during the process of burning of industrial white cement mix at 1300°C with mineralizers.

Added flux Wt (%)	C ₃ S	β-C ₂ S	C ₃ A	F-CaO	C ₁₁ A ₇ CaCl ₂	C ₄ A ₃ S
0	++	+++	-	+	-	++
0.5% Fluorspar	+++ +	++	+	+	++	+
0.5% Fluorspar + 2% CaCl ₂	+++ +	++	++	-	++	+

++++ = Major Phase, +++ = Normal Phase, ++ = Medium Phase,
+ = Minor Phase, - = Absent

Figure 2. XRD Grams of different cement minerals observed at (a) 0%, (b) 0.50% Fluorspar and (c) 0.50% Fluorspar + 2% $CaCl_2$

The clinker made from the industrial mix (a) Figure 2, is found to attain minimum level of C_3S because of the stabilization effect of SO_3 on $\beta-C_2S$ and the preferred reaction of SO_3 with lime to form C_4A_3S (9). The accelerated formation of C_3S at further lower temperatures because of 0.50% fluorspar addition is manifested from the prominent peak (D) in x-ray diffractogram (b) Figure 2. The compound mineralizer fluorspar and $CaSO_4$ is of great benefit in the cement manufacturing process as it activates SiO_2 , promotes the decomposition of $CaCO_3$, decreases temperature of melt formation and viscosity of the melt and speeds up the formation of alite through transition phases. Furthermore, the unfavorable effects of SO_3 in the clinkering of cement mixes are effectively offset in the presence of fluorides (10). X-ray diffraction studies of clinker, made by adding composite mineralizer Fluorspar and $CaCl_2$ to the industrial mix, revealed the presence of all major phases like C_3S , C_2S , C_3A , C_4A_3S , $C_{11}A_7CaCl_2$.

From x-ray diffractograms (c) Figure 2, it is evident that clinker produced at $1300^\circ C$, as a result of composite mineralizer fluorspar/ $CaCl_2$, attains maximum level of alite phases. X-ray diffraction studies of clinkers support the results obtained during the burnability and DTA/TG studies of white cement mixes.

5. PHYSICAL CHARACTERISTICS, HYDRATION BEHAVIOUR AND STRENGTH PROPERTIES OF LOW ENERGY WHITE CEMENTS.

The physical characteristics, strength properties and hydration behaviour of low energy white cements and plant cement were evaluated with same set of standard conditions as shown in Table 5.

Table 5. Physical characteristics of low energy white cements.

Sample Code	Blaine (M ² /Kg)	Gypsum added	Initial set (minutes)	Final set (minutes)	Soundness (mm)	Whiteness index
C1	387	2%	181	240	4.8	85
		4%	200	270	5.6	
C2	380	2%	54.0	95	4.81	88
		4%	90.0	112	6.00	
Plant Cement	440	5%	160	220	2.0	86

C1 = Cement from industrial raw mix containing 4% SO₃ + 0.5% fluorspar

C2 = Cement from industrial raw mix containing 4% SO₃ + 0.5% fluorspar + 2% CaCl₂

Plant Cement = Cement made at the plant with above referred industrial raw mix

The mineralized cements show rapid set behaviour in the absence of gypsum addition. However, by adding 2% gypsum in the clinkers, both initial and final set of the resulting cement C1 is found in close proximity with the setting time of plant cement. The decrease in initial and final setting times registered in the set behaviour of cement C2, in the presence of 2 and 4% gypsum may be ascribed to accelerating effect of chloride.

The soundness of the low energy cement ground with 2 and 4% gypsum pass the soundness standard limits prescribed in BS or Pakistan Standard Specifications (PSI).

The whiteness indices of cement C1 and C2 are better than the plant cement despite the lower Blaine values. The mineralizer addition to the white cement mix results in the formation of C₃S almost at the same time when C₂S is formed. The simultaneous appearance of C₃S and C₂S results in the build up of minor elements in totally different pattern, thereby, improving the whiteness of cements C1 and C2 (11). The highest whiteness indices in case of cement-C2 could be the result of CaCl₂, which was used as a bleaching agent for improving the whiteness of cement.

The compressive strength at 3, 7 and 28 days of cement-C1 as shown in Table 6, is considerably less than cement-C1, cement-C2 and plant cement.

Table 6. Compressive strength of 1" mortar cubes (Mpa)

Cement No.	Gypsum weight%	3 Days	7 Days	28 Days	% Increase in strength between 3 and 7 days
C1	2	12.56	17.05	23.42	35.75
C2	4	15.5	22.4	27.0	44.5
Plant Cement	5	9.40	11.34	19.83	20.60

The difference in the compressive strength between cement C1 and cement C2 is attributed to the higher alite contents permitted by the strong mineralizing action of composite mineralizer fluorspar and CaCl₂.

The highest intensity of the C₃S peak appeared in x-ray diffractogram (c) Figure 2, bears ample proof to the effectiveness of the composite mineralizer as compared to fluorspar and/or CaSO₄. Higher 3, 7 and 28 day compressive strength of cement-C1 and cement-C2 than the plant cement are due to the hydration characteristics of more active alite, β -C₂S, C₄A₃S and other mineral phases crystallized in the low energy clinkers. It is also evident from the test results shown in Table 6 that the increase in compressive strength between 3 and 7 days in case of plant cement is 20.60% whereas for cements C1 and C2 is 37.75% and 44.5% respectively. This behaviour of low energy

cement is discernable from the hydration characteristics of C_4AS_3 together with active alite, belite and other minerals formed as a result of added fluxes and mineralizers.

6. HYDRATION STUDIES

The hydration of different cement pastes was arrested at 7 days by crushing the specimen, washing them with acetone and vacuum drying at room temperature. Figure 3 represents the amount of $Ca(OH)_2$ released at $450^\circ C$ - $520^\circ C$ due of dehydration of $Ca(OH)_2$ found in cement pastes prepared from low energy cements-C1,C2 and plant cement. The amount of $Ca(OH)_2$ is found to be maximum for cement-C2 and minimum of plant cement. The higher contents of $Ca(OH)_2$ in cement C3 are attributed to the higher hydraulic activity of calcium sulpho-aluminates and other minerals formed in the presence of SO_3 , fluorspar and $CaCl_2$ mineralizers.

Figure 3. $Ca(OH)_2$ liberated at hydration of cement C1, C2 and Plant cement

The higher strength of cement-C1 and cement-C2 as compared to plant cement was further studied by scanning electron microscope (SEM). Figure 4, represents SEM micrographs (a) and (b) of cement pastes prepared from cement-C2 and plant cement respectively.

Figure 4. SEM Micrographs of cements-C2 (a) and plant cement (b)

The high temperature environment caused by the hydration of $C_4A_3\bar{S}$, $C_{11}A_7CaCl_2$, C_3S , β - C_2S and other minerals in low energy cement-C1 and cement-C2 is responsible for the higher early strength of mineralized cements. It can be observed through micrograph (b) that in the presence of excess sulphates, ettringite seems to be the stable hydration product. The intrusion C_3S , β - C_2S and other hydrates into the ettringite skeleton gives a very compact and dense structure to cement-C1 and cement-C2 pastes. In plant cement, monosulphualuminates are formed more stably than ettringite.

The formation of hexagonal plates Figure 4 (plant cement), with characteristic face to edge contacts having large vacant spaces are not completely filled by the hydration products of C_2S , C_3S , etc. Thus mechanical properties of such system will be inferior to cement-C1 and cement-C2.

7. CONCLUSIONS

1. It is possible to produce white cement of comparable or better performance even at a temperature of $1300^{\circ}C$ with the addition of fluorspar and/or fluorspar & $CaCl_2$ from the raw mix containing about 4% SO_3 as $CaSO_4$.
2. The clinkering of white cement mix at $1300^{\circ}C$ would lead to considerable energy savings in overall cost of production of the cement.
3. Increase in the production output is expected due to mineralizing action of investigated fluxes and mineralizes.
4. Reduction in burning temperature in the range of $250 - 300^{\circ}C$ would lower the dust losses pollutant gases and energy losses encountered in the production of white cement.

EFFICIENCY OF HIGHLY ACTIVE RICE HUSK ASH ON THE HIGH-STRENGTH CONCRETE

Qingge Feng, Hirohito Yamamichi, Masami Shoya and Shuichi Sugita

Department of Environmental and civil Engineering, Hachinohe Institute of Technology, 88-1, Myo, Hachinohe 031-8501, Japan. E-mail: Fenggg@stud.hi-tech.ac.jp

1. INTRODUCTION

As an agricultural product, rice husk contains considerable amounts of SiO_2 [1,2]. Recently, many researches have investigated the production of the rice husk ash (RHA) with high pozzolanic activity and its possible application in cement and concrete. [3,4,5,6]. The results reveal that a well-burnt and well-ground rice husk ash is very active and considerably improve the durability of cement and concrete. In previous research [1,5,6,7], RHA with 2.0-3.0mS/cm by the change of electrical conductivity that is one of the rapid evaluations of the pozzolanic activity index of rice husk ash had been used. In this study, RHA with high pozzolanic activity (the change of electrical conductivity was 4.50-4.75mS/cm) can be obtained by controlling the firing temperature using a commercial furnace. The efficiency of highly active RHA on high-strength concrete is investigated.

2. MATERIALS AND MIXTURE PROPORTIONS

In this study RHA was obtained by burning rice husks in a commercial furnace. The XRD pattern of the RHA shows that the silica in it is amorphous in form. Its chemical composition and physical properties are presented in Table 1.

Table 1. Chemical composition* and physical properties of RHA and cements used

	RHA	Cement
Loss of ignition	2.31	3.10
SiO_2	92.40	21.29
Al_2O_3	0.30	5.60

nitrogen adsorption, m^2/g	164	
median grain size, μm	7.40	26
change in electrical conductivity, mS/cm	4.75	

*Conducted by X-ray fluorescence analysis

An ordinary Portland cement with a specific gravity of 3.16 specified in JIS R 5210 (Portland cement) was used. The coarse aggregate (density 2.64g/cm^3) was a crushed sand stone with the maximum size of 20mm. The fine aggregate was river sand (density 2.60g/cm^3 , F.M. 2.84, for W/B of 0.30 and 0.35) and crushed sand (density 2.88g/cm^3 , F.M. 2.69, for W/B of 0.45 and 0.55).

In order to control the air volume and the slump of all the fresh concrete added with RHA to be 5% and 8cm respectively, an air entraining agent and superplasticizers (Polycarboxylic acid system) were used.

The concrete mixtures were made at RHA blending ratios of 0,10,20,30% and W/B of 0.30, 0.35, 0.45, and 0.55 respectively. The proportions of the concrete mixture are summarized in Table 2.

Table 2. Mixture proportions of RHA blended concrete

W/B	RHA content, %	s/a, %	Unit content, kg/m^3						AE, %	SP, %

	20			120	480	906		570	0.120	2.600

3. TESTING PROCEDURES

3.1 Pozzolanic activity of RHA

The evaluation of pozzolanic activity of RHA was determined by comparing the strength of mortar made with and without RHA, tested in accordance with JIS R5201 (Physical testing methods of cement, Japanese industrial standards, 1997). At the same time, measurements of heat evolution and hydration heat of cement with 0, 10, and 30% RHA or ground silica sand were conducted using the thermal conductivity calorimeter (Calvet calorimeter), at W/C=1.0, and 25°C.

3.2 Compressive strength

The slump test and the air content test were conducted according to JIS A1101 (Method of test for slump of concrete, Japanese industrial standards, 1998), JIS A1128 (Method of test for air content of fresh concrete by pressure method, Japanese industrial standards, 1999). The concrete 100 200mm Φ specimens were placed to moist-cure at 20°C and 85% relative humidity for 2 days, and water cure at 20°C till the data of strength were tested.

The compressive strength of the concrete specimens was tested at the age of 3, 7, 28, and 91 days respectively according to JIS A 1108 (Method of test for compressive strength of concrete, in Japanese industrial standards, 1999), 3.3 Ca(OH)_2 content

Because of the determination of the Ca(OH)_2 content in the concrete, the cured mortar specimens were cut into approximately 5mm cubes, washed with acetone to stop further hydration and treated by D-drying for one week. The Ca(OH)_2 content is calculated using TG curves. The TG analyses were carried out at the temperature from 30 to 1050°C and the heating rate of 10°C /min.

4. RESULTS AND DISCUSSION

4.1 Pozzolanic activity of RHA

The determination of the heat evolution rate is a sensitive and useful tool to characterize the way in which pozzolans influence the early hydration of cement [8]. In this study, heat evolution and hydration heat of cement pastes containing 0, 10, and 30 percent of RHA or ground silica sand were studied with the thermal conductivity calorimeter. The curves of the rate of heat evolution and heat conversion of samples are shown in Figure 1 and Figure 2 respectively.

Figure 1. Calorimetric curves from the hydration of cement

Figure 2. Hydration heat conversion of the samples

It can be seen that during the 12 hours, RHA showed an increase of hydration heat (positive values). The reason for the increase of hydration heat of cement with added RHA is due to two reactions taking place as follows: one is acceleration of the early hydration of C_3S . It is ascribed to the fineness and the high surface area of RHA, which is the availability of a large number of nucleation sites for precipitation of hydration products of C_3S (C-S-H). Another is a pozzolanic reaction. It corresponds to the second peak on the exothermic curve. The height of the second peak initially showed marked increases for cements incorporating RHA compared with the control cement, but then decreases. At the same time, the sample with added RHA was shown to shorten the dormant period. It was caused by the large amount of amorphous SiO_2 . Silica from RHA could react with Ca^{2+} , OH^- ions, and calcium hydroxide liberated from the hydration of cement minerals to form more C-S-H gel. In concrete, these reactions were known to contribute to improving the properties of concrete [8,9,10]. The results also confirmed that the pozzolanic activity of RHA is high.

In the strength test procedure, RHA replaced 10% of the cement by mass. The result is shown in Table 3. It can be seen that, compared with the control, from the beginning of hydration (third day) a significant increase in the RHA specimens' strengths is observed. This is because of the large

quantity of amorphous SiO_2 and highly active RHA, which can react with calcium hydroxide produced from cement hydration. This increased ratio does not decrease with the hydration time. As a result, this RHA is a very highly active pozzolan.

Table 3. Strength* of cement-rice husk ash Mortar

Sample	Rice husk ash(%)	Compressive Strength (MPa)				Flexural Strength (MPa)			
		3d	7d	28d	91d	3d	7d	28d	91d
Control	0	21.9 (100)**	32.4 (100)	39.3 (100)	44.0 (100)	5.16 (100)	6.40 (100)	8.10 (100)	8.45 (100)
RHA	10	26.6 (122)	44.3 (137)	52.3 (133)	55.7 (126)	5.71 (111)	7.61 (119)	9.45 (117)	10.00 (117)

*JIS R 5201 mix proportions are used, Cement/sand=1:3, water/cement=0.5

** Figure in parenthesis shows relative strength of cement-rice husk ash mortar to the strength of respective control mortar with no rice husk ash, expressed in percent.

4.2 The property of fresh concrete

The segregation of concrete with added RHA was not observed. At W/B of 0.30, 0.35, as RHA content increased the concrete appeared to become sticky. Although the slump and air content of concrete were under the control, the workability was not very good.

Because of the high specific surface area of the RHA, the RHA concrete required more superplasticizer and more air-entraining admixture compared with the control concrete to obtain the desired slump and air content, respectively (Figures 3 and 4).

Figure 3. Relationship between requirement of air-entraining admixture and RHA content

Figure 4. Relationship between requirement superplasticizer and RHA content

4.3 Strength property

The compressive strength and the compressive strength development ratio of concrete are shown in Table 4 and Figure 5. Not only at the age of 3 days, but also at the age of 28 days, the compressive strength of concrete incorporating RHA increased with the increase of RHA content. The maximum ratio of compressive strength development was found at the age of 7 days. The concrete with W/B of 0.35 containing RHA contents of 0%, 10%, 20%, and 30% at 28 days showed the compressive strength of 51.2MPa, 66.2MPa, 75.2MPa, and 82.2MPa, respectively. Its compressive strength was approximately 29-61% higher than that of the control concrete. In pace with curing time higher strength development was observed. A similar tendency of strength development of concrete incorporating RHA was observed with W/B of 0.30 and 0.45. Even at the high W/B of 0.55, the concrete with added 30 percent RHA had a compressive strength of 39.9MPa at the age of 28 days, which was still high.

Table 4. Compressive strength of the RHA concretes

W/B	RHA content, %	Compressive strength, N/mm ²			
		3 days	7 days	28 days	91 days
0.55	0	11.3	18.9	25.1	29.1
	10	12.7	20.8	30.6	35.0
	20	13.5	26.2	38.7	41.3
	30	16.0	29.8	39.9	41.0
0.45	0	18.6	27.1	36.3	43.8
	10	22.0	31.6	40.4	45.8
	20	26.4	39.5	46.4	50.4
	30	31.3	46.2	53.0	60.1
0.35	0	30.4	39.6	51.2	56.9
	10	41.4	53.0	66.2	73.3
	20	43.5	65.0	75.2	77.8
	30	49.0	70.9	82.2	88.1
0.3	0	35.7	41.8	52.3	60.5
	10	48.9	61.4	75.1	80.9
	20	52.5	65.7	77.8	78.9

Figure 5. Relative compressive strength of RHA blended concrete vs RHA content (W/B=0.45)

Figure 6. Relative compressive strength of RHA blended concrete vs RHA content (W/B=0.35)

Past research reported that RHA was ineffective in enhancing the properties of rich mix concrete [1,5,6]. Now high strengths in rich mix concrete incorporating RHA can be obtained because of the use of a new polycarboxylic acid-based superplasticizer and the highly pozzolanic activity of the RHA used for this research. It showed that the RHA was suitable for use as a supplementary cementing material to produce high-strength concrete.

4.4 Ca(OH)₂ content

The results of Ca(OH)₂ content in the RHA concrete with W/B of 0.35 and 0.45 are shown in Figures 7 and 8. Irrespective of the W/B, the Ca(OH)₂ content in the RHA concrete decreased visibly with the increasing addition of RHA. No Ca(OH)₂ content was observed in the sample with 30% added RHA. It also indicated this RHA is a highly active pozzolan and the silica in RHA could react rapidly with calcium hydroxide liberated from the hydration of cement minerals to form more C-S-H gel. In concrete, these reactions are known to contribute to improvement in the properties of concrete and the RHA concrete had shown the property of high strength.

Figure 7. Amount of Ca(OH)_2 in the RHA concrete (W/B=0.35)

Figure 8. Amount of Ca(OH)_2 in the RHA concrete (W/B=0.45)

A high pH is important for the durability of reinforced concrete, and the reduced content of Ca(OH)_2 can cause reduced resistance to carbonation because Ca(OH)_2 acts as a buffer on the total carbonation reaction. It is necessary to maintain a certain amount of Ca(OH)_2 in concrete. So the maximum mixing ratio of the highly active RHA in concrete was limited to below 30%.

5. CONCLUSIONS

By mean of studying the pozzolanic activity of RHA and the efficiency of a highly active RHA on high-strength concrete, conclusions are as follows:

1. RHA is highly active pozzolan and can be suitable for use as a supplementary cementing material to produce high-strength concrete.
2. RHA showed the behavior in the increase of hydration heat and the cement with added RHA has shown to shorten the dormant period.
3. Though the RHA concrete required more superplasticizer and more air-entraining admixture compared with the control concrete to obtain the desired slump and air content, the compressive strength of concrete incorporating RHA increased distinctly with the increase of RHA content and with decreasing W/B.
4. The reason for the improved strength in RHA concrete is that cement hydration is improved with the increase of RHA content and the rapidly pozzolanic reaction between the silica in the RHA and the Ca(OH)_2 liberated from the hydration of cement.

INFLUENCE OF THE STRUCTURAL CHANGE OF GRANULATED BLAST-FURNACE SLAG ON THE HYDRAULIC REACTIVITY

P. Z. Wang¹, R. Trettin¹ and V. Rudert²

¹Institute for Building and Material Chemistry, University of Siegen, Germany.

²Wilhelm Dyckerhoff Institute for Building Material Technology, Germany.

ABSTRACT

The paper presents the experimental results of work on the influence of the structural change of granulated blast-furnace slag on its hydraulic reactivity. The investigations were carried out on technical granulated blast-furnace slags that were modified structurally by heating. It is demonstrated that, due to heating up to 700°C, there was a change of structure of the granulated blast-furnace slag, although the x-ray determinable crystallinity of the samples remained unchanged. The hydraulic reactivity of the investigated granulated blast-furnace slags and the associated compressive strength of the slag cements decrease with increasing temperature, according to the structural changes of the granulated blast-furnace slags.

1. INTRODUCTION

It is well known that basic blast-furnace slag with a suitable chemical composition possesses hydraulic characteristics, if it is obtained by rapid cooling in water to form a glasslike solid, which is then granulated. In contrast to that, basic blast-furnace slag which is slowly cooled in air, is not hydraulic because it is completely crystallized and has a thermodynamically stable structure. The hydraulic reactivity of the granulated blast-furnace slags therefore depends strongly on the structure. Therefore it is important to explain the relationship between the structure and the hydraulic reactivity of the granulated blast-furnace slag. To explain this relationship a great deal of research on synthetic and technical granulated blast-furnace slags has been undertaken in the past [1-7]. However, so far no clear connection between the structure of granulated blast-furnace slags and their hydraulicity had been shown. The reactivity of granulated blast-furnace slag results from different characteristics, e.g. chemical composition, structure as well as crystallinity. Moreover the grinding fineness also plays an important role. In this paper an investigation on the influence of the structural change of granulated blast-furnace slag on the hydraulicity was carried out on a structurally modified sample series of technical granulated blast-furnace slags. Further influencing factors, like chemical composition, crystallinity as well as grinding fineness were kept constant. The results obtained so far are presented in the following sections.

2. MATERIALS AND PREPARATION

In order to examine the influence of the structural change of granulated blast-furnace slag on the reactivity, two industrial granulated blast-furnace slags (slag S1 and S2) with very different chemical compositions (Table 1) were used in the investigation. The granulated blast-furnace slags were first ground to a fineness less 63 µm with a ball mill and then heated in a PC-controlled electrical furnace to the relevant temperature 300°C, 400°C, 500°C, 600°C, 700°C, 750°C, 800°C and 1000°C at a heating rate of 20K/min, tempered for two hours at constant temperature and then cooled slowly to 100°C at a rate of 10°K/min. Subsequently, crystallinity was determined by

microscope and x-ray diffractometer. The crystallinity of the samples remained unchanged at temperatures up to 700°C (Figure 1), while they were completely crystallized at tempering above 800°C (Figure 2). The granulated blast-furnace slags that were tempered up to 700°C were structurally modified, whereas the chemical composition, crystallinity as well as grinding fineness were kept constant.

Table 1. Chemical composition of the granulated blast-furnace slags

Constituent [Wt.-%]	Granulated blast-furnace slag	
	S1	S2
SiO ₂	34,5	40,3
Al ₂ O ₃	11,3	9,4
Fe ₂ O ₃	0,3	0,3
CaO	43,9	37,5
MgO	7,4	8,2
K ₂ O	0,4	1,2
TiO ₂	0,5	0,7
MnO	0,2	1,2
Sulfide	1,2	1,4
CaO/SiO ₂	1,27	0,93
(CaO+MgO)/SiO ₂	1,49	1,13

Figure 1. X-ray diagram of granulated blast-furnace slags after tempering at 700°C

Figure 2. X-ray diagram of granulated blast-furnace slags after tempering at 800°C

3. INVESTIGATION RESULTS AND DISCUSSION

Granulated blast-furnace slag is a glassy solid product, which is formed by rapid cooling in water during the granulation of the blast-furnace slag. In the physicochemical sense the granulated blast-furnace slag is therefore in an unstable state, which is responsible for its hydraulic characteristics. In its glassy state granulated blast-furnace slag has no ordered crystal structure; except that merely a short-range order can be accepted. This short-range orderly structure is an important characteristic for the reactivity of granulated blast-furnace slag.

If a granulated blast-furnace slag is heated by raising the temperature, devitrification is known to occur. With rising temperature the glassy state passes on to a crystalline state. Probably the degree of structural order of the granulated blast-furnace slags was increased by the heat treatment, although x-ray detectable crystallinity remained unchanged during tempering up to 700°C. These structural changes can be confirmed by the density changes at different temperatures.

Figure 3 shows the density changes of the granulated blast-furnace slags with increasing temperature. It is shown that the densities of both slags (S1 and S2) were continuously increased during tempering up to 700°C. This indicates that the structure of the granulated blast-furnace slag was changed with rising temperature and thus the associated packing density was also continuously increased.

Figure 3. Density changes of the granulated blastfurnace slags with increasing temperature

The heat evolution of granulated blast-furnace slag S1 after heating at different temperatures is represented in Figure 4. As it can be seen from the diagram, the intensity of the heat evolution of the granulated blast-furnace slag decreases with increasing temperature although chemical composition, glass content and grinding fineness remain unchanged under the same conditions. The main reaction peaks became wide with rising temperature, i.e. the reaction is retarded. Further, the heat evolution curves show clearly two maxima after tempering at 600°C and 700°C. At 750°C only a retarded second maximum is recognizable, which disappears after tempering at 800°C.

Figure 4. Heat evolution of the granulated blast-furnace slag S1 after tempering at different temperature

It is obvious that the structural changes of the granulated blast-furnace slag took place during the thermal treatments, and the associated reactivity for the hydration was significantly decreased,

although the content of glass remained unchanged. This indicates that the glassy state or the structural order of the granulated blast-furnace slag plays an important role in hydration. During the tempering the glass state develops more and more short-range order with increasing temperature. This leads to a strong reduction of the hydraulic reactivity of the granulated blast-furnace slag.

For direct observation of hydration products on the surface of the granulated blast-furnace slag a scanning electron microscope (SEM) was used. In Figure 5 the SEM-micrographs of the granulated blast-furnace slag S1 tempered at different temperatures are shown after hydration for two hours in a NaOH-solution. The visible hydration products decrease significantly with increasing temperature. This shows that the hydraulic reactivity of the granulated blast-furnace slag has clearly decreased due to structural changes by heating to various temperatures.

Figure 5. SEM-micrograph of the granulated blast-furnace slag S1 after 2 h hydration in 2n-NaOH
a) not tempered, b) tempered at 300°C, c) tempered at 500°C, d) tempered at 700°C

Seven laboratory slag cements were prepared from the samples of granulated blast-furnace slag S1 by heating them to different temperatures 300, 400, 500, 600, 700 and 1000°C, which were subsequently subjected to compressive testing after 2 and 28 days under the same laboratory conditions. The results are shown in Figure 6. It becomes clear that compressive strength decreases with increasing temperature. The laboratory slag cement made from the granulated blast-furnace slag tempered at 700°C has e.g. only a compressive strength of 5,1 MPa after 2 days and 33,6 MPa after 28 days, while the laboratory slag cement made from the original granulated blast-furnace slag (only dried at 100°C) shows a compressive strength of 9,3 MPa after 2 days and 47,4 MPa after 28 days. The compressive strength of the slag cement, which was made from the granulated blast-

furnace slag tempered at 1000°C, which was completely crystallized, shows only 1,3 MPa after 2 days and 2,4 MPa after 28 days. This is attributed to the fact that the degree of structural order of the granulated blast-furnace slag was increased during the tempering and the associated hydraulic reactivity was strongly reduced. Therefore one should take note of this during the drying process of granulated blast-furnace slag.

Figure 6. Compressive strength development of the laboratory cements with increasing temperature; slag/clinker=79/21, w/c=0,5

4. CONCLUSIONS

The influence of the structural change of granulated blast-furnace slag on hydraulic reactivity was examined on a series of samples that had been structurally modified by heating. During heating up to 700°C the degree of structural order of granulated blast-furnace slag increased unmistakably, although the x-ray determinable crystallinity of the samples remained unchanged.

The intensity of the heat evolution curve decreased with increasing degree of structural order of the granulated blast-furnace slag and the main reaction peak became wide. The samples tempered at 600°C and 700°C are characterised by two maxima on the heat flow diagrams, while the sample tempered at 750°C shows only a temporally retarded maximum. This difference occurred due to the structural changes of the granulated blast-furnace slag.

Hydraulic reactivity depends to a large extent on the structure of the granulated blast-furnace slag. With increasing temperature or degree of structural order of granulated blast-furnace slag, a strong reduction of the compressive strength of the blastfurnace cement is observed.

RECENT PROGRESS IN SPECIAL CEMENTS IN CHINA

Tangbo Sui and Yan Yao

China Building Materials Academy, Guanzhuang, Choayang District, Beijing 100024, P.R. China.

ABSTRACT

Great progress has been made since the 1970s concerning the research and development of special cements. This paper is a review of the current status of special cements in China. Some low energy special cements with unique engineering performance and development trends in the future are also introduced.

Keywords: Special cements, Performance, Current status

1. INTRODUCTION

General purpose Portland cement has become one of the most widely used building materials since its invention in 1824 due to its better durability and lower cost. Based on the statistics of the China State Administration of Building Materials Industry, the annual output of cement in China in 2001 was close to 600 million tons, which accounts for about one-third of the total world cement production. General purpose Portland cement, however, can not completely satisfy the requirements of multi-function and high performance for different construction projects. Besides, in consideration of the conservation of energy and natural resources and of environmental protection, greater efforts have been made in the research and development of cements with special performance or functions, i.e. special cements. China has many advantages in this aspect. The main reason lies in the fact that there are many small production lines with an annual capacity of less than 100 thousand tons of cement for a single unit, which is very convenient for the production of different types of special cements. The abundance of raw materials is another benefit for the manufacturing of special cements in China.

This paper is a brief review of the research and development of special cements in China. Properties of some typical low energy special cements and development trends in the future are also introduced.

2. CLASSIFICATION

So far there is no common definition in the world concerning the classification of special cements. In China cements are divided into two categories, i.e. general purpose Portland cement and special cement. The former includes Portland cement (PC), ordinary Portland cement (OPC), Portland slag cement (PSC), Portland fly-ash cement (PFC), Portland pozzolanic cement (PPC), and composite Portland cement (CPC). The latter mainly consists of 7 types based on their performance and application, which belong to 6 systems according to the chemical and mineral compositions of clinkers, such as silicate or Portland cement (PC), aluminat cement (AC), fluoroaluminat cement (FLAC), sulphoaluminat cement (SAC), ferroaluminat cement (FAC), and miscellaneous types as shown in Table 1.

Table 1. Classification of Special Cements in China

System Type	Silicate	Aluminate	Fluoroaluminate	Sulphoaluminate	Ferroaluminate	Miscellaneous
High early strength cement	High early strength PC Modified PC	High early strength AC Set-regulated cement	Quick setting and rapid hardening FIAC	High early strength SAC	High early strength FAC	—
Expansive and self-stressing cement	Expansive PC Self-stressing PC	Expansive AC Self-stressing AC	—	Expansive SAC Self-stressing SAC	Expansive FAC Self-stressing FAC	CaO expansive agent Composite expansive agent
Cement for Hydraulic construction	Moderate heat PC Low heat PSC & PPC High belite cement Sulfate resistance cement	—	—	—	—	Low heat and mini-expansion cement
Oil well cement	Classes A, B, C, D, E, F, G, H well cement	Special well cement	—	Special well cement	Special well cement	Oil well cement without clinker
High temperature resistance cement	—	High alumina cement				Phosphate cement Water glass binder
Cement for decoration	White PC Colored PC	—	—	Colored SAC	—	Colored PC without clinker
Miscellaneous	Cement for road Masonry cement Barium PC Strontium PC	Barium AC	Cement for sand molding Cement for anchoring	Low alkalinity cement	—	Acid resistance cement Mg oxychloride cement Alkali silicate cement Supersulfated cement Alinite cement

3. R & D OF SPECIAL CEMENTS

The development of special cements in China has been carried out in 3 stages since the 1950s, i.e. the stage of imitation, development through self-reliance and renovation[1], and more than 60 types of special cements have been developed, of which around 20 types are manufactured in large scale or batch production. The annual output of special cements in China in recent years is about 8 million tons. Most of the cements have corresponding National or Ministry standards to guide their production and application. Some typical low energy special cements are briefly introduced as follows.

3.1 Modified Portland Cement (MPC)

The main mineral compositions of MPC clinker are the same as general purpose PC except for C_3A being substituted by $C_4A_3\bar{S}$, i.e.,

$$C_3S \text{ 40-55\%, } C_2S \text{ 20-30\%, } C_4A_3\bar{S} \text{ 5-20\%, } C_4AF \text{ 5-10\%[2]}$$

The raw mix is burnt at 1350°C with the addition of a certain amount of mineralizer which results in the coexistence of C_3S and $C_4A_3\bar{S}$ and the MPC clinker is therefore formed. Compared with general purpose PC, the MPC exerts expansive properties and higher early strength. The expansion rate and expansion ratio can be adjusted through the amount and the type of calcium sulfate blended in the cement, which can be used to produce high early strength concrete with shrinkage compensation. The strength development of MPC and PC are given in Figure 1.

Figure 1. Comparison of strength development of MPC and PC

3.2 Fluroaluminate Cement (FIAC)

FIAC is also a kind of low energy cement due to the inclusion of $C_{11}A_7$ CaF_2 in the clinker phase[3]. Cement sets fast and its early strength gain becomes greater with the increase in the quantity of $C_{11}A_7$ CaF_2 . Table 2 gives some properties of this cement. Because of the quick setting and rapid hardening performance of this cement, FIAC is usually used for urgent repairs where 6-hr strength is needed or as a molding sand binder where 1-hr strength is required.

Table 2. Some properties of fluroaluminate cement

System	Main Composition, %				Setting, min		1:2.5 Mortar Compressive Strength, MPa		
	C_3S	C_2S	$C_{11}A_7$	CaF_2	Initial	Final	4h	1d	28d
C_3S - $C_{11}A_7$ CaF_2	48-58	6-12	20-30		<30	<45	20-23	28-32	45-53
C_2S - $C_{11}A_7$ CaF_2	—	12-20	68-76		<15	<20	28-32	37-42	50-60

3.3 Sulfoaluminate Cement and Ferroaluminate Cement (SAC, FAC)

SAC and FAC belong to the $CaO-Al_2O_3-SiO_2-SO_3$ and $CaO-Al_2O_3-SiO_2-Fe_2O_3-SO_3$ systems respectively[4,5]. Both cements contain more than 45% of calcium sulfoaluminate, which therefore possess the characteristics of high early strength. The burning temperature of SAC and FAC clinkers is $1300-1350^\circ$. By controlling the expansion ratio, several new cements such as set-regulated cement, expansive cement, and self-stressing cement can be made, which are usually used in construction at low temperatures and for preparation of shrinkage compensating concrete, self-stressing concrete pipes and other concrete products. Some typical properties of these cements are listed in Table 3.

Table 3. Typical properties of SAC and FAC cement mortar (1:2.5)

System	Cement Type	Compressive Strength, MPa				*Linear Expansion ratio, %	28d Self stress, MPa
		12h	1d	3d	28d		
SAC	High early strength cement	35-50	40-55	45-68	52-76	<0.5	—
	Expansive cement	—	28-40	—	45-60	<1.0	—
	Self-stressing cement	—	28-40	—	45-60	0.8-1.5	4.0-7.0
FAC	High early strength cement	30-45	40-52	43-56	46-68	0.15-0.26	—
	Expansive cement	—	28-40	—	45-60	0.26-0.65	—
	Self-stressing cement	—	28-40	—	45-60	0.8-1.5	4.0-7.0

*Mortar specimen without constraint tested at 28d hydration age

3.4 High Belite Cement (HBC)

HBC is a kind of newly developed low energy cement in the $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3$ system[6-7]. Typical mineral composition of HBC clinker is as follows:

C_3S 20-30%, C_2S 45-60%, C_3A 3-7%, C_4AF 10-15%

A current study[8] demonstrates that HBC can be considered as a promising cement with characteristics of energy-saving, natural resources conservation and low CO_2 emission, which is the result of low calcium design in the raw mix. The burning temperature of HBC clinker is 1350°C .

Compared with general purpose PC, HBC exhibits better performances in workability, strength and durability. It therefore has potential in the preparation of high performance concrete, massive concrete and hydraulic engineering concrete, etc. Figure 2 shows the strength development of PC and HBC cement mortar (1:2.5) and concrete.

Figure 2. Strength development of cement mortar (left) and concrete (right) (UNF-5 is naphthalene-based superplasticizer)

Although the early compressive strength (1d-7d) of HBC is relatively low in comparison with PC, its later age strength gain is rapid. The 28d strength of HBC is more than 55MPa, which is equivalent to that of PC. The strength of HBC at 90d-180d is 15-20MPa higher than that of PC. The performance of low heat evolution and high strength gain is therefore achieved for HBC. The durability-oriented property of HBC was introduced elsewhere[6]

4. FUTURE DEVELOPMENT TREND

Great progress has been achieved in China in the research and development of special cements. Yet there still exist two major works to be done. One is the percentage of special cements among the total cement production is less than 2%, which is much lower than in many developed countries. The other is that the basic research on special cements needs to be enhanced so as to further promote the application of special cements. The future development of China's special cements will follow the strategy of sustainable development and concentrate on reducing the environmental impact, utilizing industrial wastes and improving the properties of these cements.

ABSTRACT

The possibilities of restoring historical buildings by applying optimised supersulphated cement (SGP) with low Al_2O_3 content are demonstrated on various examples (Zeitz cathedral, Stralsund “Kampischer Hof”, Magdeburg cathedral etc.). It is also recommended that optimised supersulphated cement be used to repair aged dams built with supersulphated cement concrete.

SGP is a binder based on blast-furnace slag, gypsum and Portland cement. The hydraulic stimulation of the slag with a content of approx. 80-90 M.-% is done by sulphatical or/and basic stimulation, preferably making use of gypsum as the sulphatical stimulus, but also anhydrite, whereas Portland cement serves as the basic stimulus. The strength is developed in dependence of the ettringite formation. Beside a high sulphate resistance, mortars and concretes made of SGP show - compared to Portland cement - a lower shrinkage at similar strengths. The use of blast-furnace slag - with lower Al_2O_3 -contents (<14-15%) than recommended by Kühl et al. - to produce supersulphated cement, is possible. However, it is necessary to optimise the amount of sulphatic activator (gypsum or anhydrite) and Portland cement to guarantee high strength. SGP cement shows an extremely high sulphate resistance.

Examples for production and use of various mortars with a high sulphate resistance show potential fields of application for SGP, as there are injection mortars for masonry, mortars for joint repair, and mortars for repair of sandstone buildings. In all cases of application the low shrinkage, the high sulphate resistance and the high salt resistance of these mortars offers many advantages. With the addition of an expansive compound (a mixture of aluminous cement and gypsum, ratio 1:1, 15-25% referred to binder) a shrinkage compensated SGP cement can be produced.

1. INTRODUCTION

The restoration of historical buildings or the repair of modern buildings whose materials show high sulphate concentrations - either due to environmental influences or to previously used building materials – may lead to the situation that common binders such as high sulphate resisting Portland cements cannot be used. The need for hydraulic binders under such unfavourable conditions has led to the development of a binder with very high resistance against sulphate attack.

Supersulphated cement with a very high resistance against sulphate attack was produced in Germany till 1970. The production of this cement goes back to a 1908 patent by Kühl [1]. Since 1920 French and Belgian cement plants have produced supersulphated cement under the brand names Cilor and Supercilor [2]. In Germany, supersulphated cement was first produced for commercial use in 1937 [3], and standardised in 1959 in the standard DIN 4210 which is no longer in existence.

Nowadays, the sulphate blast-furnace slag cements are still standardised in Belgium [4], France [5], Great Britain [6], Korea [7], and Spain [8]. These cements should contain at least 13 % Al_2O_3 , Kühl [9] recommended 14-15 % Al_2O_3 as necessary. Due to the modifications in the steel production process, the Al_2O_3 content consequently dropped below the limits required by DIN 4210. Due to this, supersulphated cement production had to be stopped in 1970, in spite of strong demand.

The purpose of this investigation was to optimise a supersulphated cement with slag sands containing low Al_2O_3 content, and to develop mortars for the applications for masonry injections for backfill mortars, for the jointing of brickwork and for stone substitute mortars. During the development of the slag/gypsum/Portland cement (SGP), the aim was to maintain - even using slag sands with lower contents of Al_2O_3 - the favourable characteristics of the supersulphated cements, as described in reference [9]. As raw materials for the binder, various slag sands and sulphate activators as well as a Portland cement were used.

2. RAW MATERIALS

The used SGP cement was made of slag sand (BS), a sulphate mineral (ST), and a Portland cement (PC). The chemical analyses are shown in table 1. For the production of this binder, the following materials with the given specific surfaces were used:

- Slag sand: R: Ruhrgebiet Slag sand (Germany), 4000 cm^2/g , Al_2O_3 -content 11% (BS-R)
I: Ijmuiden Slag sand (Netherlands), 4000, 5000 and 10000 cm^2/g , Al_2O_3 -content 16% (BS-I)
- Sulphate mineral: - natural gypsum, 6000 cm^2/g (Blaine), Osterode am Harz, Germany (G)
- natural anhydrite, 6000 cm^2/g (Blaine) Osterode am Harz, Germany (A)
- Portland cement: - ordinary Portland cement, ca. 3000 cm^2/g (Blaine) (PC)

Table 1. Chemical analyses of the basic materials in weight percent (%)

Slag sand produced by quick cooling and composed essentially of glass is a latent hydraulic material which must be activated in order to show a sufficiently quick rate of hardening. This can be achieved by sulphate and alkaline activators or by a combination of both. Daimon [10] described the chemistry of the hydration of slag sand (glass) in the presence of portlandite (1) and gypsum (2) by the following equations:

The hardening mechanism of sulphate activation cannot be easily compared with that of alkaline activation. When activating with portlandite [$\text{Ca}(\text{OH})_2$] or Portland cement, an alkaline environment is only created to activate the acid aluminate-silicate members of the glassy slag particles, whereas a reaction to form ettringite takes place under the sulphate activation. The ettringite phase creates strength and does not endanger the structure by expansive reaction as it mostly begins to form when the cement paste is still in plastic state. Moreover, it is a through-solution reaction because of the fact that the Al_2O_3 is homogeneously distributed in the slag sand [11]. In addition, the content of $\text{Ca}(\text{OH})_2$ is low which, according to Mehta [12], leads to the formation of well crystallised ettringite that causes minor expansion only. It is also becoming evident that the contents and the availability of Al_2O_3 , important for the slag sand's reactivity, depending on its fineness.

3. PRODUCTION AND COMPOSITION OF THE BINDERS

The composition of the cements was designed such that as much sulphate as possible is provided for hydration of slag sand. The gypsum or the anhydrite are expected to completely react with the slag sand at the latest by 28 days. Portland cement was used as an alkaline activator. Five different binder compositions were made as listed in Table 2.

G - gypsum

PC - Portland cement

3.1 Investigative Methods For Binder Optimisation

The evaluation of the binders produced was done by examining standard prisms made in accordance to DIN EN 196 (part 1). Water content was different from the standard requirements, it was based on a standard consistency of mortar (slump of $17 \pm 0,5$ cm). The following tests on fresh mortar and hardened mortar were performed:

- Slump $17 \pm 0,5$ cm according to DIN 18555 (part 2)
- Water requirement according to DIN 18555 (part 2)
- Compressive strength according to DIN EN 196 (part 1)
- Flexural strength according to DIN EN 196 (part 1)
- Expansion and Shrinkage according to Knöfel [13] Method A4M
- Leachability
- Liability to efflorescence according to Knöfel [13] Method B6

3.2 Results Of Binder Optimisation

The results of these investigations are briefly summarised below. More detailed results are described in [14]. The water/binder ratio varied between 0,50 (BS-I) and 0,52 (BS-R). The water requirement of the slag sand of the Ruhrgebiet was higher than the one of the Dutch slag sands. The sulphate types, i. e. gypsum and anhydrite, had no influence on the water/binder ratio.

As expected, the compressive strengths of the mortars increased with curing time and with higher fineness. Compared with slag sand from the Ruhrgebiet, the SGP with Dutch slag sand achieved higher strengths at similar grinding fineness (Figure 1). However, compared to Portland cement, the compressive strengths are lower. The flexural strengths developed in parallel to the compressive strengths, and 28-day data for SGP varied between 1,2 and 8 MPa. The ratio between compressive strength/flexural strength, 6,0-11,1 is more favourable when compared to Portland cements. Similar

results were reported earlier with supersulphated cements [15, 16]. With Dutch slag best results were obtained with a cement containing 85 % slag sand (S), 10 % gypsum (G), and 5 % Portland cement (P). The slag from the Ruhrgebiet achieved highest strengths with a composition of 83 % (S), 10 % (G) and 7 % (P). Its Portland cement content is higher and the slag content is lower. Reducing the Portland cement content in the favour of the slag sand contents (Ruhrgebiet) led to lower strength values.

Figure 1. Compressive strengths of the SGP and various slag sands at the age of 28 days

The shrinkage of the SGP mortars made with Dutch slag was lower than those made from the Ruhrgebiet slag. The relatively low shrinkage compared to Portland cement is consistent with the results of other authors [17]. Expansion tests on mortar specimens after 28 days of storage under water showed low values on the order of <0,3 mm/m.

The leachability test for sulphate ions was performed on mortars at the age of 28 days in order to determine the conversion of sulphate minerals. The prisms were crushed to a grain size of 2-4 mm, and shaken with distilled water for 24 h. Thereafter, SO_4^{2-} was determined by means of ionic chromatography. The mortars were made with binders having different gypsum or anhydrite contents. The leachability was lower with the Dutch slag as compared to the Ruhrgebiet slag. The investigation of liability to efflorescence was carried out for over 20 cycles during which the head sides of the prisms were put in distilled water (depth 1 cm) for 24 h and thereafter dried for 48 h at a temperature of 23°C and 50% relative humidity. Very little efflorescence was observed. The results can only be differentiated in so far as the liability to efflorescence increased with lower gypsum contents. The salts formed could be identified as epsomite and gypsum, by x-ray analysis.

In recent times, the composition of supersulphated cement with suitable Dutch slags was optimised for the repair of storage dams. Stark [18] found an optimised composition of 85 % slag sand, 13,5 % anhydrite, and 1,5 % Portland cement with a specific surface of 4500 cm²/g (Blaine) [19]. In this case, compressive strengths of 51,6 MPa of concrete could be achieved.

4. EXAMPLES OF APPLICATION OF SGP

Below, examples of application of SGP are given in the preservation of historical buildings. In these applications high sulphate resistance is a necessary precondition for the successful restoration

of buildings. In Figure 2, the expansion behaviour of various common cements and SGP is demonstrated in the sulphate resistance test according to Henkel [20]. This investigation was made by producing a mortar with a binder/aggregate ratio of 1:3, a gypsum addition of 15 % referred to the binder, and with a slump of $17 \pm 0,5$ cm. The test samples were stored for one day at 20°C and 95% relative humidity, after that 6 days at 23°C and 50% relative humidity. Afterwards they were stored under water at a temperature of $5 - 8^\circ\text{C}$ to favour an expansion caused by formation of ettringite. In Figure 2, expansion data are shown for Portland cement, Portland cement with high sulphate resistance, blast-furnace slag cement with high sulphate resistance, and SGP cement. As can be seen in Figure 2 all binders, except SGP, showed expansion and were destroyed. This proves the high sulphate resistance of SGP cements and their suitability for the restoration of historical buildings. Similar investigations have been made by Stürmer [21], who also mixed the mortars with old materials containing sulphates instead of gypsum.

Figure 2. Expansion of mortar prisms made with sereval binders after storage in 8°C water

4.1 SGP mortars for masonry injection

For grouting of multi-shell masonry, an injection mortar with high sulphate resistance was developed on the basis of the above-mentioned investigations (14, Part II). Beside standard sand, various lightweight cellular aggregates were used, such as glass globes, fly ash and foamed glass. Their proportion was between 3 and 15 % referred to the binder. The binder/aggregate ratio was 1:4. Additives such as plasticizers, stabilisers, and, if necessary, air entrainers were also used. For the laboratory investigations, the mortars were produced with a slump of $17 \pm 0,5$ cm. The mortar consistency for the pressing was increased so that the mortars had good flowing properties. The composition of the mortars and the properties of the fresh and hardened mortars are given in table 3. They show the suitability for the purpose intended.

Compared with an injection mortar made of blast-furnace slag cement, the SGP cement injection mortars showed strengths which are approx. 20 % lower. As expected, distinctly higher strengths are achieved when using plasticizers. Most of the time, the various additives do not have a strong effect, only the use of foamed glass compared to solid glass globules showed some effect. Foamed glass reduced the strengths by half, while solid glass globules increased the strength by approx. 10%. The injection mortars showed slight expansion and shrinkage, air voids had a positive effect and foamed glass had a negative effect on volume changes.

Recently, other researchers have also developed injection mortars for masonry using SGP cement or SAP cement (anhydrite instead of gypsum as a source of sulphate ions). Stürmer [23] composed a binder with foam instead of aggregate, and grouted masonry successfully with this injection mortar.

4.2 SGP Backfill mortars to conserve lime plasters

The restoration projects of the Heydau monastery, Altmorschen, Germany and the Magdeburg cathedral, Germany, have involved the development and testing of backfill mortars. They have been developed in order to conserve a permanent connection between highly sulphated historical lime plasters and the underground, so as to preserve them for future generations.

All tested injection mortars fulfilled the requirements regarding the flowing and penetration behaviour. The SGP-backfill mortars showed compressive strengths and dynamic modulus of elasticity nearly close to historical lime plasters. The additives (PUR, polymer dispersion) reduce the elastic modulus, increasingly when more are added; methylhydroxyethylcellulose (MC) even reduces compressive, bending, and bond strengths.

Two injection mortars SGP and SGP without MC were applied on test surfaces and 12 months later the bonding properties, see Figure 3, and the bonding strength were checked. The bonding properties were undisturbed, newly formed noxious salts could not be detected, and the bonding strength was within the range of the laboratory results. More information in [24].

Figure 3. Core (\varnothing 5 cm) of restaured plaster - bond between gypsum backfill mortar and loam

4.3 SGP mortar for brickwork jointing

For the production of jointing mortars, one should take advantage of the high resistance of SGP cement against sulphate and salt attack [20, 21, 25]. The carbonation of SGP may have a disadvantageous effect on these mortars leading to granular disintegration. The carbonation of ettringite leads to a considerable volume reduction, the consequence of which is the granular disintegration. This damaging process was described by D'Ans and Eick [26]. Due to this reason, SGP mortars were seldom used on the external surfaces of buildings. This negative property of the SGP cement could be improved by using, among others, redispersible polymer powders [27]. When re-jointing ancient masonry, a special situation must be considered. Jointing mortars have to provide a safe external cover of the masonry to guarantee protection against weather influences. Due to this reason, they should guarantee a perfect crack-free adhesion to the brickwork. The shrinkage of the mortars, however, causes the contrary effect. The use of expansion compounds, in turn, offers the possibility to reduce the shrinkage of the mortar. The ideal case would be a shrinkage-compensated mortar which, instead of shrinking, expands slightly until the mortar is hardened. Successful investigations in this direction were made by Knöfel, Degenkolb and Winnefeld [28, 29, 30]. Mixtures of aluminous cement and gypsum (ratio 1:1), with 15-25 % addition to the binder have proved effective in this case.

Various additives and aggregates were used to develop a pointing mortar based on SGP and SAP. The binder/aggregate ratio was 1:5. The exact compositions of the jointing mortars are given in table 4. Aggregates such as standard sand, and mixtures of standard sand and light weight aggregates such as perlite and expanded slate, were applied. The use of an expansive compound composed of aluminous cement and gypsum in a ratio of 1:1, should reduce the shrinkage and thus improve the adhesion to the brickwork. In order to improve the adhesive strength and to reduce granular disintegration, polymers were used. Methyl cellulose was used to increase the water retention capacity (WRC) and this provided the conditions for good hydration. The thickener's task is to improve the workability of the mortar but it causes higher water demand. A plasticizer was added in order to reduce the demand for water. Retarder was used to reduce the rate of workability loss.

The mechanical properties of the jointing mortars are improved by polymers (KD) and methyl cellulose (MC). The same is valid for the tendency to granular disintegration. In the same way, the use of plasticizers (FM), thickeners (Vd) as well as of retarders leads to further improvements. The expansive agent reduces the mechanical properties in the same way as the use of light-weight

aggregates. A high impermeability is usually associated with superior mechanical properties. As a consequence of this, the water absorption coefficients are reduced by the additives and the resistance to water vapour diffusion are increased. The use of expansive compound leads to a higher permeability. The expansion on moisture exposure are in general quite low. Shrinkage of unmodified jointing mortars is in the range of $-0,66$ mm/m. It is lowered by the use of KD and MC. The use of expansive compounds results in an improvement on the shrinkage to values of $-0,11$ to $-0,12$ mm/m.

After having used the mortars HF5 and HV3+ at the Kampischer Hof in Stralsund, no negative effects on of the sample surfaces including granular disintegration have been observed to date.

4.4 Artificial stone mortar for reprofiling damaged natural stone

For the repair of damaged natural stone at Zeitz cathedral, Germany, aritical stone mortar was developed: for composition and properties see table 5 and Figure 4. The natural stone used at Zeitz cathedral was a sandstone with dolomite binder. Atmospheric influences lead to the formation of epsomite and gypsum which leads to decay, see Figure 5. The salt content was up to 13 %. This high concentration of sulphates leads to the use of SGP-binder, but also of blast furnace cement with a high content of blast furnace slag. The aggregate of the artificial stone mortar was as fine and of the same colour as the particles of the sandstone.

To achieve the durability of the mortars several additives were used - redispersible polymer powder which improved the bond strength and entrained air voids and air entrainer. The amount of air voids was higher than 20% to allow space for the formation of salts permeating off the natural stone into the artificial stone mortar, see Figure 7. The properties of the artificial stone mortars used at the Zeitz cathedral are: compressive strength 8-10 MPa, bond strength 0,3-0,4 MPa, water absorption coefficient $<1,0 \text{ kg/m}^2\sqrt{\text{h}}$ and resistance to water vapour diffusion <30 as well as a high durability to freeze-thaw-cycling test. The artificial stone mortar has a high resistance against efflorescence. Special tests, were undertaken in accordance with existing tests in Germany and are reported more fully in [31]. The restoration of Zeitz cathedral took place with mortar H5OM0 in 1997, see Figure 6, no damage has been found to date.

5. CONCLUSIONS

The use of blast-furnace slag - with lower Al_2O_3 -contents (<14-15%) than recommended by Kühl et al. - to produce supersulphated cement, is possible. However, it is necessary to optimise the amount of sulphatic activator (gypsum or anhydrite) and Portland cement to guarantee high strength. This cement is called SGP cement (S – slag, G – gypsum, P – Portland cement). SGP cement shows an extremely high sulphate resistance and a low shrinkage compared to Portland cement.

Examples for production and use of various mortars with a high sulphate resistance show potential fields of application for SGP, as there are injection mortars for masonry, mortars for the repair of damaged historical plasters, mortars for joint repair, and mortars for repair mortars for sandstone buildings. In all cases of application the low shrinkage, the high sulphate resistance and the high salt resistance of these mortars offer many advantages.

The addition of an expansive compound (a mixture of aluminous cement and gypsum, ratio 1:1, 15-25% referred to binder) a shrinkage compensated SGP cement can be produced. The high volume stability is caused by the low portlandite content in this binder system. This leads to a coarse morphology of ettringite that causes minor expansion only.

The mechanical properties of the jointing mortars are improved by polymers (KD) and methyl cellulose (MC). The same is valid for the liability to granular disintegration.

ABSTRACT

The paper reviews the present state of knowledge about the entitled subject. The HPC finds application in high humidity climate conditions (building sites with poor storage conditions, The paper reviews the present state of knowledge about *Organic Hydrophobic Admixtures and especially about the Hydrophobic Portland Cement*. Such a cement finds application in high humidity climate conditions (building sites with poor storage conditions, long distance shipping of the cement etc..) and can replace the Ordinary or the Rapid Hardening Portland Cements which would deteriorate prior to use. By including in the cement a certain hydrophobic admixture, it is possible to obtain a high quality concrete, even if the cement is kept prior to use in humid air conditions or in moderate rain.

1. INTRODUCTION

Hydrophobic Portland Cement (HPC), a cement for use in high humidity climate, is not widely known. It is often confused with the waterproofing cements used to obtain impermeable concrete or other building structures. The literature is relatively limited. The present report will address these issues and it is composed of two parts, as follows:

- **Part I** represents a literature search [1-26]. It represents an extension of a report submitted by the Hebrew University of Jerusalem to the Israel Cement Foundation in April 1997, entitled "*Literature and Market Search on Organic Hydrophobic Admixtures and Hydrophobic Portland Cements*"¹, containing further quotations from other sources [especially, 17a]. The quotation of certain newer publications (1993-2002) may not be pertinent, due to the frequent terminological confusions between hydrophobic and waterproofing admixtures or between hydrophobic and waterproofing cements [24-26];

- **Part II** represents a scientific and an industrial market search on the same items. In order to perform it, we sent inquiries to many specialists in the field (scientists, producers of chemicals to improve the qualities of building materials etc.). We have obtained in answer different personal communications [17b,27-32], clarifying (at least partially) questions concerning:

¹ Report written in 1997 by Prof. M. Schieber, Dr. M. Nadu, Dr. J. Nissenbaum and Mr. M. Braiman at the Hebrew University of Jerusalem. The report was corrected following the kind suggestions given by Prof. John Bensted [17b] (corrections of the English of the draft report and a correct interpretation of what was quoted in his name [17a]).

- Why we could not find “hydrophobic admixtures” or “hydrophobic cements” in different commercial catalogues. Is there any intention of producing hydrophobic admixtures in the future? If there are not, why? Are there better alternatives?
- Data concerning the technical characteristics of these products or an existing standard that defines quality requirements and testing methods.
- Data concerning prices and other information available on the subject.

PART I: LITERATURE SEARCH

2. HISTORIC AND SCIENTIFIC BACKGROUND

A major problem which exists in humid climates the whole year, and particularly in the rainy or snowy seasons, is the storage of portland cement. On many building sites there are poor storage conditions. Therefore, these poor storage conditions problems are solved or can be solved using *hydrophobic Portland cement*, in many places, such as Russia[1-8], Romania[9-11], South Korea[12], India[13,17,23], England[15-17], Austria[18], Germany[19,20], USA[21] and Canada[22]. For instance, hydrophobic portland cement shipped from England (manufactured by Blue Circle Cement) was employed in the Falkland Islands in 1982, at the end of the war, to build an extended infrastructure, including a new airport concrete runway and to erect the exterior walls of a military cemetery[17].

Standard requirements for hydrophobic portland cement are available in some countries like the CIS (ex USSR) [8] and India[13]. There are no standards for hydrophobic cements in the countries of Western Europe or North America. In these countries hydrophobic Portland cement is produced to comply with the performance requirements of ordinary portland cement, such as BS12 in England[17] and DIN 1164 in Germany[20].

Admixtures in small amounts (up to 5% by the weight of the cement) of various organic and inorganic materials in pastes, mortars or concrete are known to interact with the hydrating cementitious system and to modify different properties in the fresh, setting, hardening or hardened state. Smaller amounts of various organic surfactant materials (<0.5%) are in current use as water-reducer/retarding admixtures and in even smaller amounts (0.02-0.1%) as air-entrainers[13,22]. However, certain organic surfactant materials added in amount of 0.06-0.3%, can act as a hydrophobic agent which, if added to dry cement, repel water from the cement grains, until mixed with aggregates and water[1-11, 15-22].

It is known that solid surfaces either can or cannot be wetted by liquids. If they can, the wetted surfaces are lyophiles (hydrophile in the case of the water). If not, the surfaces are lyophobices (hydrophobes respectively). The cement grains are hydrophylic, but for the hydrophobic cement this property is temporarily canceled because adsorption of the hydrophobic admixture by the cement grains implies the appearance of mono-molecular hydrophobic layers on their surface and a drastic reduction of the capillary absorption of water. Mixing of the concrete or of the mortar, destroys the layer, the admixture loses its hydrophobic properties and instead becomes a plasticizer, a water reducing agent and/or an air entraining agent[11,21]. Hydrophobic cements should not be confused with waterproofing cements, which are claimed to make a more impermeable concrete than ordinary portland cement. There is a controversy about the effectiveness of these waterproofing cements[11,16].

Hydrophobic Portland cements, firstly suggested by Prof. Khigerovich, came into general use in Russia after 1949. One of the authors of this report (Dr. Nadu, a former student of Khigerovich) received, some 35 years ago, favorable laboratory results: (a) Testing a sample of hydrophobic Portland cement sent to him by his former professor; (b) Preparing and testing of hydrophobic

Portland cement samples, each sample being obtained by simultaneous laboratory grinding of clinker with ~ 6% gypsum and 0.1-0.3% organic hydrophobic admixture. It was proven that *the temperature of the grinding material and/or the possibility of preliminary dissolving of the admixture in organic solvents* are significant parameters of the technology required to obtain homogeneous and high quality products. Similar experimental results were later reported[9,11,17]

For Khigerovich's theory of hydrophobic cement, a noteworthy abstract was given by Wolfgang Eitel in the 1957 Chem. Abs.[1b] : *"Surfactants added in the amounts of 0.1-0.25% to clinker during grinding give to the resulting cement a hydrophobic characteristic. Particularly efficient are admixtures of oleic acid, naphthenic acids, or higher fatty acids, their H₂O-soluble salts, oxidized petroleum, paraffin etc. The calcium stearate does not react with the cement but is included in the grain, therefore is not suitable...The naphthenic acid salts decrease the surface tension at the boundary air/water in the cement mortar and thus bring about an air emulsion in the mix....The surfactants intensify the efficiency of clinker grinding and make cement more stable in storing, even in moist air, without a loss in hydraulicity (even by "self activation") an increase in aged cements was observed). Chemisorption on the surface of the cement grain and the plastifying effect of surfactants which brings about a desirable reduction of the water/cement ratio (in concrete by 9-12%, in lean mortars even by 15-25%). This plasticity increase is not caused by the air-entraining action (which is a desirable associated effect). The polar-active groups of the hydrophobic agents are strongly adsorbed on the cement grains, in contrast with the aliphatic chains at the ends of their molecules. The latter bring about a gliding or lubricating effect by their mobility in the oriented adsorption layer on the cement grain. The adsorption systems therefore are thixotropic. Technological properties important for hydrophobic cements are their increased frost resistance and reduced capillary suction in the mortar structure, the suppression of salt efflorescence in concrete and a reduction of the water permeability by an improved homogeneity of the mortar."* The hydrophobicity of the cement depends on the hydrophobicity of each clinker mineral that decreases as follows : Tricalcium silicate > Dicalcium silicate >> Tetracalcium aluminoferrite ≥ Tricalcium aluminate[4].

3. SOURCES OF HYDROPHOBIC ADMIXTURES

Hydrophobic admixtures consist of different waste materials from the petroleum or from other industries. Examples: **(a)** Oil soaps, an oleos material, sodium salts of different organic water insoluble acids, obtained as waste from the alkaline purification process of some petroleum distillates; **(b)** "Asidol" - a viscous liquid, a mixture of similar organic acids; **(c)** Methyl and/or ethyl sodium siliconates or polyethyl hydrosiloxane, representing waste materials of the organo-silicon compounds industry [5] and other waste products; **(d)** Sodium abietate.

In order to find the best, commercially available organic additive in Israel, either solid or liquid, we have performed a literature and a commercial market search. Different technical requirements available in the literature and in different standards have been compared and optimized to the conditions in Israel. Commercial catalogues published by industry specializing in chemical products for building materials improvements that we have access to at present, do not mention hydrophobic admixtures. We have studied this aspect in detail in our market search.

4. STANDARD REQUIREMENTS CONCERNING THE HYDROPHOBIC ADMIXTURES

The Russian standard specifications for hydrophobic portland cement do not specify the type of hydrophobic agents used in its manufacture[8]. The former editions of the same standard specified the following additions, well known also as grinding aids in cement manufacture, as air entraining and as water-reducing agents: 0.08-0.10% oleic acid, 0.10-0.12% naphthenic acids derived from certain crude oils (C_nH_{2n-1}COOH where n=8-13) or 0.20-0.25% soap naphtha derived from the

alkali treatment of the oils and containing 50% water. In the CIS (Community of Independent States, former USSR), such cements are employed mainly as a protection against deterioration during storage but also as masonry cements due to their plasticity, water retentivity and ease of pumping. In addition, in the CIS, oilwell cements can be rendered hydrophobic by being treated with up to 0.3% (dry weight) triethanolamine or other hydrophobic agents in order to extend the stipulated shelf life from the normally stipulated 30 days maximum, to a new maximum of 60 days [17a, 17c].

The Indian standard specifications for hydrophobic portland cement specify that “some of the agents used in the manufacture...are oleic acid, naphthenic acid, stearic acid, pentachlorophenol etc.” The inclusion of 0.1-0.5% by weight “of approved hydrophobic agent” is specified [13].

5. METHODS OF TESTING FOR HYDROPHOBIC PORTLAND CEMENT

Hydrophobic admixtures are added to the clinker (at the cement factory or at the building site), or to the cement (only at the building site). Optimum amounts (%) of each hydrophobic admixture for each clinker exist and need to be found by individual laboratory research. An underdose does not lead to the obtaining of a hydrophobic cement; an overdose may lead to an uncontrolled air entraining, to weakening strength effects etc.

- *Khigerovich's didactic demonstration of the hydrophobicity*: Sprinkle a small quantity of hydrophobic cement on water in a container. An ordinary match may be struck after its submerging through the molecular layer formed at the surface of the water[9].
- *Indian standard qualitative test (flotation)*: Sprinkle a small quantity of hydrophobic cement on water in a container. The cement shall float on the water for a period of not less than 24 hours[13].
- *Russian standard qualitative test*: the normal cement absorbs a drop of water from its surface in 1-2 sec, the hydrophobic cement may absorb the drop in a period of not less than 5 minutes[8].
- *Indian standard quantitative test*: Take 5 g each of fresh and free flowing portland cement and the hydrophobic cement under test and spread each of the samples evenly in a thin layer in 15 cm (dia) petri dish. Expose it to a relative humidity of not less than 99.9 percent at $27 \pm 2^\circ\text{C}$ for 24 hours. Determine the mass loss at 550°C for the two samples. Hydrophobic cement shall not show loss on ignition more than 30% of the value for the ordinary portland cement[13].

All the above methods are preliminary tests to determine if the cement sample is or is not hydrophobic. The cement sample which will be found hydrophobic, will be further tested according, for example, to the requirements of the Israeli Standard #1 (Specifications for Portland Cement) and/or #466 (Concrete Code) and, in case of need, according to the requirements of some European and/or ASTM standards for portland cement.

6. STANDARD SPECIFICATIONS FOR HYDROPHOBIC PORTLAND CEMENT

What is “Hydrophobic Cement”?: a) “A cement obtained by grinding ordinary portland cement clinker with an additive which will impart to ground cement a water repelling property which shall be destroyed only by wet attrition, such as in a concrete mixer. The hydrophobic quality of cement would facilitate its storage for longer periods in extremely wet climatic conditions”[13]; b) “A cement that absorbs a drop of water placed on its surface in a period of not less than 5 minutes” [8].
Do not use hydrophobic cement together with superplasticizers [8].

Chemical, physical and mechanical requirements: as for ordinary portland cement [8,13].

7. MANUFACTURE OF HYDROPHOBIC PORTLAND CEMENT IN COUNTRIES WHERE STANDARDS ARE NOT AVAILABLE

In the countries of Western Europe and North America the hydrophobic portland cement (HPC) is produced so as to comply with the performance requirements of ordinary portland cement, like CEM I now in Europe. Bensted[17a] has reported an example of the English experience in this field. Hydrophobic Portland cement was obtained by grinding ordinary portland cement clinker with 0.34% fat (stearic acid) and gypsum with the following laboratory performances: *The chemical analysis*: 20.6% SiO₂; 0.48% insoluble residue; 6.1% Al₂O₃; 3.3% Fe₂O₃; 63.8% CaO; 0.91% MgO; 2.1% SO₃; 0.34% fat; 1.4% loss on ignition; 0.58% K₂O; 0.36% Na₂O. *The modular composition*: Lime saturation factor (LSF) = 92.8; Lime combination factor, (LCF)=88.8; Silica ratio (S/[A+F]) = 2.2; Alumina ratio (A/F) =1.9.; *The potential composition %* : C₃S =40.4; C₂S=30.5; C₃A=10.6; C₄AF=10.3. *The compressive strength* (MPa): 21.6 at 3 days, 31.5 at 7 days and 41.3 at 28 days. *The HPC sample* met the BS-12 requirements for ordinary portland cement at the time.

7.1 Examples of uses

Hostile climates and humid environments offer scope to the applications of hydrophobic portland cements in mortars and concretes. It was used in the Falkland Islands in 1982, at the end of the war, to supply major construction works. There were initially either no or inadequate storage facilities for cement in the cold, damp climatic conditions experienced in this part of the South Atlantic. Also, for repair or extension works to the changing rooms of sport clubs that are in regular use and when humidity levels are often very high, hydrophobic cements have been successfully used.

7.2 Some more on the properties

Hydrophobic portland cement is made by grinding portland clinker with gypsum and a film making compound like oleic acid to form the cement, which can be ground to ordinary portland cement fineness, but is more commonly ground to rapid-hardening portland cement fineness. The water repellent film formed around and adsorbed onto each cement grain provides a great degree of protection against premature hydration by air moisture and offers the following:

- Reduction of the rate of deterioration of cement during storage or transport under unfavorable conditions, like those where deliveries can only be made at infrequent intervals. For example, Portland clinker ground with 0.3% oleic acid gave a cement that withstood 6 months air exposure without loss of strength, whilst untreated portland cement lost over three-quarters of its strength after a month of aeration [15]. Hence this cement is of value in damp equatorial climates, dressing rooms of sport club in use etc.
- The good workability of this cement is caused by its being more jelly-like in consistency than most other cements. Concretes made with HPC normally have compressive strengths similar to those of comparable untreated portland cements. Any retarding influence of the hydrophobic additive is usually offset by the lower water : cement ratios normally used in practice.

PART II: SCIENTIFIC AND MARKET SEARCH

8. ENUMERATION OF THE RECEIVED INFORMATION

- Prof. Bensted writes: “In my opinion, why you could not find hydrophobic admixtures in different commercial catalogues of chemicals for improving cements and concretes in given situations is because of the endless confusion that exists in many users’ minds between waterproofing and hydrophobicity. Some consider all such admixtures to be waterproofers or hydrophobic agents, whilst others do appreciate the need for two separate categories. It is thus not surprising that commercial catalogues may not specifically name hydrophobic agents” [17b].

- Handy Chemicals has a long overall experience in the manufacture and in the use of organic admixtures (superplasticizers and others) to obtain high performance concrete. Their experience would dictate caution with the simultaneous presence in the concrete of two organic chemicals: the first to manufacture a high performance concrete, the second to use in the manufacture of a hydrophobic portland cement. Nevertheless, Handy Chemicals, having a joint research program on cement grindings aids with the University of Sherbrooke, have included in this program the use of some hydrophobic admixtures and plan to expand more specifically in the direction of producing hydrophobic cements [27].
- Handy Chemicals' specialists and their colleagues from the University of Sherbrooke, are fully aware that there are no specific standards in North America involving the testing of the admixtures used to produce hydrophobic cements. They intended to search such standards [27].
- Hydrophobic portland cement (HPC) is produced in India on the basis of specific orders according to IS:8043-1978, which is the current version. There is no continuous production and no precise data on the quantity being produced, but, in any case, it will be a very small proportion of the total cement production, which was about 70 million tonnes in 1996 [28].
- There is no separate class of users of HPC in India. HPC is used equally with ordinary portland cement (OPC), except when the user anticipates prolonged moist storing of the cement. In view of the above it was not possible to obtain from an Indian commercial source a sample of hydrophobic cement for testing. It is recommended to prepare test samples by laboratory inter-grinding of ordinary portland cement (OPC) with 0.2-0.5% oleic or stearic acids, obtained from leading chemical manufacturers' suppliers such as Merck, BDH etc. Such products as asidol and siliconates are formulated wastes from primary industries and should be evaluated only if locally available. Dr. Mullick kindly offers to supply on request an HPC laboratory sample [28].
- Merck does not offer compounds that might be used for the preparation of HPC in industrial quantities, their compounds are designed only for chemical laboratory and small scale production plant. It was recommended to contact: a) Henkel from Dusseldorf to supply oleic or stearic acids; b) Peter Greven from Bad-Munstereifel to supply sodium salts of oleic or stearic acids; c) International companies like Texaco to supply naphtha soaps [31].
- We did not receive any answer from Henkel and Texaco. Peter Greven Fett-Chemie informed: (i) on its competence in building protection with hydrophobic agents to obtain "water repellent high quality plasters"; (ii) on supplies of sodium oleate under the name "LIGA Natriumoleate 90%" ; that is a sodium soap of a technical oily acid, which is a "raw material for the production of cleansers" or may be used as "reactive water-repellent for the constructional proofing", or as admixture for the rubber industry. No information was given on the use of Peter Greven products to obtain hydrophobic cements [29].
- Mr. Michael Langdon informs that Sealocrete does not manufacture admixtures specifically for producing hydrophobic cements. "This is mainly because there is not a significant market in Western Europe. Most cement is transported and used fresh and recent changes have been made to bag packaging for cement to include a waterproof membrane". As suggested, we contacted Blue Circle Cements, the producers of the HPC shipped from England in the Falklands Islands in 1982 but we did not receive any answer at the time.[17a,30]
- Mr Carlos Cacon from the Spanish Branch of Sika informs that there are no hydrophobic cements in Spain and that only the Research and Development Department in Sika central offices in Zurich Switzerland can give information if Sika intend to commercialize in the future hydrophobic admixtures. We did not receive any reply from Sika-Zurich. [32].

- Some seven years ago we had a talk with leading researchers of the Romanian National Cement Institute (CEPROCIM S.A. Bucharest): There were in Romania numerous old small and middle size cement lines, now replaced by the existence of more than 12 giant dry, low fuel consumption production lines (3000 T/day). Why did the comprehensive and successfully performed studies on hydrophobic cements not end with an industrial manufacture? The answers are: 1) The manufacture of hydrophobic cement, on the basis of specific orders, is no longer a problem after the performed studies; 2) A continuous production is not justifiable because there is not and there will not be a continuous market for this cement [11].
- Some 50 years ago, a similar point of view and the alternative of the building site blending to avoid manufacturing complications, was presented to his students by Prof. Khigerovich, (Chair of Chemistry at the Moscow Civil Engineering University). At the same times, at the “Voskresensk Cement Plant” (near Moscow) a manufacture of hydrophobic Portland cement was first built.

9. CONCLUSIONS AND FUTURE PLANS

- We have produced a sufficiently exhaustive literature and market survey (1950-1997) on hydrophobic admixtures and on hydrophobic portland cements including considerations on the composition, technology, work mechanism, properties and applications. There have been no major advances in this area since 1997.
- The specialized chemical products industry to improve the quality of cement and concrete often ignores the hydrophobic admixtures partially due to terminological confusion between waterproofing and hydrophobicity and also because there is not a continuous manufacture and market for hydrophobic cement. Another reason may be due to a certain incompatibility between superplasticizers and hydrophobic admixtures and also due to recent changes made to bag packaging of cement to include a waterproof membrane.
- Standards concerning the quality requirements and the testing methods for the hydrophobic admixtures and for the hydrophobic portland cement exist in Russia and in India. In other countries (U.K., Germany, Romania) there are no specific standards but, if necessary, manufacturing would be not a difficult problem.
- In many countries, including Israel, a practical experience on the manufacture and on the use of hydrophobic admixtures and on hydrophobic portland cements, does not exist. If needed in the future, to avoid manufacturing complications in cement plants, there are two alternatives: building small scale site manufacture or/and import. We think that for both alternatives preliminary small scale laboratory experience is a necessity.

ACKNOWLEDGMENTS

The authors wish to thank the individuals and companies who responded to the market survey, which was undertaken on a neutral perspective and not an endorsement of the trade products mentioned.

CURRICULUM VITAE

John Bensted

John Bensted studied for his BSc in chemistry and for his PhD in the area of transition metal chemistry at the University of London. In 1967 he joined the Research Division of the Blue Circle Cement Group as a research scientist, eventually becoming a Principal scientist. John was not only involved in research and development over the entire range of cement types for Blue Circle worldwide, but was also heavily involved in technical service and troubleshooting as well as numerous aspects of quality control. In recognition of his research efforts, he was awarded the AITEC Medallion by the technico-economic organisation of the Italian cement industry in 1978 and the DSc degree of the University of London in for his published work in cement chemistry in 1981.

In 1985 John joined British Petroleum as a Senior Drilling Engineer at their Sunbury-on-Thames Research Centre, becoming Research Associate in Cement Technology. He directed research programmes on oilwell cements and functioned as an internal consultant on all aspects of cement technology (both oilfield and construction) for the different BP businesses worldwide.

Since 1992 John has become more involved with academic research in cement and concrete technology, primarily as a Visiting Professor in Cement Science at the Universities of London (Birkbeck College) and Greenwich. He is an International Consultant in Cement Technology for the oil, construction and chemical industries, involved in research, development, technical advising and troubleshooting matters in the cement and concrete arena. Also, he acts as an expert witness in legal cases connected with cement and concrete.

In 2000 John was a co-inventor of a new MDF type cement at Keele University (where he was a Visiting Professor 1996-2000) called MicroPaste, which has improved ductility and is manufactured under licence by Castle Cement (UK). This cement has been used to line pipes that convey drinking water.

In 2002 John was given a Distinguished Services Award by the Society of Chemical Industry for his work with their Construction Materials Group, where he has served as Secretary and later as Chairman, and with their London Section. John is also active in national (UK), European and international standardisation work. Since 1995 he has been leader of the UK delegation to the ISO sub-committee on drilling and completion fluids, and well cements.

ALKALI-AGGREGATE REACTION (AAR) IN CONCRETE IN ISRAEL

ABSTRACT

Israel is one of the last of the world's developed countries where the building engineers generally ignore a very timely subject: the alkali-aggregate reaction (AAR) in concrete and the involvement of AAR in the different durability and security problems for the building structures. Our team performed the first and only Israeli laboratory investigations on AAR. We succeeded in proving that two of the seven investigated Israeli concrete aggregate quarries are very reactive and may be dangerous in an uncontrolled use. The two highly-reactive investigated aggregates are: a siliceous limestone from "Ein Harod", and a mixture of stones from the "Zeelim" river basin. Both aggregates correspond to the requirements for the Israeli "concrete code" and to the Israeli standard specifications for mineral aggregates etc. Ensuring the durability and the security of Israeli building structures is conditional upon the continuation of AAR studies.

1. GENERALITIES ON THE AAR

AAR is a reaction, occurring between alkali hydroxide present in the pore solution of concrete, and certain aggregates containing reactive components in catalyzing environmental conditions. The reaction, having a very complex mechanism, produces expansive gels (hydrated alkali-silica, magnesium hydroxide etc.) which can cause expansion and cracking of concrete structures, with the consequent damage ranging from superficial in mild cases to loss of structural integrity in severe cases. The cracking of structures due to AAR enhances other concrete deterioration processes due to exposure of the interior of the concrete or of the reinforcement to aggressive agents in the environment. Depending on the AAR type, the time after construction for evident cracking of concrete can be up to 5, 10 or 20 years [1-4]. The global destructive effect on the concrete durability is generally a function of the combination of different possible deleterious environmental, physical, technological and chemical under-effects. If it exists, eventual AAR harmful effects may be amplified by many other factors such as the earthquakes, the defective design or construction, the effects of the hot and dry climate, drying and wetting cycles, the effects of the "classical" types of concrete corrosion (by sea water, by chloride penetration, by sulfates, by acids, by magnesium or by ammonium salts etc.)

2. AAR IS A PROBLEM THROUGHOUT THE WORLD, INCLUDING ISRAEL

The misconception until twenty years ago, that AAR is limited to certain regions of the world (e.g. USA, Canada and Denmark) and that others are free of it, starts to be more and more confuted [4]. The assertion that "Israeli aggregates do not have dangerous species attacked by AAR" [5] are

refuted by our AAR studies on Israeli aggregates [6-11]. However, in the 1980s many countries (most European countries, Japan, China [as in 12-18]) discovered concrete structures suffering from AAR, which proved that AAR occurs in many geographical locations. In a recent paper dealing with new chemical admixtures (lithium compounds) which “calms reactive aggregates”, is said that “pavement engineers now have a potent new weapon against ASR which increasingly is being recognized as a major threat to Portland cement concrete pavements and structures”, that the reactivity “is something of a ticking time bomb in pavements” or “the AIDS” of concrete...[19]. The interest in the AAR engineering problems arose significantly in recent years in Germany (especially in Niedersachsen) and in Switzerland, [20,21]. An AAR Swiss standard, based on French test methods [22] was also adopted by the European and world standards organization [23].

3. THE AAR IS RELATIVELY NEWS

The questions concerning the AAR and its most well-known types, i.e. the alkali-silica reaction (ASR) and the alkali-carbonate reaction (ACR), as there are pointed in different standards [3, 22-27], represent a relatively new chapter in the cement & concrete science and in the field of the engineering concerns with assuring the durability of concrete structures: the first reports concerning the destructive effects of AAR were published in 1940, that is 115-150 years after the “invention” of the Portland Cement and after the report of Vicat explaining the concrete destruction mechanism of the of the harbor of Alger[1]. The interest in AAR problems arose more and more in the last 25 years. Since the mid-1970s, 11 international conferences on AAR were held throughout the world, the 10th being held in Melbourne, in August 1996 (where a paper was published on the first Israeli AAR investigations [9]). The last 11th conference on AAR was held in Quebec City (Canada) in June 2000.

4. ISRAELI SPECIFIC AAR PROBLEMS

- According to ASTM and to other specifications (Canadian, European, Japan), from a geochemical point of view, an important part of the available Israeli natural aggregates are suspected to be alkali reactive, until the contrary will be proven experimentally.
- The presence of alkalis in the concrete can be due to their presence in the clinker, in the mineral admixtures, in the water (mixing or/and environmental) or in the aggregates themselves.
- The Israeli standard specifications for aggregates (IS-3) for Portland-cement (IS-1), the Concrete Code (IS-466) or other standards do not dwell on AAR problems, the possibility of there being deleterious alkali-reactive aggregates nor do they limit the maximum amount of alkalis in the cement or in the concrete.
- The cement users are generally unaware of AAR and its possible effects on the durability of the concrete structures, as was the case in the last 15 years in Belgium [16], in the United Kingdom [14] in Japan [24] and in other countries where awareness on AAR arose. The authors of this report contend that AAR research is important in Israel since various concrete aggregates may be suspected of different types of potential reactivity (alkali-silica, alkali-carbonate etc.).
- Excepting our studies, Israel is one of the last of the world's developed countries where the building engineers ignore generally the AAR in concrete problem and the associated structural durability problems. They are applying ostrich politics, i.e., they are putting their head in the sand to not see eventual dangers.
- There are an abundance of published examples of destroyed structures due to the AAR, examples coming from an array of the world's developed countries [18]. However, there are no published examples from Israel; even the published pathology studies on destroyed structures, performed generally by the National Building Research Institute (Technion-Haifa), do not take into account the possible harmful effect of AAR. To the best of our knowledge the authors of this report consider then, until the contrary is proved experimentally [28-30], that AAR effects could explain the degradation processes in important Israeli concrete structures, for example

structures in contact with the Mediterranean Sea (harbors, retaining walls, supporting pillars for the coal supply bridge in Hedera power-stations) or drainage tubs under the highway Bersheva-Dimona.

- The most significant result of our first experimental studies on AAR in Israel [6-11, 27]: two of the seven Israeli concrete aggregate quarries investigated to date (the siliceous limestone from Ein Harod and the mixture of stones of the Zeelim river basin) are very reactive and may be dangerous in uncontrolled use.

5. THE AAR INVESTIGATIONS ON SEVEN ISRAELI AGGREGATE QUARRIES

The AAR investigations were performed on the following seven Israeli concrete aggregate quarries: 1) & 2) Sheffar-Am and Hanaton, both placed at some 40 km. NW of Nazareth; 3) Ein-Harod, placed at some 40 km SE of Nazareth; 4) Modiin, placed at some 60 km SE of Tel-Aviv; 5) Har-Deragot, placed at some 50 Km SE of Beersheba; 6) Zeelim, placed at some 40 Km SW of Beersheba; 7) Ashdod harbor placed at some 60 km SW of Tel-Aviv. Table 1 gives a synopsis of the investigations.

Table 1. Synopsis of the AAR investigations

No	Name	Grading	Description	AAR results	References
1	Sheffar-Am	3 coarse and 1 fine aggregate fractions	Calcite-dolomite	Non-reactive	6, 7, 9, 10
2	Hanaton	As in 1/1	As in 1/1	Non-reactive	27
3	Ein-Harod	As in 1/1	Limestone with some 4% amorphous silica	Highly-reactive	6-11, 27
4	Modiin	As in 1/1	10-20% limestone, 80-90% dolomite	Non-reactive ¹	27
5	Har-Deragot	As in 1/1	14-22% limestone 76-86% dolomite	Non-reactive	57
6	Zeelim	As in 1/1	Stones mixture from Zeelim river basin ²	Highly-reactive	6-11, 27
7	Ashdod	Sea-sand	Quartzes	Non-reactive ³	7, 27

The following should be noted:

- The tested calcite dolomites (1, 2, 4, 5) and the quartz sea sands (7) did not show alkali-aggregate reactivity.
- For the complex mixture of stones, from a south Israeli river basin quarry (No 6, Zeelim) containing various types and proportions of amorphous SiO₂ and carbonates, the alkali reactivity reactivity was expected according to its composition and when tested in accordance with some different classical methods [6-11].
- An experimental surprise represents a limestone containing ~4% SiO₂, supplied from a quarry situated in the north of Israel (Ein Harod). The expansion kinetics of the concrete prisms showed “a late expanding alkali-silicate/silica reaction” and the same aggregate did not show reactivity according its chemical composition and when tested according to different former classical methods [6-11].

¹ It is necessary to repeat the performed tests due to the heterogeneity of the quarry, to its importance (the largest Israeli rock quarry) and to the unusual stoichiometry of the aggregate

² Containing a) amorphous SiO₂ minerals and rocks (tzor), with or without chalk or limestone inclusions;

b) Carbonate minerals and rocks (chalk, limestone, dolomite, dolomite limestone) with or without SiO₂ inclusions etc.

³ Water washing before use may be necessary to avoid the enrichment of alkalis in the concrete

All seven aggregates meet the requirements of the Israeli “concrete code” and the Israeli standard specifications for mineral aggregates etc. Further discussions relate to the two aggregates, which might be dangerous in an uncontrolled use (Ein Harod and Zeelim).

6. EXPERIMENTAL PROCEDURES

6.1 The 24-hour ASTM C289 chemical test with an altered graph (examples in [2, 9, 10, 26d])

The immersion of a graded aggregate sample in 1N NaOH solution for 24 hours at 80°C is followed by chemical analysis of the filtered solution for dissolved silica (Sc) and for reduction of alkalinity (Rc). The results are plotted on a graph showing four regions of aggregates: (A) “innocuous”; (B) “generally non-reactive”, but in this field the interference of carbonates in the reaction between SiO₂ and NaOH lead to inconclusive results requiring long-term mortar bar or concrete prism expansion testing; (C) “highly reactive, potentially deleterious”, but if the pessimum (worst) percentage of reactive silica is exceeded, the mortar bars might display insignificant expansions; (D) “deleterious reactive”. The original ASTM C-289 graph comprises only three regions the (A+B) region being considered innocuous. The ASTM chemical test was excluded from the last CAN/CSA. An alternative method consists of performing the ASTM procedure on the insoluble residue obtained by dissolution of the carbonates in concentrated hydrochloric acid [31, 32] and by a new French chemical method [22 f].

6.2 The 2-3 week NBRI⁴ mortar bar test [3e, 26g]

Mortar bars, 25x25x285-mm [26c] are maintained at 80°C, one day in water up to the zero reading (after 24 hours) and afterward in 1N NaOH solution. The following mortar bar expansion limits are suggested [32]: at 14 days <0.10% for innocuous aggregates and ≥ 0.15% for deleterious aggregates. Shayan et al [35] suggested that: (i) mortar bar expansion of 0.10% in 10 days and 0.10% in 22 days to be taken as indicating reactive aggregate of short induction period and long induction period, respectively.

6.3 The long-term mortar bar test. [3a, 26d]

The reactivity limits are 0.05% at 3 months or 0.1% at 6 months or more, for mortar bars with high alkali content (1.25% Na₂O equivalent relative to the cement weight or 7.5 kg Na₂O equivalent per 1m³ of mortar) maintained at 38°C, in wet air. According to [3b, 33] the absorbent material used in the containers might cause diminished expansions due to the alkali-leaching of the mortar bars. The test is not included in the 1994 edition of CSA Standard. It is to consider an alternative method, which would replace the bars with mortar prisms 40 by 40 by 160 mm according to the European and to the Japanese experience [4, 12, 24, 22c].

6.4 The long term concrete prism expansion methods

Two versions (ACR and AS/SR) of the CSA A23.2-14A-M90 and the French Standard NF P18-587 were applied [3c, 22d]. Each 1990 version of the CSA was intended to test concrete aggregate suspected to suffer from alkali carbonate reaction (ACR) or Alkali Silicate/Silica Reaction (AS/SR). The main difference between the two 1990 versions is the storage temperature of the specimens in moist air, being 23°C for ACR and 38°C for AS/SR. The 1990 CSA was replaced in June 1994 with a new CSA A23.2-14A-M94 [3a, 3b, 3c, 3d]. The main modifications are: (i) the cement content increased from 310 to 420 kg/m³ and an alkali content of 1.25 %Na₂O equivalent (eq.) by mass of cement, resulting in an increase of the alkali content in concrete from 3.90 to 5.25 kg. Na₂O eq./m³; (i, i) a 38°C storage temperature in moist air is required for all the specimens, independent of the AAR type. The French standard looks like the 1994 CSA, with cement content of 410 kg/m³, corresponding to 5.13 kg Na₂O eq./m³ of concrete. *ACR expansions are considered deleterious*: depending on the micro-climate to which the structure is to be exposed, if the length change

⁴ South-African National Building Research Institute

exceeds 0.010% after 3 months or 0.025-0.040% after 12 months (former CSA); independent of the micro-climate, if the length change exceeds 0.015% after 3 months or 0.025% after 6 months or 0.030% after 12 months (ASTM C1105 [26f]). AS/SR expansions were considered deleterious by the 1990 CSA, depending on the microclimate to which the structure is to be exposed, if the length change exceeds 0.040-0.075% after 12 months. The 1994 CSA considers that expansions are deleterious, independent of the AAR type, if the length change exceeds 0.040% after 12 months, noting that “in critical structures such as those used for nuclear containment or large dams, a lower expansion limit may be required” (CAN/CSA A23.1-94. Appendix B, [3b]). The French test conditions [22d] are stricter than the Canadian. To the best of our knowledge there are no French standard limits for critical AAR expansions, a 0.040% limit at 8 months seems to be accepted by scientists to indicate reactivity but it is still being discussed [12]. However it seems that the interpretation of the French test results is covered by the Canadian standard limits. Significant AAR compositions for mortar and concrete test prisms are to be prepared taking into account the experimentally found worst (“pessimum”) content of the reactive particles [12, 22 f].

6.5 Measuring the fracture energy of AAR affected concrete [11]

The influence of AAR on the fracture mechanical behavior deterioration of the concrete was determined using the wedge splitting method, elaborated and patented by K.K.Tschegg [34]. Cubic shaped concrete specimens used for the wedge splitting tests were obtained by cutting from a long time processed experimental product: a lot of two years and more old AAR concrete prisms, coming from a former laboratory study investigating the alkali reactivity of different concrete aggregate by different standard methods including a long-term concrete prism expansion method. The influence of different concrete mixes and storage conditions on AAR-induced fracture energy loss is studied on six experimental variants (concrete mix vs. storage temperature), including four concrete mixes. Each concrete mix is characterized by the aggregate, by the cement content and by the alkali content. [10-11]). The used wedge-splitting method is explained in detail in [34].

6.6 The quick 2-3 day mortar bar autoclave method [26b, 32]

The AAR process could be accelerated by an ASTM 151 treatment of mortar bars enriched in alkalis by addition of NaOH in the mixing water up to 3.5% Na₂O equivalent relative to the cement weight. The expansion is measured after 5 hours of steam curing at 1.72 Mpa (130°C). An expansion limit to define a deleterious reactivity is still in discussion.

7. AAR ANALOGOUS RESULTS ON BOTH EIN HAROD AND ZEELIM AGGREGATES

For both aggregates, the AAR studies by the 24 hour chemical method are not conclusive. On the graph the range of the tested samples is plotted on the doubtful zone B, due probably to the presence of carbonates interfering with the reaction between NaOH and the dissolved silica. In order to clarify if the tested aggregate is reactive, ASTM C33 [26a] requires long time tests. The mortar bar tests ASTM C 227 [26c] do not show reactivity. After two years the average expansion is small (up to 0.013%), less than the reactivity limits. The chemical composition and/or the petrography of the aggregate are only partially conclusive. The high reactivity of the aggregates is shown by: a) the 2-3 week NBRI mortar bar method; b) the 2-3 days mortar bar autoclave method; c) the long term concrete prism expansion method; d) the wedge splitting method to test the specific fracture energy of AAR affected concrete [11].

8. AAR RESULTS ON THE EIN HAROD CONCRETE AGGREGATES

This aggregate was known as a “pure limestone” and we considered it as a comparative blank (non alkali - reactive) sample. Considerations based on the chemical analysis corroborate the assumption of non-reactivity. The different grain sizes of the aggregate were analyzed by induction-coupled plasma. The chemical analysis corroborates the assumption of non alkali-silica reactivity since it

contains less than 5% SiO₂ insoluble residue in HCl [32]. The analysis also corroborates the assumption of non alkali-carbonate reactivity (ACR) according to a new CSA test [3f], consisting of plotting on a graph, the CaO/MgO ratio as function of the Al₂O₃ content. For a CaO/MgO ratio ≥ 24 and for a content of $\leq 0.19\%$ Al₂O₃, the sample is placed on the non-ACR zone of the graph.

The limestone sample was studied by several AAR methods which led to inconclusive results but the non-reactivity assumption was finally refuted when our investigations comprised simultaneously: (1) high alkali containing concrete specimens, stored in warm and humid air; (2) late ages (11 months and more) measurements; (3) testing by the AS/SR version of the 1990 Canadian or French concrete prism expansion method [3c, 22d].

8.1 The long term testing on concrete prisms (expansion and fracture mechanical parameters)

The results are given in Table 2. For the last variant (F), Figure 1 represents the expansion kinetics for each of the three F type studied specimens (noted #151, #152, #153 [9-11]). Figure 2(b) represents the load-displacement curves for the same specimens [11]. Figure 2(a) represents the load-displacement curves for AAR affected (F) and unaffected (A) specimens.

Table 2. Long term expansion and fracture mechanical testing on concrete prisms

Experimental variant	A	E	C	F
Cement content in concrete, kg/m ³	310	310	410	410
Water-cement ratio (W/C) ⁵	0.63	0.62	0.52	0.52
Additions of NaOH in the mixing water	No	Yes	Yes	Yes
Alkalis relative to the cement, % ⁶	0.47	1.25	1.25	1.25
Alkalis relative to the concrete kg/m ³	1.46	3.90	5.13	5.13
Storage temperature in air of 100% R.C, °C	22	38	22	38
Average 2 years length change ϵ , % ⁷	-0.005	0.011	0.002	0.188
Specific fracture energy, G _F (N/m)	152	98	125	114
Coefficient of variation C _V (%)	10	7	11	6
Horizontal force component causing the fracture F _{Hmax} (N)	2010	1470	1790	1460
Nominal notch tensile strength σ (N/mm ²)	4.56	3.54	4.00	3.28
Coefficient of variation C _V (%)	8	7	8	11

8.2 AAR studies by the 2-3 weeks accelerated mortar bar test

In a first test, after 14 days of storage at 80°C in 1N NaOH solution, an average expansion of 0.08% was recorded, showing no alkali reactivity for the tested aggregate. In a second, more accurate and longer test, with the Australian improvements, the recorded expansions (Table 3) characterize the Ein Harod quarry as giving aggregates of long AAR induction period [10].

8.3 Studies by the quick, 2-3 day mortar bar autoclave method

Conclusive and reproducible results were recorded (Table 3, [8,10]).

⁵ The amount of water (with optional addition of NaOH) should correspond to an 80 mm fresh concrete "slump" however the fresh concrete with 310 kg cement/m³ (mix 1 & 2) was "no slump" since a small increase of the water/cement ratio causes the fall of the concrete cone, immediately after the mold removal. For a cement content of 410 kg/m³, (mix 3 & 4) the desired slump was easily obtained

⁶ The total alkali content, as Na₂O_{eqv}, from cement and from mixing water

⁷ Negative (-) values represent shrinkage

Figure 1. Expansion kinetics for each of the three F type studied specimens (noted #151, #152, #153) are shown as dotted lines and are compared with solid lines “VR” and “MARG” representing the Canadian “characteristic expansion curves for concrete prisms made with the greywacke-slow/late-expanding alkali-silicate/silica reactive aggregates” compiled from page 100 of the former CSA A23.1. App B-90. The time is plotted on a square cubic root. [3a, 10].

Figure 2. Load-displacement curves for AAR affected and unaffected concrete specimens and for three F type AAR affected specimens [11, 34].

Table 3. a) Results by the accelerated (2-3 week) improved “NBRI” method;
b) Results by the quick (2-3 day) autoclave method

Name of the required parameter	Number of specimen	Mean expansion	Standard deviation	Coeff. of variation
a) Preliminary (physical) expansion (%) after 1 day immersion in water at 80°C	6	0.047	0.0056	12
a) Expansion in %, after immersion in NaOH,				
- 1 day				
- 5 days	5	0.004	0.0017	56
- 7 days	5	0.013	0.0078	60
-10 days	5	0.034	0.0149	44
-14 days	5	0.100	0.0190	19
-21 days	5	0.151	0.0240	16
	6	0.180	0.0300	17
b) Expansion in % after 5 hours of steam curing in the autoclave at 1,72 MPa (130°C),	6	0.059	0.008	14
	5	0.063	0.005	8

9. AAR RESULTS ON THE AGGREGATES FROM THE ZEELIM RIVER BASIN

The petrography is described in footnote 2, page 3. The high content of amorphous silica particles corroborates the assumption of alkali-silica reactivity. The results on the long term testing on concrete prisms (expansion and fracture energy parameters) are given in Table 4.

AAR studies by the 2-3 week NBRI accelerated mortar bar test with Australian improvements. The results (Table 5) show that the mixture of stones from the Zeelim river basin is an aggregate of an AAR short induction period. Studies by the quick, 2-3 day mortar bar autoclave method. Good reproducible results are given in Table 5.

Table 4. Long term expansion and fracture mechanical testing on concrete prisms

Experimental variant	I	J
Cement content in concrete (kg/m ³)	410	410
Water-cement ratio (W/C) ⁸	0.49	0.49
Presence of NaOH in the mixing water	Yes	Yes
Alkalis relative to the cement (%), ⁹	1.25	1.25
Alkalis relative to the concrete, kg/m ³	5.13	5.13
Storage temperature in 100% R.H. air (°C)	20	38
Average 2 years length change ϵ (%) ¹⁰	-0.002	0.037
Specific fracture energy, G_F (N/m)	149	130
Coefficient of variation C_V (%)	8	10
Horizontal force component causing the fracture F_{Hmax} (N)	2200	1390
Nominal notch tensile strength σ (N/mm ²)	5.03	3.28
Coefficient of variation C_V (%)	9	12

Table 5. a) Accelerated (2-3 weeks) improved“NBRI” method;
b) Quick (2-3 days) autoclave method

Name of the required parameter	Number of specimens	Mean expansion	Standard deviation	Coef. of variation
a) Preliminary (physical) expansion (%)after 1 day immersion in pure water at 80°C	6	0.044	0.0042	10
a) Expansion in %, after immersion in NaOH,				
- 1 day	6	0.003	-	-
- 5 days	6	0.041	0.0038	9
- 7 days	6	0.076	0.0026	3
-10 days	6	0.128	0.0024	2
-14 days	6	0.177	0.0029	1
-21 days	6	0.226	0.0099	4
b) Expansion in % after 5 hours of steam curing in the autoclave at 1,72 Mpa (130°C),	6	0.104	0.0043	4

⁸ See footnote 5, page 6

⁹ See footnote 6, page 6

¹⁰ See footnote 7, page 6

The studies performed lead to the following conclusions:

- There is a good correlation between the results based on rapid methods and between the results based on long term (2 years and more) concrete prism expansion method [6-11].
- The expansion measurements are less significant than the mechanical parameters (G_F , F_{Hmax} and σ) to quantify the AAR damage: only the specimens F and J expand significantly, for the variants A, C, E and I the length changes are insignificant and within the error of measurement [11].
- As in the case of the concrete corrosion involved by the sulfate expansion, it is never possible to find a biunivocity relation between the apparent expansion and the reduction of the strength parameters [11,36].
- We succeeded in assimilating the following rapid methods to predict the AAR behavior of slow reacting and of carbonate containing aggregates, by specifying after a few days or weeks if an aggregate is or is not potentially reactive: a) the 2-3 weeks NBRI mortar bar expansion method with Australian improvements by immersion of mortar bars in 1N NaOH solutions at 80°C; b) *the 2-3 day mortar bar autoclave methods* based on an autoclave treatment, according to ASTM C151 of mortar bars enriched in alkalis by addition of NaOH in the mixing water by up to 3.5% Na₂O equivalent, relative to the cement weight.
- The Australian improvements to the NBRI method [35] lead to a better interpretation of the results. The limestone containing ~4% SiO₂ from Ein-Harod is a “reactive aggregate of long induction period”; the aggregate from the Zeelim river basin, containing SiO₂ and carbonates is a “reactive aggregate of short induction period”. It is a good opportunity to promote an Israeli standard for the accelerated 2-3 week AAR mortar bar test (“the NBRI method”). In comparison with other classical AAR methods, the laboratory model of the NBRI method represents a better simulation of the AAR relative to marine harbor specific conditions.
- A further carrying on of the AAR studies is very timely: a) in view of the destruction of the Wedding Hall “Versaille”, built a short time ago, using the “PAL-KAL method”, it is necessary to consider other possible failures of structures such as AAR; b) to reduce the risk of seismic actions on structures suffering from earlier AAR processes.
- It is strongly necessary to draft a first Israeli standard on AAR in concrete, in order to avoid its possible harmful effects on the durability of concrete structures.

CURRICULUM VITAE

DATE/PLACE OF BIRTH: 20/12/1929, (Galatz City, Romania)

MARITAL STATUS: Married, with a son and a daughter

EDUCATION:

1972 Ph.D in engineering (“Doctor-inginer”), Chair of Chemistry and Building Materials, Institute for Civil Engineering, Bucharest, Romania.

1953 MSc in Technological Engineering for Applied Material Science, Diploma with distinction, Institute for Civil Engineering, (“MISI”) Moscow, USSR.

1948 Theoretical baccalaureate diploma at the National College “Mihai Viteazul”, Bucharest, Romania. Classified the 6th among 94 candidates passing the baccalaureate.

LANGUAGES: Very good: Romanian, French and Russian.
Good: Hebrew, English, German

EXPERIENCE

From 1989 'til now  Hebrew University of Jerusalem, Israel. Staff member of the University and Senior Research Engineer in a team headed by Prof. Michael Schieber. Project items: (1) High Temperature Crystal Growth from Solution (1989-1994); (2) Hydrophobic Admixtures and Hydrophobic Portland Cements (from 1995) (3) Alkali-Aggregate Reaction (AAR) in Concrete, under specific Israeli conditions (from 1992).

1988 Nesher Cement Enterprises, Ramla, Israel: Quality tests of cement and concrete.

1953-1986 In Romania: (1) Management in different cement or concrete plants; (2) Design of new plants or improvement of different working cement plants (3) Founder and head of a research team, dealing with the choosing and testing, especially for large dams, of materials concrete is made of, that is cements, aggregates and admixtures. (4) Investigation of the impact of environmental conditions on different structures with different technical requirements. Specific potential

 Part-time work since 1995

corrosion processes were tested and recommendations for measures to assure the durability of complex concrete structures were issued. There are in view large gravity (on Bicaz and Bistritza rivers) high and sophisticated arched dams (On Arges and on Dragan Rivers), locks, galleries, power stations like the ones on the Romanian inner rivers and on the Danube. (5) Drawing up of Romanian Standards (STAS) concerning: a) requirements and testing methods for different types of cement and concrete; b) evaluation of water and environmental aggressiveness against concrete; c) evaluation and improvement of the concrete structure durability against thermal stresses, sulfate corrosion, alkali-aggregate reaction in concrete etc; d) Test methods to evaluate the sulfate resistance of cements, the alkali reactivity of the concrete aggregates etc (6) Laboratory, pilot and industrial investigations to optimise the manufacture of special Portland cements in different plants.

PUBLICATIONS ITEMS²

- *Manufacture, use and properties of cements*: A didactic book and 5 papers
- *Concrete durability, corrosion processes and water aggressiveness*: 5 papers

ABSTRACT

A series of blended cements based on Low-Energy Cements (two sulfoaluminate belite cements, SAB, synthesised in laboratory and high belite Portland cement fired in industrial conditions) and ordinary Portland cements were investigated. Although the hydration of both cement types leads to the same hydrated products, the kinetics of hydration as well as the mechanical and physical properties fundamentally differ due to differences in mineralogical and chemical composition. While SAB are fast setting cements (set point within 30 min.) their hydration courses have been retarded by blending with OPC giving setting times of 60-80 minutes. Hydration kinetics were modified by adding Portland cement with high content of C₂S. The blending of OPC with SAB was optimised in order to get normalised setting time and to fulfil the condition of passivation of steel in mortar. The mechanical strength of cements, pore-structure, absorption capacity and dynamic modulus of elasticity are described.

1. INTRODUCTION

Sulfoaluminate belite cements (shorthand, SAB) form a group of cements belonging to the class of Low-Energy Cements (LEC) [1]. The production of SAB cements not only requires lower clinkerisation temperatures 1 200 - 1 300°C in comparison to OPC, but can be made from raw meals containing natural minerals and industrial by-products such as fly ash, red mud and blast - furnace slag [2,3].

The cement industry is an industry with a high demand for energy, thermal as well as electrical. Many investigations have been carried out to decrease this demand and consequently reduce CO₂ emission. One of the primary ideas in a development of LEC [4-6] was to reduce the CaCO₃ content of the raw meal, thereby decreasing part of the energy necessary for the decomposition of calcite. The decrease in CaCO₃ leads further to decreases in the content of the “high energy” mineral - C₃S⁺; - ultimately to its complete absence. Cements based on C₄A₃ \bar{S} are developed and studied [7]. The hydration reaction of C₄A₃ \bar{S} with C \bar{S} leads to the formation of ettringite in the earlier period, while dicalcium silicate, hydrates in the last period to form calcium silicate hydrates as with OPC [10].

In spite of the excellent experimental results obtained throughout laboratories and the numerous manifest advantages of large scale production [2,8,9], with the exception of Chinese and some UK plants, is not until now widely used and some doubts remain regarding its use as a masonry material in civil engineering[8].

⁺/ C = CaO, S = SiO₂, A = Al₂O₃, F=Fe₂O₃, \bar{S} = SO₃;

2. EXPERIMENTAL

Three kinds of Low-Energy Cements were prepared

1. Two SAB cements which are C_3S - free, but have about 20% by wt $C_4A_3\bar{S}$; other phases are C_2S , C_4AF and $C\bar{S}$.
2. High belite Portland cement which is free from $C_4A_3\bar{S}$, but contains active belite clinker with a reduced content of C_3S .

The high belite Portland cement (HBC) has been burnt from natural raw materials (limestone, burnt clay, pyrite, sand) by the dry process at 1260°C . The reduction of clinkering temperature and the total amount of calcite have led to the energy saving of 400 kJ/kg compared with production of OPC (also used in this experiment, CEM I 42,5) in the same plant. The clinkers thus obtained were ground in an industrial closed mill circuit with 3% gypsum.

2.1 Materials, mixing and curing

Ordinary Portland cement (CEM I 42.5), two samples of SAB cements, HBC and standard sand were used [11]. Then two mixes were prepared from OPC and SAB cements in weight proportion of 15 and 85 % (B1 and B2). Two mixes from HBC and SAB cements were also prepared in ratios of 30 : 70 % by weight (B3 and B4). Chemical and mineralogical composition of cements and blended cements B1 (85 % OPC + 15 % SAB1), B2(85 % OPC + 15 % SAB1), B3(70 % HBC + 30 % SAB1) and B4(70 % HBC + 30 % SAB2) are listed in Table 2 and their physical properties in Table 3. Mechanical properties at 28- and 90-days are reported in Table 4. Phase composition of the B1, B2, B3, B4 blended cements are derived by the linear interpolation to achieve mixing ratios /15 % OPC + 85 % SAB and 70 % HBC + 30 % SAB/.

Mortars with cement to sand ratio of 1 : 3 by weight and $w/c = 0.5$ were prepared as prism specimens 40 x 40 x 160 mm made in steel moulds on a vibration table (50 Hz, 0.35 mm) with a maximum vibration time of 30 seconds. The specimens were stored at 20°C and 100 % R.H. for 28 and 90 days.

The rate of hydration was measured by using conduction calorimeter. The equipment is coupled to a computer for continuous monitoring of the rate of heat generation.

Table 1. Formulation of samples

	OPC	HBC	SAB1	SAB2
	100	100	100	100
B1	15		85	
B2	15			85
B3		30	70	
B4		30		70

C _{free}	0.10	0.27	0.00	0.18	0.01	0.17	0.08	0.08

2.2 Test methods

Mortar specimens were tested on flexural and compressive strength, dynamic modulus of elasticity (DME).

Ultrasonic pulse velocities were measured on ultrasonic apparatus UNIPAN type 543 . The DME values were calculated by equation (1):

$$E_{bu} = \rho \cdot v_L^2 \cdot \frac{1}{k^2} \cdot 10^{-6} \quad (1)$$

where E_{bu} = dynamic modulus of elasticity, MPa

ρ = volume density of mortar specimens, kg . m⁻³

v_L = impulse speed of longitudinal ultrasonic waves, m . s⁻¹

k = dimensional coefficient for 40 x 40 x 160 mm prisms

For the DME calculations, three - dimensional environment in mortar specimens and Poisson coefficient $\gamma_{bu} = 0.20$ were considered according to STN-EU [12] and $k = 1.0541$ was determined.

3. RESULTS AND DISCUSSION

Blending ratios of OPC / HBC and SAB1/SAB2 had previously been optimised to the value of 15 to 85, or 70 to 30, in wt. Proportions. These were used in a series of many combinations with regard to the initial setting time as well as to maximum quantity of SAB1 and SAB2 to retain passivation of steel in mortar.

The hydration kinetics of HBC, OPC and blends (B1, B2, B3, B4) are summarised in Figures 1a-g. The evolution curves of HBC and OPC are shown in Figure 1-a. Apart from the quite initial period of hydration, little difference is observed between samples.

After a small initial peak, observed when water first comes into contact with the cement, HBC shows a slow rate of heat evolution. SAB1 does not show a second peak and is characterised by the absence of an induction period, while SAB2 shows the higher initial and second peaks with a small induction period in between.

The blended samples show important changes in the heat-evolution curves. The second peak appears (Figure 1-d and Figure 1-e) and in the case of B3 (Figure 1-f) also a little third one. The initial setting time values, in Table 3, clearly prove the change in hydration process. It is not easy to determine the initial and final setting time from calorimetric curves, although no doubt exists on the influence of the rate of the heat-evolution (as determined by the calorimeter) upon the whole process of setting and hardening. While in OPC, this process is governed by C_3S hydration, in SAB cements, it is driven by hydration reaction of $C_4A_3\bar{S}$ and $C\bar{S}$ leading to the formation of ettringite. It is why the SAB cements are often fast-setting. Indeed, cement mortar is a multi-phase assemblage composed of sand, unreacted minerals, hydrated products and voids filled by water and air. If we consider that after setting time, cement grains are enclosed by primary products formed during the initial period of hydration, and that the hydration reaction without induction period characterises fast setting process, it is expected that after long period of curing the coarse pores will remain in cement matrices, and thus, will influence their mechanical and physical properties.

Table 3. Physical properties of cements

	Specific surface [m ² /kg]	Normal consistency [%]	Setting time, Pastes	
			Initial [min.]	Final [min.]

B3	325	28	80	110
B4	310	28	80	110

Water demand is related to the mineralogical composition of given samples. Sulfoaluminate belite cement with $C_4A_3\bar{S}$ as one of mineral clinker uses more in the formation of ettringite in initial period of hydration. SAB cements are fast-setting cements within 30 minutes. By blending with OPC or HBC hydration, reactions are retarded to ensure workability of concrete.

Table 4. Mechanical properties of cements and blends in concrete

	DME [Gpa]		Flexural strength [MPa]		Compressive strength [MPa]	
	28 days	90 days	28 days	90 days	28 days	90 days
OPC	41.7	43.00	8.7	10.30	42.80	48.30
HBC	38.80	45.70	9.4	10.6	41.5	53.9
SAB1	26.4	31.40	5.60	7.30	17.4	30.10
SAB2	28.40	33.60	6.70	9.37	20.40	38.70
B1	31.90	36.20	6.90	8.40	24.60	41.30
B2	30.50	40.20	8.00	9.20	32.60	44.80
B3	32.00	37.40	6.30	8.10	28.60	48.20
B4	33.20	42.40	10.4	11.3	46.5	58.1

Both SAB cements were clinkered of 1 250°C, which is markedly lower than those reported for Chinese and British cements which are manufactured at 1 300 - 1 350°C and 1 400°C respectively. Perhaps for this reason the strength characteristics and utility properties of SAB-1 and SAB-2 cements are lower than those of the Chinese and British products. Energy saving and reduction in

CO₂ emissions of SAB-1 and SAB-2 cement production are expected to be significantly improved relative to cements fired at temperatures between 1 300 -1 400°C.

The flexural and compressive strengths of mortars are considerably influenced by curing conditions and type of cement (Table 4).

4. CONCLUSIONS

An attempt has been undertaken to investigate the possibilities of use of sulfoaluminate belite cements:

1. It is possible by blending SAB cement with Portland cement to upgrade SAB cement properties.
2. Initial set times are at least 60 minutes. This is sufficient time for mortar-making procedures.
3. The mortars made with the above blend indicate increased strength as well as dynamic modulus of elasticity compared to SAB cement mortar.
4. Mechanical and physical properties depend on the type of SAB added to HBC. The results thus obtained show that such type of cement or its blended forms can be used successfully in the replacement of OPC.

THERMOANALYSIS STUDY OF HARDENING PROCEDURE OF CLAY-HARDENING GROUT (CHG)*

Wang, Xinghua

Institute of Tunnel and Underground Engineering, Central South University at Tiedao Campus,
Changsha, Hunan, P.R.China, 410075.

ABSTRACT

As a new cheap grouting material, Clay-hardening grout (CHG) is getting close attention. But it is necessary to carefully study what hardening reaction is taking place and what compounds are produced during the hardening procedure of CHG. In this paper thermoanalysis (differential thermal analysis, DTA) has been used to study the chemical composition of resulting compounds of CHG during the hardening process. In accordance with the study results, a new model of hardening mechanism of CHG has been put forward.

Keywords: Clay-hardening Grout (CHG), Hardening Model, Hardening Mechanism, DTA.

1. INTRODUCTION

When adding cement and solidifying agent into clay-hardening grout, chemical reactions commence within the grout. As time passes, these chemical reactions continue to enable the grout getting hard till it has eventually hardened into stone. But what hardening reactions are taking place? What compounds should be produced during the hardening process of CHG? What is the hardening mechanism? All these questions puzzle us and require further careful study.

Various methods are used to study mineral components. Among them, chemical analysis, gas chromatography, mass spectrographic analysis, thermoanalysis and electron micro-identification are in common use. Since it is very difficult to purify materials like clay and silicate because of their complicated compositions, thermoanalysis and electron microidentification are usually used to analyze and identify the composition and microstructure of clay and silicate minerals. In this paper, thermoanalysis (differential thermal analysis, DTA) has been used to study the chemical composition of compounds of CHG during the hardening procedure. In accordance with the study results, a new model of the hardening mechanism of CHG has been put forward.

2. TEST MATERIALS AND PREPARATION OF CHG^[1,2]

2.1 Test materials

The clay used in this work is the clay block produced by Sichuan Minshan Mineral. With rather small clay particle size (average size of 10.1 μ m of the particle weighted 50%) and specific surface area of 6103.9cm²/g, the clay consists mainly of kaolin, smectite, oligosite, halloysite, illite, etc. The cement used is the standard silicate cement 425# produced by Sichuan Ermei Cement Plant. The self-prepared CHG Solidify B (Chinese Patent No.96117823.X) consists of some inorganic salts with main composition of 30-50%aluminate, 5-20% sulphate, 5-15% silicate, 1-10% silicon oxide, 1-10% calcium oxide, etc.

2.2 Preparation of CHG sample

The preparation procedure of CHG is as follows: first add cement into clay mud, then add Solidify B and finally solidify A (water glass). Stir the clay hardening grout with different mix proportion and make standard CHG sample and then start the thermoanalysis tests at different ages while maintain test specimens in water. Before the thermoanalysis test, the hydration of CHG samples was terminated by and heating and then grinded till it fully passed through the 4900 sieve. Japan-made Rigaku PTC-10A multi-parameter thermoanalysis instrument is the instrument used.

3. HARDENING MECHANISM STUDY OF CHG

As clay hardening grout consists of clay, cement, sodium silicate (Solidify A), Solidify B and water, the chemical reactions taking place inside the CHG should be associated with the basic reactions inside CHG, such as the hydration of cement, the reaction of cement with sodium silicate, the reaction of cement with clay and the reaction of sodium silicate with clay. But, since Solidify A is also, so the chemical reactions taking place inside CHG are not totally the same as those reactions described above.

3.1 Hydration process of CHG

The hydration taking place inside CHG includes the hydration of cement as well as the effects of Solidify B and Solidify A on the hydration process.

3.1.1 The hydration process of cement^[3,4]

Tricalcium silicate, dicalcium silicate, tricalcium aluminate and tetracalcium ferrate aluminate in the cement added into CHG first undergo hydration with water.

Among them, tricalcium silicate undergoes hydration and hydrolysis with water as below:

When tricalcium silicate mixes with water, hydration is fast. At the beginning, the compounds of lime and silica enters the solution in stoichiometric ratio, i.e. the same mole ratio 3:1 as they exist in the anhydrous compound. The quick decrease of the concentration of silica caused by the continuous increase of the concentration of lime soon yields the appearance of crystal of hydrated lime and the formation of gelatinous or near amorphous hydrated calcium silicate as well. The hydrated calcium silicate formed on the surface of tricalcium silicate produces a thin film to make it very difficult for water to enter into it, and thus to slow down the ongoing hydration.

Equation (1) is the chemical reaction equation of tricalcium silicate when it totally hydrated. But his simple equation can not reflect the complex nature of the reaction. At the beginning of hydration, the immediately yielded resultants $\text{CaO}:\text{SiO}_2$ with a ratio near 3 form a thin film covering the surface of tricalcium silicate and thus retard its hydration. Several hours later, the film of this initial compound dissolves or breaks to accelerate the hydration of tricalcium silicate and produce C-S-H second gelatinous compounds with relatively lower mole ratio (1.5 or less) which instantly turn into the stable third resultants.

Dicalcium silicate undergoes hydration with the equation as below:

When the solution is saturated with hydrated lime, the hydration of dicalcium silicate does not stop, but keeps on going. Furthermore, the reaction incessantly liberates calcium lime in the form of hydrated lime crystals and forms hydrated silicate that remains stable when contacting the saturated lime solution. Although the reaction processes are different, the hydrates of dicalcium silicate and

tricalcium silicate are in the same form. The ratio of the initial resultants CaO/SiO_2 covered on the surface of dicalcium silicate particle is near 2. About 12 hours later, it converts into lime and the ratio of CaO/SiO_2 drops to the minimum 1.1-1.2. Finally, a stable compound is produced.

Tricalcium aluminate undergoes hydration with the equation as below:

Although tricalcium aluminate reacts with water very quickly, it reacts slowly with water in the saturated lime solution. Part of the lime in tricalcium aluminate can be replaced and yields in $\text{Na}_2\text{O}\cdot 8\text{CaO}\cdot 3\text{Al}_2\text{O}_3$. At the same time, the hydration could be accelerated because of the existence of alkalis.

The hydration of tetracalcium ferrate aluminate is shown as below:

The rate of the reaction of ferric aluminate with water is in proportion to the content of aluminum oxide in ferric aluminate. The hydration of tetracalcium ferrate aluminate will not produce hydrated lime. But the hydration process in excess water^[5,6,7] is similar to the hydration of anhydrous CA with C_{12}A_7 . Both produce saturated Calcium Aluminate solution except that the mole ratio of $\text{CaO} : \text{Al}_2\text{O}_3$ varies between 2:1 and 3:1.

3.1.2 The catalysis process of Solidify B

When adding Solidify B into clay cement grout, the inorganic salt in solidify B first dissolves in the water, producing a great number of aluminate ions, sulfate ions and silicate ions. Calcium also undergoes hydration and produces hydrated lime which provides adequate conditions for equation (4) and accelerates the hydration of tetracalcium ferrate aluminate. Meanwhile, hydrated lime is soluble in water with a relatively lower solubility. The dissolution of hydrated lime produces Ca^{+2} and OH^{-1} which make saturated solution soon, reacts with aluminate ion, sulfate ion and silicate ion to produce crystal compounds of hydrated tricalcium aluminate, calcium sulfate and hydrated CaSiO_2 , and dissolves part of the silica to produce $\text{Na}_2\text{O}\cdot\text{SiO}_2$:

Where $\text{Na}_2\text{O}\cdot n\text{SiO}_2$ reacts with hydrated lime in the solution (equation 6) to produce hydrated calcium silicate, a gel with certain strength.

Where calcium sulfate in water solution decreases the solubility of hydrated lime, thus enabling the accelerations of the formation of hydrated lime crystals and accelerating the development of equation 1, 2 and 3* to right side. And also, calcium sulfate undergoes hydration with tricalcium aluminate and water as below:

This quick reaction consolidates great deal of free water in the form of crystals. The amount of free water decreased in the solution is 46% of that of cement increased.

But the content of calcium in the Solidify is low and cement has been added prior to the adding of the Solidify which resulted in the hydration of grog minerals in cement with water and the production of hydrated lime. The product of Ca^{+2} after hydrated lime has been dissolved combines with the aluminate ion, sulfate ion and silicate ion in the Solidify and yields hydrated tricalcium

aluminate, calcium sulfate and hydrated $\text{CaO} \cdot \text{SiO}_2$, thus decreasing the concentration of Ca^{+2} in the solution and accelerating the hydration of grog minerals in cement.

3.1.3 The catalysis process of solidify A (water glass)

When finally adding water glass, it hydrolyzes immediately as shown in equation 11 which is a reversible one. The amorphous silica in Solidify B accelerates this reaction to the left side to produce more $\text{NaO} \cdot \text{SiO}_2$ which reacts with hydrated lime in the solution (equation 6) to produce hydrated calcium silicate, a gel with certain strength. Now, the amorphous silica limits the hydrolysis of water glass and accelerates its reaction in the direction of producing hydrated $\text{CaO} \cdot \text{SiO}_2$, thus speeding up the reaction rate.

Figure 1. Sketch of Ladder

Figure 2. Sketch of clay cement ball

At the same time, the amorphous silica plays a role of crystal nuclei on the surface of cement particles and accelerates the formation of hydrate crystals. The crystals of hydrated tricalcium aluminate, calcium sulfate and hydrated $\text{CaO} \cdot \text{SiO}_2$ produced by the aluminate ion, sulfate ion and silicate ion in Solidify B constitute the crystal nuclei for the crystal growth of successive reactants, thus accelerating the growth of various hydrate crystals, the increase of crystal's strength and the hardening of grout and shortens the initial set time.

3.2 The Reaction of Clay Particle with Cement and Hydrates

At the same time when various hydrates of cement are produced, part of these hydrates keep on hardening to form the skeleton of cement hydrates while the other part reacts with the nearby clay particle with certain activity because the hydration and hydrolysis of cement in CHG is completely surrounded by the medium of mud with certain activity. The main ways of reaction are ion exchange, nodularization (granulation) and hardening reaction which constitute a complicated physical chemistry reaction process.

When the clay particles in CHG are dispersed into block clay in water, the surface and edge of these block clays have different charges. In a relatively larger PH range, the edge always has positive charge and the surface has opposite charge, the number of which is far more than that of positive on the edge^[8]. So, the edge and surface attract each other and form a ladder structure (Figure 1)^[9,10]. The added cement particle with positive charge on the surface is thicker than clay particles. When it meets the surface of block clay with opposite charge, electrostatic attraction between them occurs and part of the ladder structure is broken. The surface of block clay is attracted towards cement

particles and forms clay-cement ball centered with cement particle (Figure 2). Ladder and clay-cement ball structure exist together because the amount of cement added is small and it is impossible to break the ladder completely. The hydration compounds of cement particles in clay-cement ball start to form at the surface of the cement particle and then diffuse outwards and fill the vacancy of clay particle to grow strength.

Except for absorbing with cement particles with positive charge, the surface of clay particles also undergo equivalent absorption with Ca^{+2} in hydrated lime, resulting from cement hydration, and enables the dispersed clay particle to form bigger clusters to increase the strength of CHG. Because its surface area is far larger than the surface area of cement particles, the gel produced by the hydration of cement has very big surface energy and strong absorption activity. It can further combine with bigger mud cumularspherolith to form cluster structures and blockade the vacancy of each mud cumularspherolith to form a unity combination.

3.3 Thermoanalysis study of CHG reaction mechanism

When adding Solidify agents into CHG, hydration takes places quickly and solidifies very soon. At present, we can not study the hydrates in 1-2 hours after the hydration but can only study the hydrates 3 days after the hydration because of the limitation of experimental conditions.

From the previous analysis, we know that the main compounds of hydration of CHG are $\text{Ca}(\text{OH})_2$, hydrated $\text{CaO} \cdot \text{SiO}_2$ and $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$, etc. Figure 3 is the typical differential thermal curve of clay-hardening grout which clearly shows the characteristic heat liberation peak of $\text{Ca}(\text{OH})_2$ (518°C), hydrated $\text{CaO} \cdot \text{Al}_2\text{O}_3$ (580°C) and hydrated $\text{CaO} \cdot \text{SiO}_2$ (730°C).

Figure 3. Typical differential thermal curve of clay-hardening grout (CHG)
(Rate of increasing temperature $20^\circ\text{C}/\text{min}$, age 14days)

Mud viscosity 67.8", Cement 10%, Solidify A (SA)3%, Solidify B (SB) 5%

As hydration further undergoes, more and more hydrates are produced and the curves of differential age (Figure 4) proves that even more hydrated $\text{CaO} \cdot \text{SiO}_2$ and $\text{Ca}(\text{OH})_2$, which are the main hydrates playing the role of strength in CHG, are increased. Figure 4 shows that the contents of these two type of hydrates increase with the increase in age and the curves also reflects that the area of characteristic peak of these hydrates increase with the increase of time of hydration. Even at the later period of hydration, the characteristic peak ($218\text{--}225^\circ\text{C}$) of hydrated ettringite ($\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{CaSO}_4$) occurs.

Figure 4. Curves of differential age (Rate of increasing temperature 20°C /min)
Mud viscosity 67.8", Cement 10%, SA 7%, SB 5%

With the increase of Solidify A (water glass), the content of hydrated $\text{CaO} \cdot \text{SiO}_2$ in hydrates decreases while the content of Ca(OH)_2 increases. This can be reflected by the decrease of the characteristic peak area (about 710-757°C) of hydrated $\text{CaO} \cdot \text{SiO}_2$ and the increase of the characteristic peak area (about 495-525°C) of Ca(OH)_2 in differential thermal curves (see Figure 5).

Figure 5. Affecting curves of SA on hydrate
(Rate of increasing temperature 20°C /min, age 14days)
1#: Mud viscosity 67.8", Cement 10%, SA 1%, SB 5%;
2#: Mud viscosity 67.8", Cement 10%, SA 3%, SB 5%
3#: Mud viscosity 67.8", Cement 10%, SA 5%, SB 5%
4#: Mud viscosity 67.8", Cement 10%, SA 7%, SB 5%

An increase in cement will definitely increase the content of cement hydrates. The differential thermal curves shows that with increase of cement, the output of hydrated $\text{CaO} \cdot \text{SiO}_2$ increases and its characteristic peak area (about $710\text{--}778^\circ\text{C}$) also increases while the output of $\text{Ca}(\text{OH})_2$ decreases and its characteristic peak area (about $485\text{--}520^\circ\text{C}$) decreases as well till it almost disappears when cement increases to 15% (see Figure 6).

Figure 6. Affecting curves of cement on hydrate
(Rate of increasing temperature $20^\circ\text{C}/\text{min}$, age 14days)
3#: Mud viscosity $67.8''$, Cement 10%, SA 5%, SB 5%
7#: Mud viscosity $67.8''$, Cement 15%, SA 5%, SB 15%
13#: Mud viscosity $67.8''$, Cement 5%, SA 5%, SB 10%

Solidify B is added into CHG as catalyst of the hydration of cement. Reference 11 tells us that there is a optimal value for the increase of solidify B (less than 5%). This can be proved by the differential thermal analysis: with the increase of solidify B, the hydrates in CHG change by decreasing the content of hydrated $\text{CaO} \cdot \text{SiO}_2$ and $\text{Ca}(\text{OH})_2$ (their characteristic peak areas decrease) and appearing a small amount of hydrated $\text{CaO} \cdot \text{Al}_2\text{O}_3$ (heat liberation peak with characteristic peak $910\text{--}958^\circ\text{C}$) appears (see Figure 7).

Figure 7. Affecting curves of SB on hydrate
(Rate of increasing temperature $20^\circ\text{C}/\text{min}$, age 14days)
15#: Mud viscosity $67.8''$, Cement 10%, SA 3%, SB 5%
16#: Mud viscosity $67.8''$, Cement 10%, SA 3%, SB 15%
17#: Mud viscosity $67.8''$, Cement 10%, SA 3%, SB 10%

4. THE HARDENING MODEL OF CHG

Based on the previous analysis, we can draw the hardening model sketch of clay hardening grout (see Figure 8) and conclude that the reaction process of the two stages of CHG hardening process and the role of Solidify A and B have played are both directly associated with the hydration of cement.

Figure 8. Hardening modeling sketch of clay hardening grout

In the first stage, the adding of cement into CHG breaks the original ladder structure of CHG and liberates part of free water which immediately undergoes hydration with cement particle surface with the compounds dispersing in the water in the state of very little solids. Meanwhile, some part of the solid dissolves in the water and produces a great deal of ions (like Ca^{+2}) to enable clay particles to be consolidated and thickened and the grout to be viscous. Then the new surface of cement particle is again exposed and continues to react with water till the liquid around the cement particle becomes saturated. The added Solidify A and B accelerate the dissolution of cement particle surface and the crystallization of hydrates. After the solution is saturated, the compounds of the reaction of cement and water will not dissolve any more, but disperse in the solution to form amorphous colloids. Among them, part of microscopic solids is absorbed by the surface of SiO_2 and grows, part of amorphous colloid is sedimentated on the surface of the accumulated clay particle and glues them together to form certain strength. The ongoing hydration continuously adds new gels and decreases free water. The grout begins to develop strength.

In the second stage, the colloid hydration is not stable, the gels of $\text{Ca}(\text{OH})_2$, hydrated $\text{CaO} \cdot \text{Al}_2\text{O}_3$ and hydrated $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$ are gradually crystallized with the action of SiO_2 particle and closely combines with colloids to fill the voids between clay particles and form cement stone. With the prolonging of the hydration, the inner part of cement particle not yet hydrated continues to be hydrated. Crystals continue to grow and penetrate each other to fill the voids between clay particles. As a result, the strength and gelatibility of the grout keeps on increasing.

5. CONCLUSIONS

The following conclusions are made based on the previous analysis:

- The hydration hardening process of CHG are basically similar with the hydration of cement. But since CHG is added with a large amount of clay and Solidify A and B, there are some differences mainly caused by the nucleation and catalysis of the inorganic salts in Solidify B which accelerates the hydration rate of cement and the increase of strength.
- The main hydrates of CHG in hardening process are $\text{Ca}(\text{OH})_2$, hydrated $\text{CaO} \cdot \text{SiO}_2$ and $\text{CaO} \cdot \text{Al}_2\text{O}_3 \cdot \text{Fe}_2\text{O}_3$, etc.

- With the increase of age, the content of Ca(OH)_2 and hydrated $\text{CaO} \cdot \text{SiO}_2$ increase quickly. Thus the strength of grout increases quickly.
- With the increase of solidify A, the content of hydrated $\text{CaO} \cdot \text{SiO}_2$ in hydrates decreases while the content of Ca(OH)_2 increases.
- With the increase of cement, the content of hydrated $\text{CaO} \cdot \text{SiO}_2$ in hydrates increases while the content of Ca(OH)_2 decreases.

ABSTRACT

The long-time creep of concrete is a phenomenon underlying the durability of bulky reinforced concrete constructions. The mechanism of this phenomenon is evaluated from a study of the physical-chemical mechanics of dispersed systems. The theoretical and experimental fundamental of an assessment and prognosis are proposed.

Mankind strives for beautiful and stately reinforced load-bearing concrete structures. However increases of overall dimensions and length of these constructions has aggravated the problem of their trouble-free and durable exploitation.. For example, in bridges with long spans of 100 to 200 m, the building of which commenced after 1950s, there were unexpected major deflections of bridge spans developed over a rather long term time frame and these have not stabilized even after 20 to 30 years (Figure 1) [1].

Figure 1. The chart of a sag accumulation of bridge span [1]

Problems have also been reported with major reinforced-concrete bridges and tunnels. The conclusions of an international commission on the cause of higher than permitted deflections of bridge spans was ascribed to the unexplored early creep of concrete of the construction in its

compressed zone as well as long-term creep. In this case this creep was not stopped even after the addition stress of new reinforcement during renovation.

At the same time in many countries the designs of concrete structures of ancient times continue to perform, ages reaching 5 to 7 thousand years. There are pyramids and other buildings of Egypt, Cyprus, Syria and Italy etc. One of the features of such ancient structures is the absence of reinforcement and shapes which eliminate tension zones. We do not know of any case of similar durability of large dimensional and thin-wall mass concrete or reinforced concrete structures, which carry bending or tension. Therefore the opinion about durable reinforced concrete structures can only be attribute to concretes in the compression zone.

The cause of low-level durability of modern concrete or reinforced concrete structures, according to our opinion, is the inadequate knowledge of the performance of concrete at its structures subject to bending, that is in turn connected to the lack of knowledge about properties and behavior of concrete in structures which carry bending, on pre-stressed constructions, under loaded deformations, and also in conditions of an ingress of water. The methods of proportioning concretes is also imperfect and cannot supply the necessary homogeneity of reinforced concrete structures to provide durability. Different normative documents on the maintenance of engineering constructions are also incapable of forecasting durability.

1. THE REASON FOR AN ABOVE NORMAL CREEP OF CONCRETE. THE STRUCTURAL CHARACTERISTICS OF CONCRETE DETERMINING ITS CREEP AND THEIR OPTIMIZATION

As a result of this research, we established that above normal creep is explained by the non-uniformity of concrete under the structural characteristics - coefficients of expansion of coarse aggregate grains α (the relation of a volume of mortar to the void volume in coarse aggregate) and sand, the relation of a cement paste volume to the void volume in sand). These characteristics essentially influence the creep of concrete under long-term compression. With deviation α and μ from optimum values the creep of concrete is sharply increased. Creep depends also on the consumption of water and cement in a concrete mix. Thus the increase of creep is affected both by the increase of cement volume paste in the concrete, and by the increase of the true value of water-cement ratio W/C over the optimum value (≈ 0.23). Taking into account all the above, the creep of concrete and mortar can be reduced to a minimum by optimum composition with normalized α , μ and W/C . The method of determination of such structure is presented here. The concretes and mortars with normalized composition are recommended for applying both for manufacturing new structures and for repair and renewal works.

The theoretical basis for obtaining mortars and concretes with an optimum structure ensuring maximum cracking resistance and water tightness, have been developed at the sub-faculty on the basis of a colloid chemistry and physio-chemical mechanics of disperse cement systems [2]. In accordance with these ideas the structure of concrete is poly-disperse, in which different levels of structure – macro, mezzo, micro and sub-micro (Figure 2) are combined. A dispersing medium is physio-chemically bound by water. The structure-forming elements form the structure of concrete at each level (in proportion to their size and quantitative ratio).

Figure 2. Schematic of concrete structure at levels: *a* – macro, *b* – mezzo, *c* – micro, *d* – sub-micro; *B* – grain of large aggregate – broken stone (10 to 15 mm), *S* – grain of small-sized aggregate– sand (0.2 to 0.5 mm), *C* – cement particles (10 to 50 μm), *Cr*, *G* – accordingly, crystalline-hydrated (100 to 500 nm) and gel (≤ 100 nm) products of a hydration

The formation of the properties of concrete and mortar is influenced by the arrangement of small-sized fragments in an interlayer between a number of contacts arising between larger fragments (Figure 3). The structure on a micro-level is determined by water-cement ratio W/C . In Figure 4 the experimental dependence of cement paste strength R on W/C is shown. As we can see from Figure 4, the greatest strength corresponds to a value of $W/C \approx 0,23$. It is determined by the quantity of chemically bound water, – about 23 % by weight of cement. Increasing W/C results in the increase of the quantity of free water and, accordingly, porosity of the paste, and a reduction leads to the decrease of the degree of cement hydration.

Figure 3. Schematic of inter-layer formation between structure-forming elements *SE*: *B-S-B* – on macro-level, *S-C-S* – on mezzo-level, *C-(Cr,G)-C* – on micro-level; *a, c* – non-optimum; *b, d* – optimum

Figure 4. The dependence of cement paste strength R on the 28 day Hardness vs water-cement ratio W/C

For mortar and concrete compositions with maximum strength and impermeability it is necessary to achieve true values of W/C (taking into account for water requirements of aggregate), close to 0.23. The mobility of such mixes is provided for the application of the super-plasticizer. At such W/C the creep of a cement paste, mortar and concrete is minimised according to our opinion, by the optimum structure of new-formations (crystalline-hydrated and gel) between incompletely reacted cement grains (Figure 3).

The nature of structure on mezzo-level is determined by a ratio of the quantity of both sizes of cement particle and grains of sand and on macro-level – by the ratio of quantity both aggregate size of sand and coarse aggregate. Maximum strength, impermeability and minimum creep of concrete and mortar are reached in that case when inter-layers between grains of stone sand are filled with one full series of grains of sand particles of cement. (Figure 3, *b*). When the quantity of finer grains (particles) is less than optimum, (Figure 3, *a*) is formed and when their quantity exceeds optimum, (Figure 3, *c*) is formed. In these cases, as we can see from Figures 3, *a*, *c*, the quantity of contacts between elements and packing density of more small-sized particles decreases, that results in decreasing of strength and density. It is necessary to draw attention particularly to the fact that indicated regularity has a statistical property and the packaging shown in a Figure 3, are average values of the sizes of elements and the thickness of inter-layers, i.e. ensuring maximum packing density of all the elements and the quantity of contacts between them.

The stated ideas about the structure of concrete (and of in inter-layers between the grains filling and about the mechanism of the structure-formation of these inter-layers allows us to deduce mathematical expressions for best values of coefficients of expansion α_{opt} and μ_{opt} :

$$\alpha_{opt} = 2,1 \cdot \left(1 + \frac{d_s}{d_b}\right)^3 - 1,1, \quad \mu_{opt} = 2,1 \cdot \left(1 + \frac{d_c}{d_s}\right)^3 - 1,1, \quad (1)$$

where d_s , d_b , d_c – mean sizes, accordingly of grains of sand, coarse aggregate and particles of cement.

The stated ideas have also allowed us to work out methods of determination of concrete and mortar structure with maximum strength, waterproofness, crack resistance and minimum creep of both mortar and concrete [3] as follows:

$$B = \frac{1}{\frac{\alpha_{opt}}{\rho_b^w} \cdot V_b + \frac{1}{\rho_b}}, \quad S = \frac{1 - \frac{B}{\rho_b}}{\frac{\mu_{opt}}{\rho_s^w} \cdot V_s + \frac{1}{\rho_s}}, \quad C = \rho_c \cdot \left(1 - \frac{B}{\rho_b} - \frac{S}{\rho_s} - \frac{W}{\rho_w} \right), \text{ kg/m}^3 \quad (2)$$

where W – minimum according to the required workable (with super-plasticizer).

To decrease long-time creep and increase of waterproofness of concrete it is expedient to use super-plasticizing admixture in a concrete mix. In this case there will be an increase of the consumption of cement at the expense of the reduction of water quantity. In this case fine fillers – substitutes of cement can be used. However it should be accompanied by the necessary research. Alongside a long-time creep of concrete the considerable influence on the operational properties brought about by creep of concrete showing itself in particular, during tests of pre-stressed concrete sleepers and beams, and also during transit of rolling stock above them. As tests have shown, it also strongly depends on the above mentioned characteristics α and μ and the consumption of water W .

2. THE COLLOIDAL-CHEMICAL NATURE OF CREEP OF HARDENED CEMENT PASTE

In accordance with [2, 4 etc.] the main cause of a creep is the deformation of cement gel, paste gel or migration of water under pressure. Electron microscopic and colloidal - chemical research of cement paste structure and its components executed by us on the basis of existing and our own experiments, allow us to consider-cement paste as a colloidal-chemical system consisting of micro-structural blocks – of incompletely reacted cement particles, bound by elastic-plastic crystalline-hydrated skeleton consisting of submicroscopic particles of portlandite and hydro-sulfoaluminate of calcium, filled with saturated highly disperse hydro-silicate gel. The indicated elastic deformations and micro-cracking as carriers of plastic deformations take place in a crystalline-hydrated skeleton (larger fragments in Figure 5 [5]), and creep deformations – in hydro-silicate gel (more small-sized fragments of the spherical shape in Figure 5).

Figure 5. The cement paste, hydrated within 6 hours at 70 °C [5]

In the connection with a prevailing volume of hydro-silicate gel (75 % among all hydrated new-formations [4]), the compressive stress is not immediately carried by the crystalline-hydrated skeleton and its contacts, and is transmitted at the beginning to gel components and the water in it.

In the process of extrusion of water from the gel the elastic skeleton accepts the increasing pressure, and the amount of gel and water in it becomes less and the contribution of water to pressure decreases. Under pressure, increasing plastic deformations of a crystalline-hydrated skeleton, is influenced by micro-fractures. On achieving the stresses, which are equal to the strength of the crystalline skeleton, cement paste and concrete are being destroyed.

Thus, the sub-microstructure of cement paste consisting of a crystalline-hydrated skeleton, filled with water-bearing hydro-silicate gel, stipulates the development (of elastic-plasticity and flowability) by concrete simultaneously with the properties of solid-shaped and aqua-shaped bodies, accordingly,

Thus the elastic and plastic properties are affected by the process of squeezing water from gel and transferring pressure to the crystalline-hydrated skeleton and, consequently are limited by properties of flowability. It gives the basis to consider the deformation properties of concrete as rheological. The typical rheological properties thus are relaxation and creep.

3. FULL RELAXATION AND KINETICS OF CONCRETE CREEP

Creep deformations affected by squeezing of definite quantity of water from hydro-silicate gel of cement paste (gel water,) to be subordinate to the law of a filtration of a Darcy. Thus time and volume of squeezed water are in relation, flowing out from this law

$$t = \frac{\Delta W_g h}{SK_f P}, \quad (3)$$

where ΔW_g – water volume squeezed from the gel during t , m^3 ; h – path of a filtration (size of a sample or considered piece of a construction), m ; S – cross-sectional area of a filtration flow (cross section of a sample or piece of a construction), m^2 ; P – hydrostatic head (delivery head) of waters at a filtration, m , which is equal to the pressure in gel water at compression of concrete; K_f – coefficient of filtration of concrete, m/s .

The value of the coefficient of filtration k_f determines the kinetic regularity, i.e. the speed of deforming of concrete under compression, and value ΔW_g the amplitude of volumetric deformation during t . In the case corresponding to an ultimate deformation, the value t corresponds to a maximum relaxation time t_r^{max} , and value ΔW_g to the limiting (maximum) volume of squeezed gel water for this period of time. Unlike the conventional concept of a relaxation time t_r , a maximum relaxation time t_r^{max} , means time, at which the pressure in gel water disappears and its compression stops.

For a cross-sectional area of a sample S the value ΔW_g is determined by its limiting deformation Δh during time t_r^{max} :

$$\Delta W_g = \Delta h^{lim} S = \varepsilon^{lim} h S, \quad (4)$$

Hydrostatic head P we shall express through the equivalent to him pressure in concrete:

$$P = \frac{\sigma}{\rho_w g}, \quad (5)$$

where σ – pressure load in a concrete; ρ_w – density of water; g – acceleration of gravity.

The value of ultimate deformation of concrete corresponds to its compressive strength R , and can be determined approximately from the expression

$$\varepsilon^{lim} = R / G, \quad (6)$$

where G – module of deformation of concrete under compression.

Let's substitute expressions (4), (5) and (6) in (3):

$$t_r^{\max} = \frac{Rh^2 \rho_w g}{GK_f \sigma} = \frac{h^2 \rho_w g}{GK_f y}, \quad (7)$$

where $y = \sigma/R$ – the level of loading of concrete under compression.

Let's enter parameter, having called its as time factor

$$T_t = \frac{t}{t_r^{\max}} = \frac{t}{h^2} \frac{R \rho_w g}{GK_f \sigma} = \frac{t}{h^2} \cdot \frac{GK_f y}{\rho_w g}. \quad (8)$$

Corresponding to a known expression in a colloid chemistry, the relative creep deformation of cement paste in concrete at compression ε_t in an instant t will follow the form of:

$$\varepsilon_t = \varepsilon^{\lim} \cdot [1 - \exp(-T_t)]. \quad (9)$$

According to (7) and (9) the kinetics of creep deformation of concrete are determined mainly by the magnitude of a design h , by the coefficient of filtration of concrete k_f and by the level of loading y . Accordingly, the bigger the size of a structure, the less the coefficient of filtration of concrete and the less the level of loading, the slower creep deformations of concrete under compression (Figure 6).

Figure 6. Development of calculated deformations ε_t in time t

Figure 6 was obtained from (9) with allowance for (8). The limiting values of deformations $1000\varepsilon^{\lim}$ are adopted for unit. As we can see in Figure 6, the limiting deformation does not depend on h and is identical to concrete. At the same time h renders strong influence on speed of development and general duration of deformation. For $h = 0.5$ m the speed of deforming is higher, and its ultimate value can be reached in 2÷3 years. For $h = 5$ m the ultimate deformation is reached only in several hundreds of years.

After the above explanation, the experimental research of the mechanism of a customary and long-time cement paste creep was investigated with the purpose of prediction in structures. The experimental studies of deformations were undertaken on a prismatic sample of the dimensions $10 \times 10 \times 40$ cm from cement paste obtained at $W/C = 0.4$, hardening under normal conditions. The aging base of deformations compounded (made) 30 sec. The experimentally obtained curve mirrors the instantaneous elastic deformation (Graph 1), then an exponential field of elastic-plastic deformation, or customary creep (stage 2), reducing flow (streaming) 10 to 20 days, then long-lived

linear (stage 3) reducing over more than 150 days, and at last, horizontal field observing within 1 month, testifying about the termination of further deformation.

Figure 7. Kinetics of relative deformations of creep cement of a rock at pressure load 14 MPa ($W/C = 0.4$, normal conditions of concreting).
dots – experimental data, full line – on the equations 9 & 8

The linear relation of most extended 3-rd stage mirrors plastic deformation and confirms to the reality of long-lived creep of the cement paste [1] and testifies to the filtration mechanism.

Usage of elastic-plastic deformation [2] and Dharcy law of filtering with reference to the cement-aqueous system, has permitted the introduction physical and mathematical models for complete deformation cement paste under compression to an instant t at a long-lived loading

$$\varepsilon_t = \varepsilon_{el}^{lim} + \varepsilon_{cr}^{lim} \cdot [1 - \exp(-T_t)] + \frac{tK_f\sigma}{h^2\rho_w g}, \quad (10)$$

where ε_{el}^{lim} – limiting elastic deformation; ε_{cr}^{lim} – limiting deformation of creep of the cement paste; T_t – time by the equation (8); K_f - coefficient of the cement paste filtration.

Defining the role of hydro-silicate gel and water in the creep of concrete allows us to determine strain amplitude of creep of cement paste, on volume basis wrung out from hydro-silicate gel, V_{cav}^g .

$$\varepsilon = \frac{C(W/C - \alpha_h W_{cb}/C) - V_{cav}^g}{3C(1/\rho_c + W/C)} \cdot K^c K^{nf}, \quad (11)$$

where C – expenditure of cement on $1m^3$ cement paste; $W_{cb}/C = 0.23$ – water-cement ratio conforming chemically to bound water; K^c , K^{nf} – quotients which are taking into account influencing of frame cement paste.

The permeability and deformation properties of concrete are determined already at the stage of making the concrete and is confirmed by the data of Figure 8. As is visible, at $\mu < \mu_{opt}^{exp}$ experimental sizes of density ρ_{exp} is much lower than design ρ_{des} , particular from the principle of absolute volumes which have been used in traditional methods of calculation of concrete proportioning. It allows us not only to forecast long-term creep and durability of reinforced-concrete structures, but also substantially to control durability of concrete and structures by designing the proportioning of concrete with the optimum structural performances α_{opt} and μ_{opt} .

Figure 8. Dependences of density of cement-sandy solution ρ from coefficients of expansion of grains of sand μ (sand with modulus of grain size $M_{gs} = 2.5$).

The closeness of fit above confirms all design and experimental data.

ABSTRACT

Fly ash can be treated at high temperature and the pozzolanic activity index of heat-treated fly ash is improved. Heat-treated fly ash may be more suitable as a cementing material than the original fly ash. The phase compositions and pozzolanic activity of the fly ash, which was treated at the temperature 950°C with the chemical reagent CaO, CaF₂ and Na₂CO₃, was studied with XRD, TGA etc. in this paper. The physical properties of partially heat-treated fly ash were also tested. The results illustrate that the reagent added in the fly ash could change the phase compositions during the heat-treatment process. For example, the new phases of NaAlSiO₄ or (Na,Ca)(SiAl)₄O₈ exist in the heat-treated fly ash. Moreover, the chemically bonded water content of heat-treated fly ash, which hydrated for different ages, increased according to the TGA result. The Ca(OH)₂ content in the hydrated heat-treated fly ash with CaF₂ is less than that of the fly ash without CaF₂. The compressive strength of the heat-treated fly ash with 3.0wt% gypsum is more than the control s. For example, the compressive strength of heat-treated fly ash hydrated for 21 days may reach 1.67 MPa and the control's is 1.13 MPa.

Keywords: Fly Ash; Heat-treated; CaF₂; Pozzolanic Activity

1. INTRODUCTION

Pozzolanic activity of fly ash is well known for a long time.^[1] However, the development rate of the pozzolanic activity is very low. There are many methods, such as ultra-grinding and alkali activation, to improve the pozzolanic activity index of fly ash. In this paper, fly ash was heated at the temperature 950°C for 30 min with the chemical reagent CaO, CaF₂ and Na₂CO₃. The phase compositions and pozzolanic activity of heat-treated fly ash were researched.

2. EXPERIMENT

2.1 Raw Materials

The chemical composition of fly ash is shown in Table 1. Figure 1 is the XRD pattern of the fly ash. The chemical reagent includes CaO, CaF₂ and Na₂CO₃ (class Analytical Reagent).

Table 1. The chemical composition of the original fly ash

Component	Loss	SiO ₂	Al ₂ O ₃	CaO	Fe ₂ O ₃	MgO	Σ
Content (%)	3.17	47.22	38.94	2.92	4.34	1.09	97.68

Figure 1. XRD pattern of the original fly ash (d: nm)

There is a characteristic that the Al_2O_3 content in the fly ash is very high. According to the ASTM classification, it is considered as class F fly ash. The mineral mullite is the main mineral phase according to the XRD test result. (see Figure 1).

2.2 Heat-treated Method and Strength Test

Fly ash mixed with the different chemical reagents is heated at the temperature 950°C for 30min. The phase composition of the heat-treated sample is tested with the method of XRD. The heat-treated fly ash hydrated for different ages is tested with XRD and TGA. Specimen size of the fly ash paste is $2\text{ cm} \times 2\text{ cm} \times 2\text{ cm}$ for the strength test. The ratio of water to fly ash is 0.48.

3. RESULTS AND DISCUSSION

3.1 Effect of Na_2CO_3 on the Composition of Fly Ash

The mass ratio of fly ash to Na_2CO_3 is shown in Table 2. The XRD patterns of part of the heat-treated fly ash with Na_2CO_3 are shown in the Figure 2.

Table 2. The mass ratio of fly ash (abbr. FA) to Na_2CO_3 (abbr. N)

No.	P-1	P-2	P-3	P-4	P-5	P-6	P-7	P-8
FA:N	1.0:1.0	1.0:0.75	1.0:0.5	1.0:0.25	1.0:0.15	1.0:0.1	1.0:0.05	1.0:0.0

Figure 2. XRD patterns of part of the heat-treated fly ash with Na_2CO_3

The phases of fly ash were changed because of the addition of Na_2CO_3 . NaAlSiO_4 is the only mineral existing in the heat-treated fly ash when the ratio of fly ash to Na_2CO_3 is equal to 1.0 (No.

P-1). The mullite and quartz disappeared. The quantity of the mineral type in the heat-treated fly ash increases as the addition amount of Na_2CO_3 decreases. For example, there are the minerals NaSiAlO_4 and $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ in the sample No. P-3. However, the mineral mullite and quartz have completely reacted with Na_2CO_3 and the characteristic peak of mullite and quartz in the XRD pattern could not be found. Although the new phases NaSiAlO_4 and $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ have been formed in the No. P-4, the mineral mullite also exists. The phase composition of Nos. P-5, P-6 and P-7 are similar to that of the No. P-4.

3.2 Effect of Na_2CO_3 and CaF_2 on the Composition of Fly Ash

The addition of Na_2CO_3 and CaF_2 in the fly ash, which contains 20wt% CaO , is listed in the table 3 and the XRD patterns of some heat-treated fly ashes are shown in Figure 3.

Table 3. The addition of the Na_2CO_3 and CaF_2 (%)

No.	PF-1	PF-2	PF-3	PF-4	PF-5
CaF_2	0.4	0.4	0.4	0.2	0.6
Na_2CO_3	0.0	5.0	3.0	3.0	3.0

Figure 3. XRD patterns the heat-treated fly ash No. PF-1, 2, 3 and PF-4

The results of the XRD test illustrate that the reaction of Na_2CO_3 with the CaO , SiO_2 , Al_2O_3 has taken place and the new crystalline phase $(\text{Na,Ca})(\text{SiAl})_4\text{O}_8$ has formed. It is deduced according to the chemical characteristic of CaF_2 that the melting temperature of fly ash is decreased and the phase $11\text{CaO-7Al}_2\text{O}_3\text{-CaF}_2$ will form because of the reaction CaF_2 with CaO and Al_2O_3 . It is apparent that the glass structure of the fly ash will be changed because of the addition of CaF_2 .

3.3 The Hydration of Fly Ash with CaF_2 and Na_2CO_3

The heat-treated fly ash (No. PF-1, 2, 3, 4 and 5 in the table 3) was ground to the specific surface fineness $500 \text{ m}^2/\text{kg}$ (Blaine). The paste of the heat-treated fly ash (water/ash=0.5) cured for 2 months and the hydrated fly ash is tested with the method of TGA (testing temperature range: from ambient to 350°C ; rate of temperature increase: $20^\circ\text{C}/\text{min}$). The test results of TGA are shown in the table 4.

Table 4. The TGA results of the hydrated fly ash (ambient $\sim 350^\circ\text{C}$)

No.	PF-1	PF-2	PF-3	PF-4	PF-5
Weight loss (%)	2.032	1.487	1.831	1.284	1.687

From the table 4, it is shown that the content of the chemically bonded water in No. PF-1 is 2.032%. It is illustrated that the hydration degree of No. PF-1 is highest among all of the samples. That is to

say, there is the most appreciable addition 0.4% for the CaF_2 when the addition of Na_2CO_3 in the fly ash is 3.0%. For the heat-treated fly ash with the same addition of CaF_2 , the content of the chemically bonded water in the hydrated fly ash decreases as the addition of Na_2CO_3 increases.

3.4 Compressive Strength and Hydration of the Heat-treated Fly Ash

3.4.1 Compressive strength of the heat-treated fly ash

In order to research the effect of CaF_2 and Na_2CO_3 on the strength of fly ash, the addition of CaF_2 is respectively 0.5wt%, 1.0wt% and 1.5 wt% (based on the weight of fly ash which contains 20wt% CaO) and the addition of Na_2CO_3 in the sample is 3.0wt%. Table 5 is the addition of CaF_2 and Na_2CO_3 in the fly ash.

Table 5. The addition of CaF_2 and Na_2CO_3 in the fly ash (%)

No.	SP-1	SP-2	SP-3	SP-4	SP-5	SP-6	SP-7
Na_2CO_3	0.0	0.0	0.0	0.0	3.0	3.0	3.0
CaF_2	0.0	0.5	1.0	1.5	0.5	1.0	1.5

The above-mentioned samples were heated at the temperature 950°C for 30 minutes and the specific surface fineness of the heat-treated fly ash with 3.0wt% gypsum was $500 \text{ m}^2/\text{kg}$. The compressive strength of the heat-treated fly ash with 3.0wt% gypsum is listed in the table 6.

Table 6. The compressive strength of the heat-treated fly ash with gypsum (MPa)

No.	SP-1	SP-2	SP-3	SP-4	SP-5	SP-6	SP-7
21 days	1.13	1.67	1.41	1.25	<0.5	<0.5	<0.5
42days	3.96	4.55	4.60	4.07	/	/	/

From the table 6, it is deduced that the compressive strength of the heat-treated fly ash decreased with the increase of CaF_2 content. For example, the paste strength of heat-treated fly ash with the 0.5wt% CaF_2 hydrated for 21 days may be attain to 1.67MPa. However, the paste strength of the sample with 1.5wt% is only 1.25 MPa at the same hydration age. The compressive strength results of the heat-treated fly ash certified the above-mentioned TGA results.

According to the test results of sample Nos. SP-5, SP-6 and SP-7, Na_2CO_3 has a negative effect on the strength of the heat-treated fly ash although it could apparently change the phase composition and the structure of the original fly ash.

3.4.2 Hydration of the heat-treated fly ash

(a) XRD analysis

Figure 4 is the XRD patterns of sample Nos. SP-1, SP-2, SP-3 and SP-4 hydrated for 21 days.

Figure 5 is the XRD patterns of sample Nos. SP-5, SP-6 and SP-7 hydrated for 42 days.

Figure 4. XRD patterns of the sample No. SP-1, SP-2, SP-3 and SP-4 hydrated for 21 days

Figure 5. XRD patterns of the sample No. SP-5, SP-6 and SP-7 hydrated for 42 days

For the fly ash without CaF_2 , the calcium hydroxide and gypsum exist in the hydrated paste. However, the calcium hydroxide content in the hydrated sample with CaF_2 is less than that of the fly ash without CaF_2 . It could be certified from the change of the characteristic peak strength of the mineral calcium hydroxide in the hydrated sample.

There are two assumptions about the change of the gypsum content in the hydrated sample. One is that gypsum reacted with the compositions of the heat-treated fly ash in a large degree and its characteristic peak could be detected in the XRD patterns when the CaF_2 addition in the fly ash is less than 1.0wt%. Another assumption is that the reaction content of gypsum with the compositions of fly ash is small when the CaF_2 addition in the fly ash is 1.5wt%.

Ettringite exists in all of the hydrated samples with CaF_2 and its peak strength in the sample No.SP-5, SP-6 and SP-7 is less than that of sample No.SP-2, SP-3 and SP-4.

(b) TGA analysis

The TGA results of the hydrated fly ash cured for 21 days and 42 days were shown in the table 7.

Table 7. The TGA results of the hydrated fly ash cured for different ages (weight loss %)

No.	SP-1	SP-2	SP-3	SP-4	SP-5	SP-6	SP-7
-----	------	------	------	------	------	------	------

Chemical-bonded water	2.46	4.65	5.36	4.93	4.88	4.07	4.27
Ca(OH) ₂	1.51	0.0	0.0	0.30	0.0	0.0	0.0
CaCO ₃	1.39	0.54	0.48	0.74	1.48	0.79	0.60

Note: No. SP-1, SP-2, SP-3 and SP-4 hydrated for 21 days; No. SP-5, SP-6, SP-7 hydrated for 42 days.

The weight loss of calcium hydroxide of the sample SP-1 is 1.51wt% and the weight loss of CaCO₃ is 1.39wt%. However, at the same hydration age the weight loss of calcium hydroxide of sample SP-2, SP-3, SP-4 is zero and the weight loss of CaCO₃ is very low.

The chemically bonded water of the sample containing Na₂CO₃, which hydrated for 42 days, is lower than that of the sample without Na₂CO₃ which hydrated for 21 days.

4. CONCLUSIONS

The effect of Na₂CO₃, CaF₂ and CaO on the composition and strength of fly ash was studied in this paper. The following conclusions were drawn:

- (1) Na₂CO₃ could react with the compositions of fly ash at the temperature 950°C and the crystal phases NaSiAlO₄ and CaO-Al₂O₃-SiO₂ have been formed. But Na₂CO₃ is not beneficial to the strength improvement of the heat-treated fly ash.
- (2) CaF₂ could change the structure of fly ash at the temperature 950°C and the pozzolanic property of the fly ash is improved. CaF₂ additions in appreciable quantities to the fly ash could increase the strength of the heat-treated fly ash. The optimum addition of CaF₂ based on the fly ash containing 20wt% CaO is 0.4wt%.
- (3) The hydration degree of the heat-treated fly ash with CaF₂ is increased and the content of Ca(OH)₂ in the paste of heat-treated fly ash with CaF₂ is less than that of the paste of the original fly ash at the same hydration ages. The hydration product for all of the heat-treated fly ash is similar.

ABSTRACT

Oilwell cements are used in the oil industry both in exploration and in the production of oil and gas. Their primary use is to seal the annular space between the walls of a borehole and the steel casing that lines the well. The hydration characteristics of Class G oilwell (OWG) at 20°C and 5°C with the addition of calcium chloride, calcium formate and sodium aluminate as accelerating admixtures have been investigated. There is no universal mechanism of acceleration of cement hydration. The actual mechanism depends upon the particular accelerating admixture, its concentration, the time of acceleration and the temperature. The rate-of-heat evolution of the OWG with the different admixtures at 20°C and 5°C is discussed.

1. INTRODUCTION

Normally, in gas- and oil-well cementing, the temperatures are mostly above ambient and pressures above atmospheric, often considerably so, which necessitate the use of retarders in the cement slurries to produce workable thickening or setting times. However, during the casing cementing of well sections at or near the surface under cold conditions, where the temperatures may be as low as around 0-5°C the cement hydration reactions are slowed down and chemicals, like 'accelerating' admixtures, are used to promote hydration. These admixtures adequately accelerate the cement hydration reactions so that the cement performs its intended function, whether this is chemical, physical or both, and consequently aids the extraction of oil or gas.

The original aim was to investigate the hydration of OWG at 20°C and 5°C and to characterise and understand how its microstructure develops with time in the presence of accelerating admixtures using a variety of experimental techniques and methods *viz*; isothermal conduction calorimetry, thermal analysis, X-ray powder diffractometry, infrared spectroscopy, scanning electron microscopy and development of compressive strength [1]. At low temperatures the cement hydration reactions are kinetically slowed down and it is not practicable both logistically and economically to accelerate the hydration of the cement simply by heating the cement and mix water prior to pumping the resulting slurry down the borehole. Thus other cheaper and more efficient means of accelerating the cement hydration processes are required.

Calcium chloride, calcium formate and sodium aluminate were employed in this study. Here we report the comparison of these admixtures with respect to conduction calorimetry. Other aspects of

hydration can be found elsewhere [1,2,3,4]. At present the manner in which these admixtures are thought to function upon the cement hydration process is far from completely understood, despite their extensive employment in practice. The findings of this research work apply equally to hydraulic Portland cements used in the oil and construction industries.

2. EXPERIMENTAL METHODS AND TECHNIQUES

The OWG cement was obtained from Blue Circle Industries. This cement was a coarsely ground high sulphate-resisting cement with the potential phase composition (Bogue weight %) of tricalcium silicate ~53.3, dicalcium silicate ~21.9, and tricalcium aluminate ~1.5 and tetracalcium aluminoferrite ~15.9.

The calcium chloride, calcium formate and sodium aluminate of analytical grade were obtained from British Drug Houses Chemicals Limited, Dorset, UK. The rate-of-heat evolution was measured using the JAF Wexham Isothermal Conduction Calorimeter [7] and the development of cement microstructure was examined using a JEOL JSM-35CF scanning electron microscope.

The cement was mixed with distilled water to give a cement paste having a water to cement ratio of 0.44. The admixtures were dissolved in the mix water prior to mixing. This is the recommended ratio used for testing [8]. Further experimental details are given elsewhere [1]. The concentrations of the admixtures in the mix water are given in Table 1 below and are referred throughout this paper as Molar concentrations.

Table 1. Concentration of Admixtures in the Mix Water

Molar (mol/l)	Concentration of Admixtures in the Mix Water As Weight Percentage of Cement [Weight Percentage of the Mix Water]		
	Calcium Chloride CaCl_2	Calcium Formate $\text{Ca}(\text{HCO}_2)_2$	Sodium Aluminate NaAlO_2
Control	0	0	0
0.1	0.5 [1.1]	0.6 [1.4]	0.4 [0.9]
0.3	1.5 [3.4]	1.7 [3.9]	1.1 [2.5]
0.5	2.4 [5.5]	2.9 [6.6]	1.8 [4.1]
1.0	4.9 [11.1]	5.7 [13.0]	3.6 [8.2]
1.3	6.3 [14.3]	7.4 [16.8]	4.7 [10.7]

3. HYDRATION OF OWG

The effect of temperature upon the rate-of-heat evolution of the paste hydrating at 20°C and 5°C is shown in Figure 1.

The first heat peak, Peak 1, could not be measured since, in the type of calorimeter that was used, the samples were externally hand mixed for three minutes outside the calorimeter before data could be recorded.

At 20°C the second heat peak, Peak 2, which is primarily due to the hydration of the alite phase, occurs earlier and has a greater rate-of heat evolution than that at 5°C. In addition the length of the induction period is smaller.

Figure 1. Rate-of-Heat Evolution Curves of OWG Hydrated at 20°C and 5°C

At 5°C, the heat evolution is spread out over a greater length of time than at 20°C. At later times, greater than 24 hours, the amount of heat that is evolved at 5°C is higher than at corresponding times at 20°C. This is to be expected since at the lower temperature the hydration reactions will be kinetically slowed down and consequently take a longer time to complete.

3.1 Hydration Of OWG With Calcium Chloride

The rate-of-heat evolution of the paste with or without the addition of calcium chloride at 20°C and 5°C is shown in Figures 2 and 3 respectively.

Figure 2. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Calcium Chloride at 20°C

As the dosage of calcium chloride is increased, the acceleratory effect is shown by Peak 2 occurring at earlier times and becoming more intense. In addition the length of the induction period decreases. Similar results have been reported elsewhere [8,9]. The positions of the various parts of the rate-of-heat evolution curves could indicate acceleration or retardation [10]. The shoulder on the left of Peak 2, visible in the control sample, becomes less obvious with the addition of calcium chloride. This shoulder is thought to be from hydration of the ferrite phase.

Figure 3. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Calcium Chloride at 5°C

At 5°C, there is surprisingly no longer a sequential response to the increased addition of calcium chloride in contrast to the pattern observed at 20°C. The greatest acceleration is shown with the 0.3M and 0.5M additions. With the 0.5M addition the shoulder on the left of Peak 2 is almost evident. The 1.0M addition causes a long induction period suggesting a retardation effect, but contradicting this, the height of the induction period is increased and Peak 2 is enhanced relative to the control sample suggesting an acceleratory effect. In addition on the right of Peak 2 there are two shouldering peaks.

As the dosage of calcium chloride is increased, the acceleratory effect is shown by Peak 2 occurring at earlier times and becoming more intense. In addition the length of the induction period decreases. Similar results have been reported elsewhere [9,10]. The positions of the various parts of the rate-of-heat evolution curves could indicate acceleration or retardation [11]. The shoulder on the left of Peak 2, visible in the control sample, becomes less obvious with the addition of calcium chloride. This shoulder is thought to be from hydration of the ferrite phase.

The rate-of-heat evolution curves of the paste with additions of calcium chloride (0.1-0.5M) are higher than that of the control. After 24 hours, however, the control paste evolves considerably more heat than that of the accelerated paste. This suggests that some different hydration processes are occurring with the addition of calcium chloride to the paste.

3.2 Hydration Of OWG With Calcium Formate

The rate-of-heat evolution curves of the OWG hydrated with various additions of calcium formate at 20°C and 5°C are shown in Figures 4 and 5 respectively.

The 0.1M and 0.3M additions to the paste show an acceleration, as indicated by the advancement of Peak 2 relative to the control paste. Maximum acceleration is indicated with the 0.3M addition. An adaptation of the JAF calorimeter so that the cement paste could be mixed internally and hence allow the measurement of the first heat Peak on first contact with the mix water was made [1]. The height of the first heat peak with the 0.3M addition is nearly twice as high as that of the control paste. The 0.5M addition shows Peak 2 occurring slightly later with the induction period lengthened in comparison to the control paste. With 1.0M, addition Peak 2 occurs earlier than that of the

control paste, but has a lower heat output at all times. This can be interpreted in two ways; first, as an acceleratory effect since Peak 2 occurs at an earlier time as compared to the control and second, as a retardation effect as the hydrating cement evolves heat at a lower rate than the control sample due to lowered cement hydration.

Figure 4. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Calcium Formate at 20°C

Figure 5. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Calcium Formate at 5°C

The addition of calcium formate to the paste results in complex rate-of-heat evolution curves at 5°C. The 0.1M addition shows an acceleratory effect *i.e.* Peak 2 occurs at an earlier time than observed for the control paste. With 0.3M addition both acceleratory and retardation effects are shown; Peak 2 is enhanced relative to the control sample but the induction period is lengthened. The

0.5M and 1.0M additions appear to retard the hydration as shown by lengthening of the induction period with the result that Peak 2 occurs at later times than observed for the control paste.

3.3 Hydration Of OWG With Sodium Aluminate

The rate-of-heat evolution curves of the paste with additions of sodium aluminate at 20°C and 5°C are shown in Figures 6 and 7.

Figure 6. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Sodium Aluminate at 20°C

Figure 7. Rate-of-Heat Evolution Curves of OWG Hydrated with Various Additions of Sodium Aluminate at 5°C

At 20°C, the 0.1M addition of sodium aluminate produces a heat evolution curve more typical of a Portland cement or alite phase. The 0.1M and 0.3M additions show an acceleratory effect in terms

of Peak 2 occurring at shorter times than the control paste. The first heat peak, measured by the adapted JAF calorimeter with 0.3M addition is much higher than observed for the control paste [1]. The 0.5M addition shows an enhancement of Peak 2, whereas with 1.0M addition Peak 2 occurs at a later time suggesting a retardation effect.

The heat evolution curves are further complicated, however, by the presence of supplementary peaks, which lie between Peak 1 and the beginning of Peak 2. These supplementary peaks increase in magnitude and change position as the amount of sodium aluminate in the paste is increased. With 0.1M addition no supplementary peaks were observed. With 0.3M addition, there is a single peak which occurs in the descending portion of Peak 1. With 0.5M addition, two supplementary peaks occur between the end of the induction period and the maximum of Peak 2. With 1.0M addition, however, the first supplementary peak occurs during the normal induction period whilst the second is as the start of Peak 2.

At 5°C, the 0.1M and 0.3M addition to the paste both show an acceleratory effect, as revealed by the advancement of Peak 2 relative to the control paste, of which the 0.3M addition is the most effective. With higher additions (0.5M and 1.0M), Peak 2 occurs after that of the control paste, implying a retardation effect. Although the 0.1M and 0.3M additions show an acceleratory effect, the height of the Peak 2 in both cases is significantly lower than that of the control paste. This is also observed with 0.5M and 1.0M addition.

As at 20°C there are supplementary peaks on the heat evolution curves. With 0.3M addition, a peak appears on the descending part of Peak 1. With 0.5M addition, two peaks appear, the first on the downside of Peak 1 before the induction period, and the second during the induction period. In contrast, the 1.0M addition to the paste causes a long induction period to develop, with one peak before its end and another on the rising part of Peak 2. The lengthening of the induction period with 1.0M addition suggests that paste hydration is not accelerated, but retarded.

The two supplementary peaks can be tentatively be assigned as ' $C_3A_{(aq)}$ sodium aluminate' and ' $C_3A_{(aq)}$ ferrite phase. The order of releasing aluminate ions into solution is:

Sodium aluminate >> tricalcium aluminate >> tetracalcium aluminoferrite

The supplementary peaks are likely to be from the sodium aluminate and tetracalcium aluminoferrite phase since the cement contains about 1.5% and 15.9% tricalcium aluminate and tetracalcium aluminoferrite phase respectively.

The variation in the rate-of-heat evolution curves of the OWG with the various admixtures strongly suggests that the hydration of the ferrite phase plays an important part in the sequence of hydration products that are subsequently produced during the course of hydration [1, 2, 12]. Clearly, the definition of what is an accelerator needs careful thought. In this paper we have demonstrated how an accelerating admixture can behave as a retarder as a function of the type of admixture, the dosage level used and the temperature of hydration.

4. CONCLUSIONS

- Acceleration of cement hydration by accelerating admixtures depends upon which property is being measured on the rate-of-heat evolution curves.
- The accelerating admixtures in some instances cause a retardation effect.
- Supplementary peaks occur before the main heat Peak 2 with sodium aluminate.

- There is no universal mechanism of acceleration of cement hydration. The actual mechanism depends upon the particular accelerating admixture, its concentration, the time of hydration and the temperature.

BIOGRAPHY

Dr Jasbir Singh Lota has gained 15 years experience in cement science and technology (Imperial College, Building Research Establishment, Concrete Technology Unit - Dundee University and Birchall Centre - Keele University) covering its chemistry, materials science and engineering aspects relating to chemical admixtures, mineral additions, mechanisms of hydration and instrumental techniques. Other interests include processing, properties and application of cementitious materials employed in the oil and construction industries. Following a year at the Institute of Education (University of London), he is teaching science at secondary level and actively encouraging schoolchildren to develop interests in science and engineering.

Professor John Bensted has worked for 25 years in the cement and oil industries (Blue Circle Industries and British Petroleum) in cement technology and is a visiting Professor of Cement Science at the Universities of London (Birkbeck College) and Greenwich. In addition, he is an international consultant in cement technology to the construction, chemical and oil industries. He has been at the cutting-edge of cement science and trouble-shooting, covering construction Portland, oilwell, high alumina, blended, decorative and other cements. Also he is an expert witness in legal matters concerning cement and concrete.

ABSTRACT

An integrated model is proposed to understand and to predict the properties of polymer modified cementitious materials. The reciprocal influences between the polymer particles and the cement hydrates are discussed and implemented in the model.

The influence of a lower drying rate on the film formation process as well as the retardive effect of the polymer particles and polymer film the cement hydration are discussed. The results demonstrate the coincidence of the polymer film formation process and cement hydration in the case of dry curing conditions.

1. INTRODUCTION

The properties of polymer modified cementitious materials (PCC) are determined by the components, i.e. cement particles and cement hydrates and polymer particles and polymer film. However, the properties of the individual components are as important as the synergetic action between these components. The influence of the presence of the cement particles on the polymer film and polymer film formation is investigated, as well as the influence of the polymer particles on the cement hydration.

To understand and to predict the properties of polymer modified cementitious material, an integrated model of structure formation is proposed in which these mutual influences are incorporated. Based on the three-step model presented by Ohama [1], an integrated model of structure formation is proposed in which the interaction between the cement hydrates and the polymer particles in relation to a time-scale is presented. Modifications and remarks on the Ohama-model, proposed by different authors [2, 3, 4] are also taken into account.

Drying of the polymer dispersion in the hardening PCC environment causes three important alterations of the drying conditions of the polymer dispersion compared to the pure air drying of the polymer particles. A high relative humidity is present in the case of water and moist cure, accompanied by a large dilution of the polymer dispersion in combination with the mixing water. The water phase almost immediately changes into an alkaline solution due to the start of the cement hydration. Finally a change in drying rate is noticed, which influences the minimum film formation temperature of the polymer dispersion. The influence of these alterations on the film formation process of different types of polymer dispersions is presented.

Also the influence of the presence of the polymer particles and polymer film on the hydration and the properties of the cement particles is examined. Through strength measurements, the retardive influence of polymer modification is observed. On the other hand, the increase of the flexural strength, measured at a young age on mortar prisms, indicates the coincidence of the polymer film formation process and the cement hydration in the case of dry curing conditions. More detailed information is presented in [5].

2. POLYMER FILM FORMATION IN THE PRESENCE OF CEMENTITIOUS MATERIAL

The influence of the altered conditions on the minimum film forming temperature (MFT) [6] of the polymer dispersion is important for the film formation process in the presence of cementitious material. The variation of the MFT determines if a continuous film is formed throughout the cement matrix, even at temperatures lower than the MFT, or if the polymer particles will act separately on the cement particles and cement hydrates.

2.1. Influence of Relative Humidity on Film Formation and Drying Rate

Film formation, and especially the drying rate are influenced by relative humidity (RH). At high relative humidity, the equilibrium between the atmosphere and the pore solution is reached almost immediately and only a few water molecules escape to the atmosphere. Therefore, the water molecules that are present at the outer surface of the polymer particles due to the presence of surfactants, are only released very slowly. Rearrangements of the molecules may take place. At low relative humidity, a large amount of water molecules escapes to the atmosphere to obtain equilibrium between the atmosphere and the liquid. The water molecules surrounding the polymer particles are released very quickly and no further rearrangement can take place. In that case, a continuous film will only be formed if the polymer particles have sufficient thermal energy to coalesce together, i.e. when the curing temperature is higher than the MFT. However, due to the different drying rate at high R.H. and at low R.H., the MFT is altered and will be higher at lower R.H. than at higher R.H. This is illustrated with an example.

Figure 1. Weight variation of polymer dispersion after curing at 60% R.H. and 86% R.H.

To investigate the influence of the relative humidity on the film forming capacity of the polymer dispersion, three different curing conditions were taken: curing at R.H. higher than 98%, at R.H. of 86% and at R.H. of 60%. An atmosphere with R.H. of 86% was obtained in a sealed desiccator partly filled with a saturated KCl-solution. Temperature was equal to $20^{\circ}\text{C} \pm 3^{\circ}\text{C}$ for the three conditions. The influence of the R.H. was investigated for the 8 different types of polymer dispersion, with MFT ranging between 0°C and 32°C . Samples were prepared pouring a thin layer of the polymer dispersion on a glass plate. The amount of solids poured on the glass plate was kept constant to obtain an equal thickness for all samples. The results indicated a delayed film formation in the case of 86% R.H. for all specimens with $\text{MFT} < 20^{\circ}\text{C}$, compared to film formation at 60% R.H. At higher relative humidity, the film was formed only after 6 hours in the case of the pure polymer emulsion, where it needed less than 2 hours at a R.H. of 60%.

Figure 1 presents the results for a SBR polymer dispersion, with MFT of 5°C , cured at 60% R.H. and at 86% R.H. The pure polymer dispersion was tested as well as a diluted solution, containing 50% polymer dispersion, i.e. 25% solids, 25% emulsion water and 50% tap water. The results indicated a rapid linear decrease in weight, due to the evaporation of the water until only the solid part of the dispersion was left. The results of the different dispersions reflected a constant drying rate. In the case of the SBR1 samples dried at 86% R.H., this was not clear due to the lack of measuring points between 5 hours and 24 hours after the start of the test, as indicated by a dashed line between both points. A constant drying rate may be presumed until the 50%, respectively 25% relative weight is reached. From the results a simple calculation of the drying rate is possible extrapolating the drying rate between 0 and 2 hours. Only in the case of the pure dispersion, dried at 60% R.H., the drying rate could not be calculated since the 2 hours interval time was too long. The drying rate in this case was smaller than 0.21 g/h. The results are given in Table 1.

Table 1. Drying rate to obtain a pure polymer film

Composition	Curing at 60% R.H.	Curing at 86% R.H.
100% SBR1	<0.21g/h	0.08g/h
50% SBR1, 50% tap water	0.27g/h	0.08g/h

The results indicated very little alteration of the drying rate due to the dilution of the polymer dispersion, especially for drying at high R.H. The increased relative humidity on the other hand reduced to a large extent the drying rate of the polymer dispersion.

Although a small drying rate decreases the MFT, no continuous film was formed in the case of SAE dispersion, MFT of 32°C , even not at a R.H. of 86%. Curing at a R.H. higher than 98% resulted in a white-transparent material. This points at a slight reduction of the MFT. Also in the case of the other dispersions, with a MFT lower than 20°C , no continuous film could be seen after 7 days storage for the samples stored at 98% R.H., although some alterations were noticed. Some of the polymer dispersions changed into a slimy white paste and in some cases into a fragile film. After storage during 7 days at the high R.H., the specimens were stored at R.H. of 60% and 20°C , without stirring the formed paste or fragile film. This resulted in coalescence into a continuous film if the MFT of the dispersion was lower than 20°C . Extending the curing time at higher R.H. resulted in a continuous film, even for the polymer dispersions with higher R.H.

2.2 Influence of the Alkalinity

Due to cement hydration and release of CaO, the alkalinity of the pore solution becomes very high. This could cause interaction with the surfactants and result in a delayed or even completely stopped

film formation. To test the influence of the alkalinity of the pore solution, a simulation has been done with pure dispersion. The test was carried out on the SBR dispersion. The polymer dispersion was mixed with a NaOH-solution with pH equal to 13. The solution contained 50% of polymer dispersion which corresponds to 25% parts of solid, and 50% of the NaOH solution and had a pH value of 12.70. after stirring the solution, it was then poured on a glass plate and stored at laboratory conditions, R.H. 60% and at a R.H. of 86%.

Figure 2. Weight variation of the SBR1 dispersion after dilution with distilled water, a NaOH-solution and a H₂SO₄-solution respectively

Figure 2 gives the results in comparison to the diluted dispersion with 50% tap water. At the same time, a 50% dilution with an H₂SO₄-solution, with pH of 1, was made to see the influence of an acidic environment. Obviously, this is not the case in the fresh concrete. The pH of the solution with H₂SO₄ measured 1.39. The results are also presented in Figure 2. Analogous to Table 1, the drying rate was calculated. The results are presented in Table 2.

Table 2. Drying rate to obtain a polymer film

Composition	Drying at 60% R.H.	Drying at 86% R.H.
50% SBR1, 50% tap water	0.27g/h	0.08g/h
50% SBR1, 50% NaOH	0.21g/h	0.07g/h
50% SBR1, 50% H ₂ SO ₄	0.23g/h	0.07g/h

The results indicate a small reduction in drying rate for the dispersions diluted with the NaOH solution as well as for the dispersion diluted with the H₂SO₄-solution, possibly due to the interaction between the surfactants and the ions in the solution. However, the effect was limited. In all cases, a continuous film was formed. The influence of the relative humidity is much more important than the pH value of the solution.

2.3. Polymer Film Formation in the Pore Solution of Cementitious Material

The film formation process and especially the MFT is mainly influenced by the drying rate. Therefore, the variations of the film forming process in the pore solution of cementitious material can be reduced

to the influence of the altered conditions on the drying rate of the polymer dispersion.

Only limited variation of the drying rate was observed in an alkaline and acidic environment. Film formation of the tested dispersions was not hindered in these environments. The relative humidity on the other hand altered the drying rate to a large extent. A reduced drying rate was measured at higher relative humidity. This resulted in a decreased film forming temperature for the pure polymer dispersion at higher relative humidity. This explains partly why, even after curing at temperatures lower than the MFT of the pure polymer dispersion, as was the case for the mortar and concrete specimens modified with SAE, a continuous polymer film was noticed throughout the cement matrix

In addition, due to cement hydration supplementary forces may be exerted on the water of the polymer particles. Extra water-withdrawal results in more closely packed polymer particles and coalescence can take place at even lower temperatures [7]. As is shown in the following section, this was the case for the SAE dispersion. A clear continuous polymer film was formed even at curing temperatures of 20°C, which is lower than the MFT of 32°C. Measurement of the temperature at the inner part of the specimens showed only a limited increase of the temperature due to the release of heat caused by hydration.

3. CEMENT HYDRATION IN POLYMER MODIFIED MATERIAL

Cement hydration in polymer modified material is influenced by the presence of the polymer particles and polymer film in the fresh state, during hydration as well as in the hardened state. The properties of the fresh mixture are influenced to a large extent by the surfactants, present at the surface of the polymer particles. The cement particles are better dispersed in the mixture and a more homogeneous material is formed. Since hydration is closely related to the strength development of the material, the influence of polymer hydration is investigated through the influence on the strength development at early ages.

3.1. Strength Evolution at Early Age

The strength evolution at early ages is closely related to the hydration of the cementitious material and the film formation. The influence of the polymer modification is twofold. Due to the polymer and the surfactants, a retardation of the cement hydration can be noticed. This is especially visible in the compressive strength of the mortar beams. On the other hand, due to the film formation or due to the interaction between the cement hydrates and the polymer particles, the tensile strength of the binder matrix as well as the adhesion strength between the aggregate and the binder increase. This is especially seen in the flexural strength of the mortar beams. To illustrate and to clarify these statements, the compressive and flexural strength of mortar beams are presented in relation to time and to polymer-cement ratio. Polymer modification was done with the SAE emulsion. The curing conditions applied for the test were standard curing, wet curing and dry curing.

The flexural strength and the compressive strength of the mortar are given in Figures 3 and 4. Due to the small amount of sand in the mortar, sand-cement ratio of 0.16, the samples were subjected to large shrinkage. In the case for wet or standard cured samples, where a long moist or water curing condition was followed by a dry period, micro-cracks appeared due to the shrinkage which resulted in a loss of strength. Therefore, only the results of the dry cured specimens are discussed.

In general the flexural strength increased with increasing p/c ratio with a maximum around 15% p/c ratio. The addition of polymer emulsion acted as a retarder for the hydration of cement. The retardive effect was more pronounced with increasing p/c ratio. In Table 3, the relative increase (>0) or decrease (<0) of the flexural and compressive strength with varying p/c ratio are given in relation to the strength of the non-modified mixture.

Figure 3. Flexural strength, constant w/c ration, porous concrete mortar composition

Table 3. Relative increase and decrease of the compressive and flexural strength for the dry-cured samples

p/c-ratio	7 days curing		28 days curing		251 days curing	
	compr. strength	flex. strength	compr. strength	flex. strength	compr. strength	flex. strength
0%	60 N/mm ²	8.1N/mm ²	72 N/mm ²	5.7N/mm ²	73 N/mm ²	6.4N/mm ²
5%	- 1.8 %	+ 44 %	+ 8.7 %	+ 88 %	+ 11 %	+ 133 %
10%	- 10.5 %	+ 77 %	+ 8.5 %	+ 123 %	+ 1.3 %	+ 192 %
15%	- 22.5 %	+ 23 %	- 6.4 %	+ 153 %	+ 0.6 %	+ 234 %
20%	- 24 %	+ 19 %	- 11.1 %	+ 132 %	- 3.4 %	+ 220 %

The results indicate a decrease of compressive strength during the first days of curing. This points at a delayed cement hydration, since after longer curing periods, the modified as well as the unmodified specimens reach equal compressive strength. The negative influence of the polymer modification on the compressive strength is therefore minimized if a long curing period is considered, at least in the case of modification with the SAE dispersion. A maximum compressive strength is reached with a polymer-cement ratio equal to 5%. However, higher compressive strength would be obtained in the case where a longer wet curing period was introduced, followed by a dry curing period, if shrinkage is limited.

Two different, but related mechanisms are at the base of the retardive effect on cement hydration. First, the presence of surfactants is important. When the mortar is modified with a polymer emulsion, part of the water has to come from this emulsion. This water is partly bound to the hydrophilic part of the surfactants present at the surface of the micelles by hydrogen bonds. The release of this water takes time, so hydration is retarded.

Figure 4. Compressive strength, constant w/c ration, porous concrete mixture composition

On the other hand it is also possible that by mixing the unhydrated cement particles and the polymer emulsion, some of the micelles clings to the surface of the unhydrated cement particles and form there a continuous film, due to the water extraction by the first hydration of the cement particle, i.e. the formation of the outer C-S-H phase. This results in a partly or fully covered cement particle. The hydration of this particle will be much slower since the water first has to migrate through the layer of polymer film or closely packed polymer particles.

From the results of the mechanical tests, conclusions regarding the film formation mechanism and especially the time at which film formation takes place may be drawn. When the compressive and flexural strength after 7 days dry curing are looked at (Figures 3 and 4) together with the reduction, respectively increase of the strength in relation to the strength of the unmodified mortar (Table 3), an increase in flexural strength is noticed, although the cement hydration is retarded when the polymer-cement ratio is increased (lower compressive strength). This points at the existence, already at an early stage of curing, of a polymer film or at least at the interaction between polymer particles and cement particles. However, the incapacity of the modified “porous” mortar specimens to overcome the large shrinkage stresses after 7 days or 28 days moist curing, indicates that the continuous polymer film is not yet formed in the case of water saturated conditions. No influence of the polymer modification on the flexural strength is noticed in the case of standard cured and water cured samples as long as no dry curing period is applied.

So, one may conclude that at high relative humidity, the influence of polymer modification on the flexural strength at short term is limited. From the moment a dry curing period is introduced, a polymer film starts to build up through the binder phase and an increase in flexural strength is measured with increasing polymer-cement ratio. The influence on the flexural strength of the retardation of the cement hydration is compensated by the presence of the polymer film. When long term behaviour is considered, a maximum of flexural strength is established around 15% polymer-cement ratio.

4. INTEGRATED MODEL OF STRUCTURE FORMATION

The mutual influences between the cement hydrates and the polymer particles and film are incorporated in an integrated model of structure formation. The model is based on the three-step model as proposed

by Ohama, but stresses the positioning of the mechanisms on the time scale and the interaction between the different components.

Figure 5. Step 1, immediately after mixing

The formation of the polymer film can take place from the moment two polymer droplets have sufficient energy to overcome the repulsion forces originating from the surfactants. In other words, if the temperature is high enough to cause sufficient Brownian motion, or if additional forces are working on the liquid layer around the polymer droplets, such as capillary forces or water withdrawal by further cement hydration, two droplets can come close to each other and can coalesce into each other and a polymer film is formed. This process simultaneously can take place with the cement hydration mechanism, especially in the case of dry curing conditions. Therefore, partial or full encapsulation of the cement hydrates is possible, which retards the hydration process. The different steps of the conclusive model are presented in Figures 5 to 8.

Immediately after mixing, the cement particles and polymer particles are dispersed in the water. The first hydration of the cement takes place, which results in an alkaline pore solution. This is indicated as step 1, Figure 5.

Figure 6. Step 2, after mixing. The polymer particles interact with the cement particles and the aggregates. In the case a dry curing period is introduced. A continuous film may be formed locally.

The second step is presented in Figure 6. A portion of the polymer particles is deposited on the surface of the cement grain and the aggregate. The polymer-cement ratio determines the amount of polymers present in the pore solution and present at the aggregate surface. Part of the polymer particles may coalesce into a continuous film. This preferably takes place at the surface of the cement hydrates where extra forces are exerted on the polymer particles due to the extraction of water for cement hydration. The polymer film can partly or completely envelop a cement grain which results in a retardation or even a complete stop of the hydration of the cement grain.

Figure 7. Step 3, cement hydration proceeds, a polymer film formation starts on specific spots.

The following step, Figure 7, consists of cement hydration, polymer flocculation and possibly polymer coalescence into a film. The processes that take place depend on the curing conditions. If no dry curing period, i.e. curing at a lower R.H., is included, the overall film formation is retarded and the influence on the properties of the fresh mixture is limited at this stage. If a dry curing period is included, polymer film formation takes place during this step, which influences the cement hydration process as well as the strength development at early ages. In the bulk liquid phase, hydrate precipitations are present, which form a combined inorganic and organic product. The fractions of the different types of product formed depend on the polymer/cement ratio used. The polymer fractions included in these hydration products do not contribute to the strength development of the specimen [7].

Figure 8. Final step 4, cement hydration continues, the polymer particles coalesce into a continuous film

The final step, Figure 8, includes further hydration and final film formation. Through the cement hydrates, a continuous polymer film forms as water is further removed from the pore solution. The part of the polymer particles, that is still present in the dispersion, is restricted to the capillary pores and at the interface of the aggregates and the bulk polymer-cement phase. It is this part which contributes the most to the elastic and final strength properties. The continuity of the polymer phase through the binder matrix is more pronounced in the case of a higher polymer-cement ratio. In the case the MFT of the polymer dispersion is much more elevated than the curing temperature, the polymer particles may not coalesce into a continuous film, but remain as closely packed polymer particles.

The use of the model can be illustrated with the different curing conditions. From the results it is concluded that optimal conditions towards the strength development are a wet curing period followed by a dry curing period. The longer the moist and water curing period is, the higher the final flexural strength will be if shrinkage is prevented and if a curing period at lower R.H. is introduced. This means that first cement hydration takes place and only limited film formation. Therefore, the polymer particles remain in the pore solution and a larger amount of polymer particles will be incorporated into the continuous film that is formed in the final stage. If the drying period is introduced earlier in the process, the film formation will start sooner, i.e. before and simultaneously with the cement hydration, resulting in enlarged encapsulation of the cement hydrates as well as incorporation of the polymer phase in the hydration product precipitated from the pore solution.

5. CONCLUSIONS

The influence of polymer modification on the cement hydration process as well as the influence of the presence of the cement particles on the polymer film formation process was investigated. The results were incorporated in a descriptive model for the structure formation of polymer modified material, based on the model of Ohama and taking into account the modifications and developments proposed by different researchers.

The polymer film formation process is influenced by the presence of the cement hydrates in different ways. First there is the large dilution of the dispersion by the mixing water which quickly changes into an alkaline solution. Test results on a diluted polymer emulsion showed little or no influence on the film formation process due to the alkalinity for the investigated types of polymer dispersion. The relative humidity of the surrounding atmosphere had a large influence on the film formation and especially on the drying rate. The higher the relative humidity of the surrounding atmosphere, the lower the drying rate became. This influences to a large extent the film forming temperature of the dispersion. The lower the drying rate, the lower the amount of energy needed for the polymer particles to coalesce into a continuous film. Therefore, the MFT is reduced with a reduced drying rate. Tests indicated that even at laboratory circumstances, i.e. 20°C, the SAE dispersion with a MFT of 32°C, could form a continuous film, as long as the drying rate was low enough.

This is also revealed in the microstructure of the SAE-modified specimens. Through the cement matrix, a continuous polymer film is visible. At a p/c-ratio lower than 5%, the continuity is only present through small tiny bridges at a limited amount of spots. At higher p/c-ratio's, the film is more dense. The film connects the different aggregates and is homogeneously present over the material. However, in the case of small p/c ratio's, a preferred positioning close to the aggregate is noticed.

The cement hydration is retarded due to polymer modification. From the moment a dry curing period is introduced, polymer film formation and cement hydration coincide. This results in a partly or completely encapsulation of the cement particles which reduces the hydration rate. Encapsulation also occurs due to the extra water withdrawal from the polymer particles situated at the surface of the cement grains. The cement hydration is also influenced by the fact that water is longer retained due to the presence of the surfactants at the surface of the polymer particles. This results in a better dispersion of the polymer particles and the cement hydrates, but also retards the cement hydration. The influence increases with increasing p/c-ratio.

The presence of the polymer particles also influences the hydration products and especially the portlandite crystals. In the case of polymer modification, the portlandite crystals will be less distorted in the presence of the polymer dispersion. This increases interlaminar bonding forces, which increase the resistance of the portlandite towards aggressive solutions to some extent. Besides the presence of the polymer film throughout the cement hydrates in the bulk binder phase, the transition zone is also influenced by the polymer modification. Clear connections between the aggregate and the bulk binder

matrix exist and become more continuous and dense at higher polymer-cement ratios. Study of the microstructure of the polymer modified material points out that the p/c-ratio should be higher than 5% to obtain a sufficiently continuous polymer film throughout the material. This is confirmed by the results of the mechanical tests.

The previous findings are incorporated in a model of structure formation. This model accentuates two important changes towards the original model of Ohama. First of all, a relation to the time scale of the different processes is made. In the case a dry curing period is included, cement hydration and polymer film formation coincide and the encapsulation of cement particles is possible. Further, the formation of an interstitial phase, consisting of inorganic and organic precipitates in the bulk phase is pointed out.

This is important towards an optimal benefit of polymer modification since the polymers present in this phase are contributing less to the final properties of the material. The optimum conditions are evident from these findings, i.e. a long period of water or moist curing (up to 28 days) during which the cement hydrates develop followed by a period of curing at lower relative humidity during which the polymer film formation is promoted.

IMPROVED PERFORMANCE OF BLAST FURNACE SLAG CEMENT MADE WITH HIGH ALKALI CLINKER

B. Mus

Denizli Cement Plant, P.Box 29, 20100 Denizli, Turkey.

ABSTRACT

A series of laboratory tests are described with ISDEMiR blast furnace slag (BFS) and four different cement plant clinkers.

Materials are ground up to 4.500- 4.000 cm²/gr (Blaine, specific surface) for OPC and BFS respectively. Mixture samples prepared with 40, 50, and 60 % BFS contents were tested for compressive strengths both in the Denizli & Iskenderun cement plant and the Turkish Cement Manufacturers' Association Laboratories.

It is concluded that:

- In the light of 2, 7, 28 and 80 days compressive strength figures, under normal and sulfated water conditions, clinkers containing around 1.1 % total alkali are best suited for BFS cement production.
- % total alkali content is sufficient to activate BFS activity index grade 80.
- Clinker C increases BSF content up to 60.28% additive ratio in BFS cement production (the approach is done with the aid of 2-day compressive strengths, an exponential approach)

1. INTRODUCTION

Different characteristic behaviors are observed in the tests done with Isdemir BFS and four different character clinkers. The most significant result is observed by clinker C; although its compressive strength is 17% lower than A,B and D clinkers (3.000 cm²/gr in finess), it is a better activator for BFS at higher additive contents. The behavior of OPC and blast furnace slag cement (BFSC) in sulfated water is described.

1.1 As a summary

- Chemical and mortar tests are applied for 40%, 50%, 60% BFS content mixtures prepared in laboratory. BFS activity indexes are determined according to ASTM 989 (TS 24 and TS 687).
- Mortar tests were done according to EN 196-1.W/C ratio was 0,50. Concrete prisms's dimensions were 40*40*160 mm. Four prisms have been used at each age. Two day compressive strengths were the limiting parameter for adding BSFslag due to the validity of two day compressive strength limits in Turkish Standards. (the early strength figures are decreasing with increasing BFSslag content). Exponential regression was applied in derivation of the mathematical function of two days compressive strengths.
- Behavior of different BFS content cements are observed in sulfated water as specified by ASTM 1012 (5% Na₂SO₄)
- Hydration followed in 7 and 28 day mortars kept under sulfated and normal water are analyzed by XRD and electron microscope.
- Setting time of cement is analyzed while clinker characteristics and BFS content changing.

2. METHODS

2.1 Analysis Plan

Material: BSF ; 10 Kg of Iskenderun Iron Plant blast furnace slag ground by Denizli & Iskenderun Cement Plant's closed circuit ball mill ($3.920 \text{ cm}^2/\text{gr}$ in fineness) CLINKER; 10 Kg of Denizli and 3 different Plants' clinkers each.

2.2 Analysis Conditions

Each plant's clinkers will be tested separately.

- OPC SAMPLE;
Prepared in a test mill with 4% gypsum ground up to $3100 \pm 100 \text{ cm}^2/\text{gr}$ in fineness
- BFS SAMPLE;
Ground ($3920 \text{ cm}^2/\text{gr}$)
- HIGH GYPSUM CONTENT CEMENT: (HGC)
Prepared in test mill with 8% gypsum ground to $4.450 \pm 100 \text{ cm}^2/\text{gr}$ fineness
- BLAST FURNACE SLAG CEMENT SAMPLE;
%40 BFS; %60HGC
%50 BFS; %50 HGC
%60 BFS; %40 HGC

2.3 Analysis standards to be applied

Chemical analysis : EN 196-2

Mortar analysis : EN 196-1

BFS activity index : ASTM 989

Behaviors in sulfated water are analyzed only in compressive strength basis according to ASTM 1012 and pH trend of sulfated water is additionally observed

3. RESULTS

- Chemical and mortar analysis results of clinker and slag samples (Four different type of clinkers were tested as a function of time.
- After mixing ground BFSslag & high gypsum content cement; Chemical and mortar analysis results of prepared samples of 40%, 50%, and 60 % BFS content mixtures (three different type clinkers were tested for different periods).
- Slope and mathematical function of max. BFS addition capability.
- Compressive strength profiles of 7, 28, 80 days prisms ($40 \times 40 \times 160 \text{ mm}$, dimension) under normal and sulfated water condition. 4 samples were tested.
- Setting times changed as a function of BFS content and clinker type.
- XRD and electron microscope results in 7 and 28 days prisms under normal and sulfated water.

There is no numerical finding of about solubility of K₂S₀₄ of clinker C in water. An assumption could be made as 28 days compressive strength loss of clinker C prisms in comparison with clinker A & B may be caused because of + 1 % more soluble K₂S₀₄ content.

Summary 3: Slope and mathematical function of maximum BFS addition capability

It is observed that the limiting parameter for maximum BFS addition capability is the 2-day compressive strength limit (as 10,0 Mpa). In other words the BFS addition capability of 59 -60 % could be increased up to 62 -63 % if there would be no validation of 2 days compressive strength limit in TS 20, EN 197-1 standards.

Clinker	Max. BFS Addition Capability	2 Days Compressive Strength Exponential Function	R ²
A	60,58	$23.604\exp(-0.2883x)$	0,9987
B	55,70	$23.037\exp(-0.3228x)$	0,9917
C	60,28	$26.945\exp(-0.3288x)$	0,9993
D	58,90	$70,442\exp(-0.0331x)$	0,9769

Summary 4: Compressive strength profiles of 7, 28, 80 day prisms under normal and sulfated water conditions.

Behaviours of cements under sulfated water of 5,0 % Na₂S₀₄ content could be summarized as, If figure 2-a & 2-a/s and figure 3-a & 3-a/s are visualized it could be observed that cement prisms prepared by clinker A are absolutely defected by sulfated water and loose compressive strength in 28 and 80 days period.

Figure 1. Graph for clinker-A: 7, 28, 80 day strength in normal/sulphated water condition

Figure 2. Graph for clinker-C: 7, 28, 80 day strength in normal/sulphated water condition

Figure 3. graph for clinker-D: 7, 28, 80 day compressive strength in normal/sulphated water condition

Figures 1, 2 and 3 show that cement prisms prepared by clinker C are positively affected by sulfated water in 28 and 80 day periods.

- No significant effect evidence in the 2 and 7 day periods.
- At the end of 28 days period

For clinker-A:

- Mortars prepared with OPC are negatively affected by 28 days strengths decrease from 48.8 to 48.2 N/mm²
- The positive effect of BFS is apparent at 40% content and increases at BFS contents of 50% and 60 %. The mortar compressive strength increases from 40.5 to 44.4N/mm² in sulfated water.

For clinker-C:

- Mortars prepared with OPC undergo a decrease in compressive strength from 41.7 to 43.5 N/mm² at 28 days, a drop of 4.3%.
- In BFS containing cements the positive effect is observed in sulfated water with increasing BFS content at 60% BFS content, a 6% compressive strength increase occurs from 37.4 to 39.9 N/mm² by 28 days.
- At the end of 80 days period (figures 1 and 3)

For clinker-A:

- Negative effect of sulfated conditions have increased on mortars prepared by OPC to decrease compressive strengths from 53.2 to 51.2 N/mm² (fig 1)
- The tests show that in 80 days, even the addition of BFS has not stopped the negative effect of the sulfated condition on mortars prepared with the clinker.

For clinker-C:

- Mortars prepared with OPC continued to be affected positively by sulfated water and their compressive strengths increased by 7.3% from 43.6 to 46,8 N/mm².

An absolute positive effect of sulfated water on OPC prepared using clinker C and BFS is obtained.

In OPC from 43.6 to 46.8 N/mm², => %7,3 ↑

%40BFS from 52,7 to 54,2N/mm² => %5,3 ↑

%50BFS from 49,6 to 51,0N/mm² => %3,0 ↑

%60BFS from 46,3 to 48,4N/mm² => %4,8 ↑

As it will be seen fig.3 the positive effect of sulfated water on compressive strengths with respect to normal water are observed after 80 days. The effects of sulfated water at longer ages will also be followed.

Summary 5:

Table 5. Setting time data in accordance with clinker type and BFS content

BFS cements prepared with clinker A & B exhibit longer set times with increasing BFS contents. The cement prepared with clinker C is affected because of activation by its high alkali content.

3.1 Results of XRD and electron microscopes

1 cm particles broken from mortar prisms were covered with gold by POLARON PS 100 and their microstructure analyzed in the secondary electron mode using a LEITZ AMR 1000 scanning electron microscope but no figures are included.

Mineralogical structure of mortar prisms of OPC and BFS cements of 40%, 50%, 60 % contents were analyzed by XRD after hydration in normal water conditions. The results are given below.

3.1.1 Clinker-C in 28 days period under normal /sulphated water:

- More Portlandite forms in Portland cement mortars in comparison with BFS cements. Additionally hydrogarnet formation is observed.
- Portlandite formation is more significant in sulfated water.
- In BFS cements there is less portlandite formation in comparison with sulfated waters. Formatted portlandite quantity is not affected by BFS content of cement.

3.1.2 Clinker-A at 28 days. Normal /sulphated water:

- More Portlandite forms in Portland cement mortars in comparison with BFS cements. Additionally hydrogarnet formation is observed.
- When sulfated water conditions are analyzed there is no significant difference among the BFS cement mortars. Portlandite formation is not observed in 60% BFS-containing cement mortars.

In the 2, 7, 28 day study of industrial slag significant hydration was only observed after 28 days. The $\text{Ca}(\text{OH})_2$ content decreases in samples containing 20 and 50 % slag and disappears in cements with an 80 % Slag content. The slag hydrate is richer in MgO and Al_2O_3 than that Al_2O_3 from OPC.

To avoid any harmful alkali-aggregate reaction, it is recommended that low alkali cement (not more than 0.6 % Na_2O equivalent) be used. Alternatives for avoiding alkali-aggregate reactions are adding pozzolans to the concrete mix. They combine rather rapidly with the alkalis. Blastfurnace slag has a similar effect. This takes place at a time when the concrete is still deformable without deterioration.

3.2 The role of alkalis in concrete

The soluble alkali compounds (present mainly as alkali sulphate) influence the composition of the solution in the fresh cement paste. Alkalis reduce the solubility of lime and increases that of alumina and silica, thus increasing rate of hydration of the main constituents of cement.

The presence of water soluble alkalis accelerates the hydration of cement and thus increases the early strength whereas the 28-day strength is reduced.

Alkalis in hardened concrete may react with some reactive types of aggregate forming a voluminous gel. Reactive aggregate can be: Opal, chert, flint, chalcedony, cryptocrystalline or amorphous silica, shaly dolomite, or badly crystallized volcanic rock.

The volume increase linked with the formation of alkali silicate hydrate gel or the dedolomitization induces expansion and severe deterioration of concrete. Whether the reactions of alkalis are beneficial or detrimental depends on their timing. If they occur when the concrete is still deformable, they are beneficial.

Similarities and differences between the hydration of Portland cement and Portland-BFS cement mixtures are important in explaining their properties.

For slag hydration, Portland cement and the alkalis, gypsum and CaOH_2 (all of which derive from the cement) act as activators and reactants. NaOH has a greater effect than CaOH_2 with increasing addition. Alkali activators accelerate the dissolution of ions containing Si and Al by breaking the Si-O and Al-O bonds in the slag glass structure which is followed by precipitation of low-solubility calcium silicate and calcium aluminate hydrates due to increased ionic concentrations in the liquid phase. At high pH values dissolution of Al is accelerated which initiates slag hydration when the pH of the liquid phase reaches approximately 12, at which condition ettringite is formed stably. The hydration is most accelerated CaOH_2 after hydration of cement causes the carbonation reactions its rate depending on cement content, w/c ratio, compaction of concrete and climatic conditions in order to avoid from the carbonation reactions pozzolanic reactions contribute to strength formation.

4. CONCLUSIONS

It is better to produce Blastfurnace slag cement with high total alkali contents (around 1,1 and higher) in clinker, especially for service in the sulphated water.

Total alkalinity of clinker C is 0.60 % higher than clinkers A,B and D. It can be accepted that this excess alkali is enough to activate BFS as illustrated by the setting time figures.

It is possible to add 60% BFS to clinkers A & C. Although clinker A has 10 N/mm^2 more compressive strength than OPC, both clinkers A and C reach the same point in the case of added BFS. At this point this can be claimed that total alkali content of more than 1.1% is sufficient to activate BFS of activity index of 80. High Na_2SO_4 content water cure results in positive strength gains in 28 - 80 days. Tests on prisms using clinker containing more than 1.1% total alkali and Iskenderun iron plant BFS. Compressive strength reductions are observed in the 80 day period when clinkers with only 0,60 % alkali content are used.

ABSTRACT

The effect of melamine formaldehyde resin addition to ordinary cement on its properties like heat of hydration, setting time, compressive and tensile strength has been studied by adding 0.5 to 5.0% additive by weight of cement. Hardness has been tested using the Vickers indentation method. Fracture toughness of cementitious bond and bending strength have been determined by using three point bending system. Corrosion resistance of resulting products has been tested against 0.1 and 1.0 N HCl and H₂SO₄ and seawater respectively. Water absorption/open porosity and microstructure have also been determined. It was observed that strength, hardness, toughness and corrosion resistance increase up to 5.0% addition of melamine formaldehyde resin in ordinary Portland cement. The polymeric phase is interspersed in cement causing a decrease in water absorption/open porosity. Its interaction with hydrating cement caused additional bond formation leading to the increase in strength.

1. INTRODUCTION

Building materials such as cements based on calcium silicates, calcium aluminate and calcium sulfate which exhibit low flexural strength with their differing chemical compositions, varying degrees of hydration and setting mechanism are never used in flexure or tension without reinforcement. Flexural as well as the compressive strengths of cement are increased with polymer addition. Polymer cement mortars and concrete have potential applications in the engineering aspects of the new class of high strength materials. Organic polymer used in cement mortar and concrete can be divided in to three groups namely latex, liquid resin and water-soluble polymer. In the process of modification with liquid resins, considerable amounts of polymerizable low molecular weight polymers are added in a liquid form to cement mortar and concrete during mixing.

In this modification, polymerization is initiated in the presence of water to form a polymer phase, and simultaneously the cement hydration occurs. As a result, a co-matrix phase is formed with a network structure of interpenetrating polymer and cement hydrate phases which binds aggregate strongly. Consequently, the strength and other properties of modified mortar and concrete are improved. Preparation of polymer admixtures requires special attention for modifying cements to get changes in their microstructure, physico-chemical and physico-mechanical properties. The effect of different quantities of such additions on kinetics of hydration of cement and the characteristics of hydration products are of considerable importance [1-7]. The present work, undertaken in view of these considerations, reports the effects of melamine formaldehyde resin on the properties of ordinary cement. The properties studied include setting time of cement, compressive and tensile strength and corrosion resistance of cement mortar and microstructure, flexural strength, fracture toughness and hardness of neat cement products.

2. EXPERIMENTAL

Ordinary Portland cements taken from the local market, sands from the Sone river and reagent grade melamine formaldehyde resin were chosen for the present work. The effect of melamine formaldehyde resin has been studied by mixing 0.5 to 5.0 percent additive by weight of cement. 1:3 cement/sand mortar was used for the determination [2] of strength. For determination of heat of hydration, different percentages of additive were dispersed in water required for standard consistency of cement paste. Dispersed additive was then mixed with cement and the paste so obtained was filled in specimen tubes (20×20 mm) corked and then sealed with wax. They were stored in vertical position at $25 \pm 2^\circ\text{C}$ in 90% relative humidity. The heat of hydration was obtained from the difference of the heat of solution of unhydrated and hydrated cement samples.

The calorimeter consisted of assembly of units as per Bureau of Indian Standards [2], which was calibrated with analytical reagent grade zinc oxide. Infra-red spectra [5] of neat cement and also with additive (cured for 90 days) was recorded on JASCO, JAPAN, FT/IR-5300 with KBr. X-ray diffraction patterns of neat hydrated cement and modified cement containing additive were taken on x-ray diffractometer (RICH SEIFERT CO. GmbH & COKGD-2076, Germany, Model No. ID 3000) using CuK_α radiation with Ni filter. Intensity and d-values of observed peaks were compared with the values given in JCPDS cards [3] for different phases. The initial and final setting time of cement with and without additive were determined as per Bureau of Indian Standards [2]. Cube samples of 50-cm^2 cross-section were prepared on a vibrating machine (AIMIL 416) for the determination of compressive strength and standard briquettes were prepared for the tensile strength. Samples for both the tests were kept in 90% relative humidity at $25 \pm 2^\circ\text{C}$ for 24 hours and then demoulded and cured at the same humidity and temperature for 7, 28 and 90 days.

Hardness of neat cement samples with and without additive was determined using the Vickers Indentation method at 5, 10, 50 and 100N loads on 90 days cured polished samples. Flexural strength and fracture toughness were determined on rectangular ($1 \times 1 \times 5\text{ cm}^3$) bar samples under three point bending flexure using a Universal testing machine (Shimadzu, Japan). Toughness was determined using single-edge notched beam (SENB) at 20 mm span length and cross head speed of 0.5 mm/min. Water absorption was determined using cube samples with 25 cm^2 cross-section area. Resistance to corrosion in five aggressive media (0.1 and 1.0N H_2SO_4 , 0.1N and 1.0N HCl and seawater) was determined on cube mortar specimens ($25 \times 25 \times 25\text{ cm}^3$) containing 0.5 to 5.0 percent additive.

3. RESULTS AND DISCUSSION

Ordinary cement constituents e.g. C_3A and C_{12}A_7 ($\text{C} = \text{CaO}$ and $\text{A} = \text{Al}_2\text{O}_3$) react with water to produce hydrates like CAH_{10} , C_2AH_8 and C_3AH_6 ($\text{H} = \text{H}_2\text{O}$) and calcium silicates e.g. C_3S and C_2S ($\text{S} = \text{SiO}_2$) to produce C-S-H_I, C-S-H_{II} and $\text{C}_5\text{S}_6\text{H}_5$ etc. In the presence of the polymer additive, some new phases are also formed. Infrared spectra of the 90 days hydrated cement and mix with 5% melamine formaldehyde are shown in Fig.1.

It shows that the bands between 972 and 3645 cm^{-1} are because of hydrated calcium aluminates and between 3437 and 3645 cm^{-1} are predominantly due to water molecule [5] or OH group vibration from $\text{Ca}(\text{OH})_2$ and other hydrates present in the systems. The bands between 453 and 873 cm^{-1} are quite broad and not properly resolved. They may be due to the Si-O and Al-O stretching vibration of silicate and aluminate groups. The bands between 800 and 972 cm^{-1} are strong and broad indicating polymeric silicate (SiO_4) and aluminate group vibrations. The band observed at 972 cm^{-1} is due to the higher shifting of absorption band of C_2SH_2 and C-S-H phases present in cement.

Figure 1. IR of 90 days hydrated cement and cement containing 5.0% melamine formaldehyde resin

The bands between 1500 and 2000 cm^{-1} are not very well resolved. The bands at 1637 cm^{-1} may be because of monosulfate group [5] which indicate the heterogeneous character of the materials involving cement components and the gypsum which are hydrated and their infrared bands overlap. As compared to the infrared absorption band of hydrated cement, some new bands were detected in the sample hydrated with melamine formaldehyde resin.

The new band at 3645 cm^{-1} of OH group vibration was found to be absent in the cement-melamine formaldehyde resin mix cured under similar conditions. Fig. 1 shows that two new bands were observed at 2926 and 2854 cm^{-1} in the mix which may be because of -CH stretching vibration from -CH_2 group. A new band at 1743 cm^{-1} may be because of -NH bending group present in the melamine formaldehyde resin. The bands at 3423 and 1629 cm^{-1} may be because of O-H stretching and monosulfate group at 875 and 520 cm^{-1} may be because of polymeric silicates and aluminates and C_3AH_6 group respectively. The shift in positions as compared to neat cement may be because of the interaction between melamine formaldehyde resin and hydration products of cement.

X-ray diffraction patterns of 7, 28 and 90 days cured hydrated cement show the important peaks of cementitious phases formed during hydration (Fig.2A, B & C). Cement on hydration produces hydrated calcium silicate namely $\text{Ca}_2\text{SiO}_5\text{H}_2$ which has intense peak at $2\theta=26.60^\circ$ ($d=3.34\text{\AA}$), 18.05° (4.90\AA), 34.40° (2.62\AA), 47.17° (1.92\AA) and CaO_2H_2 at $2\theta=50.84^\circ$ ($d=1.79\text{\AA}$) in 7 days hydrated cement samples.

Their intensities decrease as the hydration time increases from 7 to 90 days. The peak intensity of tobermorite phase ($\text{C}_5\text{S}_6\text{H}_5$) at $2\theta=29.39^\circ$ ($d=3.03\text{\AA}$) increases from 26 to 93 with increase in hydration time from 7 to 90 days. The peaks of trisulfate phase ($\text{C}_3\text{A}.3\text{CaSO}_4.32\text{H}_2\text{O}$) were detected at $2\theta=15.73^\circ$ ($d=5.62\text{\AA}$), 24.29° (3.66\AA), 25.13° (3.53\AA), 26.60° (3.34\AA), 37.81° (2.37\AA) and 38.57° (2.33\AA) in 7 days hydrated cement sample while the peaks of monosulfate ($\text{CA.CaSO}_4.11\text{H}_2\text{O}$) appeared at $2\theta=19.90^\circ$ ($d=4.45\text{\AA}$), 31.34° (2.85\AA) and 34.84° (2.48\AA) in 28 days cured samples and $2\theta=32.99^\circ$ ($d=3.86\text{\AA}$), 25.05° (3.55\AA), 32.27° (2.77\AA), 36.95° (2.43\AA) and 56.56° (1.62\AA) in 90 days hydrated cement sample. The other important phases detected in hydrated cement were C-S-H_I at $2\theta=41.25^\circ$ ($d=2.18\text{\AA}$) and 60.10° (1.53\AA) at 7 days and CSH_{II} at $2\theta=42.32^\circ$ ($d=2.18\text{\AA}$), 59.92° (1.54\AA) and $2\theta=36.95^\circ$ ($d=2.43\text{\AA}$) and 60.01° (1.54\AA) in 28 and 90 cured samples respectively. Important phases detected in 90 days cured cement samples were $\text{Ca}_2\text{SiO}_5\text{H}_2$ at $2\theta=11.10^\circ$ ($d=7.59\text{\AA}$), 15.81° (5.59\AA), 25.05° (3.55\AA), 26.67° (3.33\AA), 34.12° (2.62\AA), 50.82°

(1.79Å) and $2\theta=62.57^\circ$ ($d=1.48$ Å), $\text{Ca}_3\text{Al}_2\text{O}_{12}\text{H}_{12}$ at $2\theta=26.67^\circ$ ($d=3.33$ Å), 32.27° (2.77 Å), 38.66° (2.32 Å) and $2\theta=50.82^\circ$ ($d=1.79$ Å), $\text{Ca}_5\text{Si}_6\text{O}_{22}\text{H}_{10}$ at $2\theta=29.38^\circ$ ($d=3.03$ Å) and $\text{Ca}_3\text{Fe}_2\text{O}_{12}\text{H}_{12}$ at $2\theta=51.88^\circ$ ($d=1.76$ Å) and $2\theta=62.57^\circ$ ($d=1.48$ Å). The organic additive to cement influences the hydration of cement and is also influenced by the hydration of cement because of chemical interaction. The ions or molecules formed during the hydration of cement control the formation of cement-melamine resin products. On the addition of melamine formaldehyde resin in cement the relative intensities of the peaks corresponding to hydrated cement phases were altered and a few new peaks were detected along with the disappearance of some of the peaks shown in 90 days hydrated neat cement samples. In the 5% melamine resin-cement mix, XRD pattern (Fig.2D) has shown that new peaks appear at $2\theta=23.53^\circ$ ($d=3.77$ Å), 26.17° (3.40 Å) and $2\theta=28.20^\circ$ (3.16 Å).

Figure 2. X-ray diffraction pattern of cement hydrated for (A) 7 days, (B) 28 days, (C) 90 days and (D) 90 days hydrated cement containing 5.0% melamine formaldehyde resin

The peaks of monosulfate at $2\theta=22.92^\circ$ ($d=3.87$ Å) and $2\theta=25.56^\circ$ ($d=3.48$ Å) and C-S-H_{II} at $2\theta=58.82^\circ$ ($d=1.56$ Å) have increased intensities as compared to their intensities in 90 days hydrated neat cement. Some of the peaks of 90 days hydrated cement were adversely affected by the

melamine formaldehyde resin addition and their intensities were considerably reduced e.g. peak intensities of free lime at $2\theta=18.87^\circ$ ($d=4.90\text{\AA}$), the intensity of which was reduced from 46 to 12 and of $\text{Ca}_2\text{SiO}_5\text{H}_2$ at $2\theta=11.70^\circ$ ($d=7.96\text{\AA}$), 34.26° ($d=2.62\text{\AA}$) and $2\theta=47.07^\circ$ ($d=1.92\text{\AA}$) from 33 to 16, 43 to 18 and from 25 to 11 respectively. A new peak formed at $2\theta=23.53^\circ$ ($d=3.77\text{\AA}$) due to melamine [3] compound, indicates the formation a distinct new phase in the melamine formaldehyde resin-cement mix during interaction which may be causing the increase in strength.

3.1 Heat of Hydration

When cement reacts with water, the process is accompanied by the evolution of heat and leads to the decrease in the energy of the system [4]. The hydration process of cement can be assessed by the measurement of the heat evolved during hydration. Several of the properties important to the user of Portland cement and other hydraulic materials are direct results of the hydration reaction taking place between the components of the cement and water.

3.2 Kinetics of Dissolution

If T_e is the maximum temperature rise ($^\circ\text{C}$) after complete dissolution and T , the temperature at any time, t (min), the following relation can express [22] the dissolution kinetics of cement:

$$\log T_e - \log (T_e - T) = Kt \quad (1)$$

where K is a constant. It is the equation of a straight line and represents a first order kinetics. Cement dissolves in the mixture of nitric acid and hydrofluoric acid and thereby the temperature of the reaction mixture rises. It increases rapidly in the beginning and, thereafter, slows down. Fig. 3 shows the plot of temperature-rise against the time of dissolution for the dry cement as well as the cement hydrated for 3, 7, 28 and 90 days. As the time of hydration increases from 3 to 90 days, the final temperature rise decreases from 5.19 to 3.91 $^\circ\text{C}$. Dry cement gave a value of 5.29 $^\circ\text{C}$, while the same was 5.19, 4.85, 4.56 and 3.91 $^\circ\text{C}$ for cement samples hydrated for 3, 7, 28 and 90 days respectively. The curves were found to be parabolic where rapid temperature rise takes place in the beginning and, thereafter, it slows down. Knowing the rise in temperature, one can assess the quantity of cement dissolved in the acid mix at a particular time. The data show that it is higher for dry cement as compared to the same for hydrated samples dissolved at a particular time. The maximum temperature rise obtained after the complete dissolution of a known weight of cement is a constant value (T_e). Thus $\log T_e$ may be assumed to be a constant in the equation (1) and ($T_e - T$) varies with time, t . A plot of $\log (T_e - T)$ Vs t was found to be a straight-line relationship. The values of slopes (Table 1) of straight lines were 0.70, 0.67, 0.64 and 0.58 for 3, 7, 28 and 90 days hydrated cement respectively. The dry cement gave a straight line of slope 0.73. As the hydration time increases, the slope values decrease.

Table 1. K values for dissolution process

Hydration time (days)	K values (min^{-1})	
	Cement	Cement-5% melamine formaldehyde resin mix
3	0.70	0.66
7	0.67	0.59
28	0.64	0.54
90	0.58	0.50

Figure 3. Temperature-rise during the dissolution of cement and hydrated cement in $\text{HF} + \text{HNO}_3$ mixture.

The plot of temperature rise against the time of dissolution for the cement-5% melamine resin mix hydrated for 3, 7, 28 and 90 days was also parabolic. In this system, as the time of hydration increases from 3 to 90 days, the final temperature rise decreases from 5.09 to 3.91°C. The maximum temperature rise (T_e) is a constant value of each sample. Plots of $\log (T_e - T)$ Vs t (Fig. 4) for cement-melamine resin system were also found to be a straight-line relationship. The values of slope were 0.66, 0.59, 0.54 and 0.50 for 3, 7, 28 and 90 days hydrated samples respectively. The average K value obtained was lower with melamine resin additive compared to the values for neat hydrated cement. The dissolution of cement with and without additive was found to be of first order reaction kinetics.

Figure 4. Plot of $\log (T_e - T)$ vs. time of dissolution for cement hydrated with 5.0% melamine formaldehyde resin

Table 2 shows the heat of hydration of cement-melamine resin mixes as calculated by the difference in the heat of solution of unhydrated and hydrated samples. The values of heat of hydration of cement were 259.57, 326.41, 364.11 and 439.95 J/g for samples hydrated for 3, 7, 28 and 90 days respectively. The values for cement-melamine resin mixes were 264.09, 328.67, 368.04 and 440.99 J/g with 0.25%, 268.69, 330.93, 371.89 and 442.41 with 0.50%, 277.80, 335.40, 379.92 and 446.80 with 1.0%, 286.03, 344.34, 395.05 and 451.81 with 2% and 303.80, 348.48, 399.81 and 452.19 with 3.0% and 304.50, 349.43, 402.81 and 456.46 J/g with 5.0% melamine formaldehyde resin addition in cement hydrated for 3, 7, 28 and 90 days respectively. The values of heat of hydration (Table 2) increase with increasing concentration of melamine formaldehyde resin in cement up to 5.0%.

Table 2. Values of heat of hydration of cement with different quantities of melamine formaldehyde resin

% Additive	Heat of Hydration (J/g)			
	3 days	7 days	28 days	90 days
0.00	259.57	326.41	364.11	439.95
0.25	264.13	329.76	366.41	439.96
0.50	269.23	332.39	368.75	440.53
1.00	278.93	339.87	373.44	441.53
2.00	296.06	352.83	382.84	444.04
3.00	310.78	354.09	392.25	446.38
5.00	318.22	358.63	396.91	448.78

3.3 Setting Time

The hydration of cement constituents gives a variety of hydrates (Fig. 5 &6). The calcium silicates have been shown to have tetrahedral $[\text{SiO}_2(\text{OH})_2]^{2-}$ structure having accessible sites for the interlocking of hydrates. The gel structure of the tobermorite phases and the interlocking of hydrated aluminates and silicates bring about the stiffening of the paste and are responsible for setting of the cement paste [2]. The setting times of cements containing 0.1 to 5.0% melamine formaldehyde resin are given in Table 3. The value of initial setting time and final setting time of cement used was found to be 130 and 230 minutes respectively. Melamine formaldehyde resin mixed in cement has brought changes in its setting time as shown in Table 3. It was found to act as a retarder and has increased the initial setting time from 132 to 169 minutes with 0.1 to 5.0% addition in cement. Final setting time was also increased from 232 to 273 minutes for similar percentages of melamine formaldehyde resin added in cement.

Table 3. Setting time of cement with different quantities of melamine formaldehyde resin

% additive	Setting time (min)	
	Initial	Final
0.0	130	230
0.1	132	232
0.3	135	237
0.5	141	242
1.0	149	250
3.0	157	259
5.0	169	273

Figure 5. Microstructure of 90 days Hydrated Cement [x20]

Figure 6. Cement mixed with 5.0% melamine Formaldehyde resin [x20]

3.4 Compressive and Tensile Strength

The strength is caused by the intergrowth and welding together of the splines of calcium silicate hydrate and other phases in set Portland cement. Fig. 7 shows the compressive strength of cement mortars cured for 7, 28 and 90 days. The values are 31.60, 43.32 and 58.10 MPa respectively. The variations in the strength of cement with 0.5 to 5.0% melamine formaldehyde resin are also shown in Fig. 7. The values are 32.67, 32.79, 33.45 and 34.62 MPa at 7 days cured cement mortar, 45.10, 47.24, 49.79 and 52.76 MPa at 28 days and 59.48, 60.70, 63.96 and 66.10 MPa at 90 days with 0.5, 1.0, 3.0 and 5.0% melamine formaldehyde resin mixed in cement respectively. The values of compressive strength increase with increasing concentration of melamine formaldehyde resin up to 5.0% in cement. Cement is weak when tested under tension and organic additives have been found to increase the tensile strength. Fig. 8 shows the tensile strength of cement mortar cured for 7, 28 and 90 days. The values are 3.10, 4.43 and 5.75 MPa respectively. When melamine resin was mixed in the cement mortar, the values of tensile strength (Fig. 8) were 3.59, 3.80, 4.04 and 4.30 MPa at 7 days, 4.79, 5.03, 5.28 and 5.47 MPa at 28 days and 6.13, 6.41, 6.56 and 6.94 MPa at 90 days respectively with 0.5, 1.0, 3.0 and 5.0% melamine resin mixed in cement. The values of tensile strength increased up to 5.0% melamine resin addition in cement.

Figure 7. Compressive strength of cement with different percentages of melamine formaldehyde resin

Figure 8. Tensile strength of cement with different percentages of melamine formaldehyde resin

3.5 Indentation Hardness

With progress in setting reactions, new bonds are formed in cement products and their strength as well as hardness increase. Polymer present in the products contributes additional bonds, which causes further increase in the hardness values. Hardness (H) values were calculated by the equation: $H = 1.854 P/d^2$ in which the values of diagonal length (d) and the applied indentation load (P) were substituted. Fig. 9 shows hardness values of 90 days cured samples of neat cement as well as melamine formaldehyde resin modified cement. The hardness values of neat cement were 6.26, 6.38, 6.64 and 6.13 MPa when tested at 5, 10, 50 and 100N load respectively. In melamine resin modified cement system, the hardness (Fig. 9) value increased with the melamine resin content in cement up to 5.0%. The values were 6.62, 6.79, 6.94 and 6.98 MPa with 0.5%, 7.04, 7.39, 8.29 and 8.72 MPa with 1.0% and 8.67, 8.90, 9.27 and 9.52 MPa with 3.0% and 9.00, 9.50, 10.50 and 11.00 MPa with 5.0% melamine resin in cement tested at 5, 10, 50 and 100N loads respectively. Hardness increased at the indentation loads with increase in concentration of melamine resin.

Figure 9. Hardness of cement with different percentages of melamine formaldehyde resin

3.6 Flexural Strength and Fracture Toughness

The flexural strength (FS) of neat cement samples, as calculated by equation $FS = 3WL/2bd^2$ (Where W = Fracture load, L = Span of the bar between the two supporting edges, b = Width of the sample and d = depth of the sample at the fracture plane) was 8.82 MPa after curing for 90 days. The flexural strengths of melamine formaldehyde resin modified cement systems containing 0.5 to 5.0% additive is shown in Fig. 10. The flexural strength values obtained were 9.17, 11.63, 14.77 and 16.14 MPa with 0.5, 1.0, 3.0 and 5.0% melamine formaldehyde resin respectively after curing for 90 days. It increases with increasing concentration of melamine resin up to 5.0% in cement. The fracture toughness (K_{Ic}) of 28 and 90 days hydrated neat cement samples were 0.62 and 1.06 MPa $m^{1/2}$ respectively as calculated by equation $K_{Ic} = P_Q S / BW^{3/2} f(a/w)$ (where P_Q = Fracture load in Newton, S = Span length, B = Width of the sample, W = Depth of the sample and a = Notch depth).

Figure 10. Flexural strength of cement with different percentages of melamine formaldehyde resin

Figure 11. Fracture toughness of cement with different percentages of melamine formaldehyde resin

The average fracture toughness of cement containing 0.5 to 5.0 percent of melamine formaldehyde resin is shown in Fig. 11. The values were 1.12 and 1.42 MPa m^{1/2} with 0.5%, 1.34 and 1.61 with 1.0%, 1.56 and 1.83 with 3.0% and 1.75 and 2.14 MPa m^{1/2} with 5.0% melamine resin in cement respectively. In this system the values of fracture toughness increases with increasing concentration of additive up to 5.0% at both the ages. 5.0% additive has given good resistance to crack propagation against the applied load as evidenced by a value of toughness equal to 2.14 Mla.m^{1/2} as compared to 1.06 MPa m^{1/2} of cement under the experimental conditions.

3.7 Water Absorption

Cement mortar and concrete absorb water because of their porosity when they are brought in contact with water. The water absorption in 90 days-cured cement mortar was 9.91% by weight. Fig. 12 shows the water absorption of cement melamine formaldehyde resin mortars containing 0.5 to 5.0-wt. % additive. The values were 9.79, 9.56, 8.51 and 8.15 percent with 0.5, 1.0, 3.0 and 5.0% melamine resin addition in cement respectively (Fig. 12). The values of water absorption decreased with increasing concentration of melamine formaldehyde resin up to 5.0% as compared to unmodified cement mortar.

Figure 12. Water absorption of cement mortar with different percentages of melamine formaldehyde resin

3.8 Corrosion Resistance

The corrosion resistances of the cement- melamine resin composites were measured by the weight loss in the mortar samples after 4 days (2 renewals each day) immersion in 0.1 and 1.0N H₂SO₄ and HCl respectively. The weight loss is much less in the composites as compared to the blank cement mortar. It shows that the polymer is able to impart corrosion resistance to cement. These findings are similar to earlier results reported on corrosion resistance of polymer composites. The weight loss in 90 days cured ordinary cement mortar after 4 days immersion in 0.1 and 1.0N H₂SO₄ were 1.15 and 6.24% respectively. The percent weight loss in samples made with different quantities of melamine formaldehyde resin mixed in cement is shown in Fig. 13. It can be seen that the percent weight loss decreases with increasing concentration of melamine resin in cement up to 5.0%. The values were 0.69 and 6.14% with 0.5%, 0.46 and 5.35 with 1.0%, 0.02 and 3.50% with 3.0% and 0.01 and 1.90% with 5.0% additive in cement after immersion in 0.1 and 1.0N H₂SO₄ respectively for 4 days.

Figure 13. Corrosion resistant cement with different percentages of melamine formaldehyde resin in different aggressive media

The weight loss values were less as compared to the values for neat cement mortar with different percentages of additive. The value of weight losses in ordinary cement mortar after 4 days immersion in 0.1 and 1.0N HCl were 4.95 and 8.61% respectively (Fig. 13). The weight losses were 4.28 and 8.11 percent with 0.5%, 3.36 and 7.48 with 1.0%, 2.77 and 6.74 with 3.0% and 2.42 and 6.38 percent with 5.0% melamine formaldehyde resin in cement and immersed in 0.1 and 1.0N HCl respectively.

The 5.0% melamine resin additive to cement was found to be more resistant than other proportions. The weight loss of ordinary cement-mortar after one-month immersion in seawater was 3.48 percent. The weight losses were also determined with 0.5 to 5.0 percent melamine formaldehyde resin in cement-mortar after one-month immersion in seawater. The values were 2.48, 2.34, 2.23 and 2.00 percent with 0.5, 1.0, 3.0 and 5.0 percent additives (Fig. 13) respectively. The percent weight loss decreases with increasing concentration of melamine formaldehyde resin in cement up to 5.0%.

3.9 Microstructure

Microscopic examination of the composite revealed the presence of polymer in the capillary canals, pores and micropores of the hydrated cement gel. The microscopic photographs have shown a difference between the modified and ordinary cement samples (Fig. 5&6). The microphotograph of the melamine resin modified cement paste shows a glassier surface than the cement gel, probably due to the presence of melamine resin within the high-surface area structure of the hydrated cement.

There is mutual influence of both organic polymer and cement on the hydration and polymerization process under the preparation and curing conditions. In mixes, cement and melamine resin are interspersed and react with each other at room temperature to create a material with high flexural strength, which is free from major defects. The microstructure of these composites consists of close packed, cement particles, embedded in a continuous matrix.

4. CONCLUSIONS

1. The studies indicate that modified cement possess higher strength compared to ordinary neat cements.
2. This increase has been related to the decrease in porosity. The decreased porosity may be due to high water solubility and presence of organic material in pores.
3. The melamine resin modified cements are also more resistant to corrosion.
4. Melamine formaldehyde resin interacts with neat cement through the NH_2 reactive/functional group.

BIOGRAPHY

Author presenting the paper, Dr. V.K.Singh was born on June 10, 1944. Married to Dr. Sushila Devi, has three sons. He obtained his B.Sc. Silicate Technology in 1968, M.Sc. Ceramic Engineering in 1970 and Ph.D. Ceramic Engineering in 1976. He joined as Faculty member of the Banaras Hindu University in 1971 and since then he is continuing his services and at present he is a Professor and Head, Dept. of Ceramic Engineering, Institute of Technology, Banaras Hindu University. He has about 65 published papers in Journals like American Ceramic Society, British Ceramic Transactions and Journal, Journal of Material Science, Journal of Material Science Letter, Ceramic International, Cement and Concrete and National Journals of repute.

He was awarded International Scientific Exchange Fellowships to work in U.K., South Korea and Slovak Republic. He has attended and presented papers in U.S.A., Sweden and Slovak Republic. He is a fellow of Indian Institute of Ceramics and also a member of the Award Committee of the Indian Ceramic Society. At present he is also the In-charge of the Library and Museum of Indian Ceramic Society at Banaras Hindu University. An Ex-Officio Council Member of Indian Ceramic Society and a member of Center for Development of Glass Industries, Govt. of India, he is also an Expert Member of Bureau of Indian Standards.

GHG, OTHER GASES AND POLLUTANT EMISSION TRENDS AND PROJECTIONS FOR THE CEMENT INDUSTRY IN INDIA

Sumana Bhattacharya¹, S P Ghosh² and A. V Srinivasan³

Winrock International-India, Cement Manufacturers' Association of India.

ABSTRACT

Global warming and the consequent climate change is likely to pose a serious threat to the present habitat and many life-forms on the planet. This has raised concern amongst all nations. The UN Framework Convention on Climate Change (UNFCCC) binds all countries which are party to this Convention to take up a common but differentiated responsibility in addressing the issues of Climate Change. The concentration of CO₂ has increased by 31% since pre-industrial times and is earmarked for priority abatement through the mechanism of "carbon trading" between developed and developing countries. The cement industry consumes 5% of the total global industrial energy and contributes to 5% of GHG emission. The present article is a summing up of inferences for the Indian cement industry from several on-going studies in India on estimation of GHG emission during the last two decades in different sectors of the national economy. Among GHGs Carbon dioxide (CO₂), and Nitrous oxides (NO_x) and, in addition, Sulphur oxides (SO_x) are emitted by cement manufacturing process. In general, about 1 ton of CO₂, is released from 1 ton of cement manufactured. (NO_x) and (SO_x) emissions are relatively insignificant in comparison and are in the 10 to 20 kg per ton of cement produced. The emission of these last two can also be brought to negligible levels through the adoption of modifications in process parameters and operations. The approximate contributions of each of the 3 main sources of CO₂ emissions are: Calcination = 50 – 55% Fuel Combustion = 40 - 50% and Electricity including captive power generation = 0 - 10%. Thus for the 1990s, the Indian Cement industry emitted CO₂ on an average annually about 50 million tons due to the process of calcination, 40 million tons from coal combustion, and 7.4 million tons from electricity consumption, using grid or captive power.

The Indian cement industry being the second largest in the world in installed capacity and annual production, has a major role to play in CO₂ emissions reduction. A review of the Indian cement industry over the last two decades shows that although state-of-art plants are comparable to the best in the world in energy consumption and CO₂ emission, the industry average of 1.102 tons of CO₂ emissions per ton of cement is much higher than the world average of 0.746 tons. The calculated CO₂ emissions for the Indian cement industry on annual basis for the period 1980 to 2000 shows that technological upgrading has curbed the annual growth rate of CO₂ emissions. Thus, although India emitted a total of about 778 million tons of CO₂ from all activities in 1995 and about 1000 million tons in 2000, the share of the cement industry to the total CO₂ emission has increased marginally from 4 to about 5% during these years. The present annual growth rate of the industry (8 to 10%) and its pattern portend this trend of CO₂ emissions to continue. However, the expected massive upsurge in the long-sought infrastructure development in the coming years may lead to a quantum leap in growth of cement capacity and production.

¹ Expert Consultant, Winrock International India

² Advisor (Technical), Cement Manufacturers' Association of India

³ Secretary General, Cement Manufacturers' Association of India

This will call for Clean Development Mechanisms and other devices to be adopted on a large scale to minimise CO₂ emissions.

1. INTRODUCTION

There is overwhelming evidence that rapid industrialization since the last century has led to a rise in greenhouse gas (GHG) emissions such as CO₂, CH₄ and N₂O in the atmosphere leading to an additional warming of the Earth's atmosphere. Over the 20th century the increase in the earth's surface temperature has been $0.6 \pm 0.2^{\circ}\text{C}$ and under the combined influence of Green House Gases and sulfate aerosols, climate may warm globally by 1.4 to 5.8°C by the year 2100 [1]. As a result the global sea level will rise between 0.09 to 0.88 m in the period 1990 to 2100 and extreme events like excessive rain, flash floods, droughts, cyclones and forest fires are likely to increase, threatening major climate change and impact on the entire earth system in an unprecedented manner [1]. Global leaders have by and large accepted the fact that climate change is the most pressing and dangerous threat to life on earth today.

Among the responses to counter this major threat, the most significant response formulated is the United Nations Framework Convention on Climate Change (UNFCCC) of May 1992 ratified so far by 182 countries. The three important provisions in the Convention required developed countries to (a) bring down their Green House Gas (GHG) emissions by 2000 to the level at which it was in 1990; (b) prepare national communications with information on policies and measures undertaken for reducing GHG emissions, and, (c) provide financial resources to meet the agreed full costs incurred by developing country parties in complying with their commitments relating to national communications. The annual Conference of Parties (COP) is the consequence of this framework. In 1997, the third such meeting (COP-3) at Kyoto adopted a Protocol, which sought to reduce emissions even more. The Kyoto Protocol required Annex 1 countries (Annex 1 listed 41 countries: industrialised and developed nations as well as Economies in transition like the former Soviet Union countries and Eastern European nations) to collectively reduce GHG emissions by 5.2% below 1990 levels in the course of the implementation period of 2008 to 2012.

So far, countries contributing 37% of Annex 1 countries' total emission had ratified the Kyoto Protocol. Now, Russia contributing 17% and Canada contributing 2% of global GHG emissions have indicated the likelihood of their ratifying the Kyoto Protocol at COP-8 to be held at New Delhi.

1.1 Significance of the Present Study

In addition to the aforesaid, the Annex-1 Parties in the Kyoto Protocol, individually or jointly, agreed to reduce their overall emissions of the six GHGs to at least 5 percent below 1990 levels in the first Quantified Emission Reduction commitment period 2008-2012. Cuts in the three most important GHG gases viz, Carbon dioxide (CO₂), Methane (CH₄) and Nitrous oxide (N₂O) will be measured against the baseline year 1990 while the cuts in other 3 gases viz, Hydrofluorocarbons (HFC), Perfluorocarbons (PFC) and Sulphur Hexafluoride (SF₆) can be measured against baseline year 1990 or 1995. 180 Signatory countries to the Kyoto Protocol are therefore putting their acts together for a reliably accurate assessment of emission of the stated gases over the past decades and are formulating action plans for emission reduction in the coming years.

India is a Party to UNFCCC but, being a developing country, it does not have any emission reduction commitments under the Kyoto Protocol. India has taken many steps to achieve energy efficiency, fuel switching, afforestation, and use of renewable energy technology (RET) as a part of the national planning process. These deliberate actions have aligned economic development to a more climate friendly path. In order to achieve sustained economic growth, India cannot stop growth in energy consumption. The energy consumption in India is rising due to growing

industrialisation, rising incomes, expanding urbanisation, and modernisation of agriculture. Carbon emissions, the major GHG emitted, has almost grown parallel to energy use. Local pollutant emissions show a slower rate of growth. Biomass emissions which contribute significantly to total emissions, have grown below 2% per year.

The present article is a summing up of inferences for the Indian cement industry from several on-going studies in India on estimation of GHG emission during the last two decades in different sectors of the national economy.

2. MAJOR SOURCES OF EMISSION

The activities that are believed to be responsible for climate change induced by GHG emission are the levels of anthropogenic activities. Fossil fuel (coal, oil, natural gas) burning in the energy and transportation sector, industrial processes, agriculture activity, land use, land use change and forestry, and waste generation due to industrial activities since 1750s has led to the increase in CO₂, CH₄ and NO_x concentrations in the atmosphere by 31%, 151% and 17% respectively [1]. In the urban and industrial centres, energy intensive activities in various industrial processes such as power generation, chemical (fertilisers, pesticides, pharmaceuticals, textile fabric etc) and metallurgical processes (iron and steel and various metals production), mining and construction and related activities (cement, brick and other construction materials), consumer goods, heating and cooling systems (airconditioners, refrigerators, heaters) have contributed to significant emission of the 7 major GHGs like Carbon dioxide, Methane, sulphur oxides, nitrous oxide, Hydrofluorocarbons (HFC), Perfluorocarbons (PFC) and Sulphur Hexafluoride (SF₆). The major sources of these emissions are:

Carbon dioxide: It is the biggest villain. The sources for its emission include human exhalations, industrial and economic activities, limestone dissociation in industrial processes like lime, cement, fertilisers, chemicals and pesticide manufacturing etc., biomass burning, incomplete combustion of vehicular fuel and land use and land use change.

Methane: The sources include emissions from agriculture such as rice cultivation, enteric fermentation, collection and storage of organic matter like animal manure, extraction and transport of fossil fuel.

Nitrous oxide: The sources of this gas are supply and use of fossil fuel, fertiliser, high temperature processes leading to combination of atmospheric nitrogen and oxygen.

Sulphur Hexafluoride: Is used as an electric insulator, heat conductor and freezing agent.

Hydro Fluoro Carbons/Per Fluoro Carbons: Used as ozone safe replacements.

In 1995-1996, the greenhouse gases emitted in India were about 1259 million tons in terms of CO₂ equivalent which is only about 3% of the total global GHG emissions. Out of the total Indian GHG emissions, CO₂, CH₄ and N₂O emissions were at 778, 18 million and 0.225 million tons respectively. Additionally, about 5.3 million tons of SO₂ and 3.4 million tons of NO_x, which are local pollutants, were also emitted. Table 1 gives the GHG and pollutant emissions from various sectors in India for the year 1995-1996.

Table 1. GHG emissions from India in 1995

<i>CO₂ emissions</i>	<i>Million tons</i>	<i>% of the total</i>
Electric power generation	348	44.6
Transport sector	113.4	14.6

Source: [4], [5].

As can be seen from Table 1, within the industrial processes, CO₂ emissions from steel production exceed those from cement production contributes CO₂ only next to the emissions from steel production. Since the cement production in the country in the year 2000 has increased by about 35% since 1995, the GHG and pollutant emissions from this sector will also have grown. The cement industry involves mainly the emission of the following GHGs:

2.1 Carbon dioxide

- (a) Dissociation of limestone in the raw mill
- (b) Burning of fossil fuels
- (c) Captive power generation either from diesel generating sets or from thermal power plants
- (d) Fuel and power use respectively for mining of limestone and other raw materials and packing and handling of cement

The average quantity of CO₂ emitted is in the range of about 1 ton per ton of cement produced.

2.2 Nitrogen dioxide

Nitrogen oxides are generated in the process of burning of fuel at high temperatures of about 1500°C where atmospheric nitrogen and oxygen combine to form Nitrogen oxides. The quantity generated however, is insignificant and ranges between 1.7 to 2.1 gms per kg of clinker. The quantity released is thus relatively small.

2.3 Sulphur Oxides

These are released in the process of combustion of fossil fuel and also from oxidation of sulphur contained in the raw materials in the process of clinker formation. Almost 70 to 90% of sulphur oxide released during the burning process is absorbed by the nascent clinker. The balance, released as stack emission, varies from 2 to 5 gms per kg of clinker. The quantity released is also relatively small.

The other components of GHGs are not emitted during the process of cement manufacturing.

It is clear from the aforesaid that CO₂ constitutes the lion's share amongst all the GHG emission from the cement manufacturing process, and almost equals the quantity of cement produced. In this paper, we therefore present the account of GHGs and pollutants emitted from the cement sector with specific focus on CO₂ emission and try to link this emission with the change in technology over the years.

3. THE INDIAN CEMENT INDUSTRY

The cement industry in India has been growing at a fast pace during the last 20 years - both in terms of its capacity and improved technology, particularly after 1982, when the Government adopted the policy of partial decontrol. The progress has been possible through modernisation of cement production technology, development of infrastructure, energy-efficiency, and the R&D work carried out by the research institutions. In 1999 and 2000 India produced about 7% of the total global production and is second only to China (see Table 2).

Table 2. Major cement-producing countries

Country	Production (million tons)	
	1999	2000
China	573.0	597.7
India	99.1	101.8
USA	85.0	84.7
Japan	83.47	85.95
South Korea	49.5	52.2
Other countries	711.22	742.34
TOTAL GLOBAL	1601.29	1664.69

Source: CEMBUREAU [6]

Cement industry is a core sector industry and forms the backbone of infrastructure development of the country. The Industry has shown steady and consistent growth in the last three decades. The industry grew 4 times both in terms of capacity and production in the last two decades. The capacity and production, which were nearly 29 MT and 21 MT in 1981, shot up to 133.55 MT and 98.35 MT respectively in 2001, with the capacity utilization in the industry being 70%-80% over this decade. The industry is presently growing at the rate of 8% - 10% per annum (Table 3).

Table 3. Production, capacity and capacity utilization of Major cement plants in India (Excluding Mini and white cement plants)

Year	Cement production (million tons)	Capacity at the end of year (million tons)	Production Growth(%)
1981	20.77	28.87	
1982	22.54	31.78	8.5
1983	25.14	35.86	12.7
1984	29.14	39.10	14.7
1985	31.11	41.85	6.8
1986	33.65	49.10	8.2
1987	36.97	55.51	9.9
1988	40.72	55.04	10.1
1989	42.07	56.36	3.3
1990	44.87	58.12	6.7
1991	49.47	60.61	10.3
1992	50.87	62.46	2.8
1993	52.78	66.90	3.8
1994	57.57	73.19	9.1
1995	62.08	82.06	7.8
1996	68.86	90.17	10.9
1997	74.75	99.92	8.6
1998	79.42	108.41	6.2
1999	91.72	109.44	15.5
2000	95.94	116.82	4.6
2001	98.35	133.55	2.5

Source: Basic Data, Indian Cement Industry, 2001, 2002

Cement manufacturing in India is location-specific. Most cement plants (65%) have been built in clusters in areas which have limestone deposits. The regional distribution of plants, specifically for large plants, leads to long haul of cement to consumption areas by rail and road transport. Distances being large in India, the transport of cement assumes an important aspect of cement business. Road transport which is less eco-friendly due to its entire dependence on fossil fuels than the railways and waterways, carries nearly 68% of the cement produced. A reduction in road-share of cement transport will lead to a reduction in CO₂ emissions – a potential contribution of cement business.

In the year 2001, the entire Indian cement industry, comprised 123 large cement plants and 365 mini plants, with a total installed capacity of about 144.65 million tons and a production of 102.35 million tons, comprising ordinary Portland cement (57.3%), blended cements (40.5%) and others [Basic data, Indian Cement Industry, 2001-2002]. However, as indicated in Table 3, the production of cement from large plants only was about 98.35 million tons out of the capacity of 133.55 million tons. In an industry which is in its ninth decade of existence, there is naturally a spread in the age, technology and capacities of the plants but this has steadily been sought to be narrowed down by renewal, modernisation and expansion. The energy performance of Indian cement plants is comparable to the best in the world (Table 4).

Nearly 94% of the plants are based on the modern dry process technology with suspension pre-heaters and precalciners, and 63 out of 123 large plants have annual capacity of 1 million tons and over, many of them approaching international benchmarks in specific thermal and electrical energy consumption. Semi dry and wet process are used by 2% and 4% respectively of the Indian cement manufacturing capacity. Dry process is the most energy efficient of all the technologies in use. Figure 1 shows how the plants have shifted to use dry technology from wet technology from 1980 onwards.

Table 4. Best Energy Performance by State-of-art Indian Plants and the Best in the World.

Energy Performance (2001)	Best in India	Best in the World
Thermal (Kcal/kg of clinker)	665	650
Electrical (kwh/tons of cement)	69	65

Source: Forecasting Technologies for the Indian Cement Industry, Department of Science and Technology, Government of India, 2002.

For the production of cement, three types of clinkers are distinguished from energy consumption and gaseous emission viewpoint: rotary kilns (large), rotary kilns (small) and shaft kilns. Out of a total 144.65 million tons installed capacity in 2001, large rotary kilns constituted 133.56 million tons, mini rotary (including white cement) and shaft kilns constituted 11.10 million tons capacity. Out of the latter category, rotary mini plants constituted about 4 million tons and shaft kilns about 7 million tons. Out of a total 102.35 million tons cement production in 2001, 98.35 million tons was contributed by large plants and only 4 million tons by the others. Out of a total 125.30 million tons installed capacity in 2000, large rotary kilns constituted 116.3 million tons, mini rotary (including white cement) and shaft kilns constituted 9.0 million tons. Out of the latter category, rotary mini plants constituted about 4 million tons and shaft kilns about 5 million tons. Out of the total 102.35 million tons production in 2001, 95.94 million tons was contributed by large plants and only 6.24 million tons was contributed by the others [7]. These figures substantiate the relatively insignificant role of small rotary and shaft kilns in cement manufacture.

Figure 1. The changing face of technology mix in the Indian cement sector since 1980s

4. PROCESS PARAMETERS

Presently most of the cement produced in large cement plants is through the dry process. In the year 1997 approximately 88% of the country's total production was from dry process (source: CMA Basic Data, 1998). Dry process is the most energy efficient of all the technologies in use. In contrast, in the year 1947 almost 100% of country's production was from the wet process and only Ordinary Portland Cement was produced.

Each unit operation in cement making involves either thermal (fuel) or electrical energy and related GHG emission. These are designated as (f) for fuel related emission and (e) for electrical energy related emission (thermal power plants and captive power generation).

5. ENERGY CONSUMPTION PATTERN

As mentioned earlier, cement manufacturing is a very energy-intensive process. The most energy-intensive stage of the process is clinker production, which accounts for up to 90 percent of the total energy used. The grinding of raw materials and of the cement are both electricity-intensive steps and account for much of the remaining energy used in cement production.

Coal (as a thermal energy source) and electricity are the two major energy sources for Cement production in India. Besides these, some petroleum (HSD & Furnace Oil) is used in the manufacturing process.

Figure 2. The Cement Production Process

Figure 3 shows the trend of coal consumed in the country for cement production. This data includes use of coal, lignite, and petroleum products for captive power plants.

Energy requirements for cement grinding are roughly double those for raw material preparation because the cement is harder and needs to be ground more finely than the raw materials. An important issue when considering “best practice” energy requirements for grinding is that energy use is related to the hardness of the raw materials and the additives included before cement grinding as well as the desired fineness of the finished product. These features can vary, so it is important to specify the fineness and composition of the product when discussing energy use.

Figure 3. Fuel consumption in the cement sector

The Specific energy consumption of a cement plant is reckoned in two forms: –

- kilo calories/kg. of clinker for the thermal energy and
- kWh/t of cement produced for the electrical energy

The average values for these two on an overall Indian cement industry basis are 840 kcal/kg and 114 kw/t respectively. There are also some cement plants, which have very low specific energy consumption and are comparable with the best in the world.

Specific energy consumption values of the Indian cement industry have been coming down over the past several years with the changes taking place from wet to semi-dry and then to dry process and also with the adoption of energy efficient technologies and improvement in the energy management systems.

Various studies carried out by the Confederation of Indian Industries (CII), NCB and Cement Manufacturing Association (CMA) show that thermal and specific energy consumption levels in different technologies vary between 800-1600 Kcal/Kg clinker and 98-135 Kwh/t cement produced respectively for different processes (Table 5).

Table 5. Energy consumption levels of different technologies in Indian Cement Sector

Technology	Specific Fuel Consumption (Kcal / Kg of Clinker Formation)	Specific Power Consumption (Kwh/t of Cement Production)
Dry Process	800 -1060	98 - 114
Semi Dry / Semi Wet Process	950 -1140	112 - 145
Wet Process	1 300-1600	114 - 135

The total consumption of fuel and electricity in the cement industry has grown significantly. However, the specific fuel consumption has reduced over the years. Also, electricity consumption per ton of cement has been significantly reduced due to the compensating effects of the closure of old energy-inefficient wet process plants and setting up of modern dry process plants with progressively more and more energy-efficient machinery for grinding and clinkerisation. Some of the recent studies carried out by the Confederation of Indian Industry (CII) & National Council for Cement & Building Materials (NCB) for cement plants indicate that the average specific thermal energy consumption is around 815 Kcal/kg for dry process and 1340 kcal/kg of clinker for wet process. Also, the average specific energy consumption for dry process is pegged at 112 kWh/T and for wet process it is 101 KWh / T (see Tables 6 and 7). Almost all cement plants have installed captive power plants to meet the essential power supply as the power supply from the grid system is unreliable and has wide fluctuations. The captive power plant capacity in megawatts of the cement industry is given in Table 8 both for Diesel Generating (DG) Sets and for thermal generation.

Table 6. Data on Energy Consumption for 33 Dry and 3 Wet Process Cement Plants

Energy Consumption	Dry Process		Wet Process	
	Range	Weighted	Range	Weighted
Specific Thermal Energy Consumption (Kcal / Kg)	671 - 1017	815	1279 - 1406	1340
Specific Electrical Energy Consumption (Kwh / T)	86 - 152	112	90 - 111	101

6. GREENHOUSE GAS, OTHER TRACE GASES AND POLLUTANT EMISSIONS FROM THE CEMENT INDUSTRY

Cement manufacture is based on consumption of major quantities of non-renewable natural resources like limestone, coal, gypsum etc.; the clinkerisation process involves generation of CO₂- a greenhouse gas. In the year 2000, 1.66 billion tons of cement was produced throughout the world and 1.4 billion tons of CO₂, CO and NO_x were released into the atmosphere, contributing thereby to a major share of global warming. The effect of greenhouse gas to global warming is now widely accepted and efforts are being made to limit these emissions. This has given a boost to efforts for energy efficiency as stated above.

Alternative energy-economic routes of cement manufacture (eg., microwave clinkerisation) or large value-addition to the main down-stream product (eg. concrete) through high performance (high durability) binders (eg., Macro Defect Free, Densified System of Phases) with lesser cement consumption are new areas of technology evolution. The other area of environmental concern is the emission of Suspended Particulate Matter (SPM) that causes dust pollution.

The cement industry has looked upon this problem positively, as efforts to reduce SPM could increase output of cement and therefore thermal efficiency. It is with these efforts that cement industry, which was considered as a highly polluting industry in the early days, is now accepted as one of the modern industries which is far less polluting than many others. This has been achieved by fitment of efficient ESPs, use of bag filters, etc. These modifications have resulted in bringing down SPM levels to 70 mg/Nm³ and even up to 50 mg/ Nm³ in some cases.

Cement production is also one of the most energy intensive processes. This industry consumes about 2% of the global total of primary energy consumption or almost 5%. Due to the dominant use of carbon intensive fuels, e.g. coal, in clinker making, cement manufacture is a major emitter of CO₂. Besides energy consumption the clinker making process also emits CO₂ due to calcining process of limestone involving the release of CO₂ from dissociation of calcium carbonate in limestone. About 5% of the total global emissions of CO₂ are attributed to the cement sector.

Emissions in the cement industry comprise five gases considered as GHG viz. carbon dioxide, carbon monoxide, NO_x, sulphur oxides (SO_x), and hydrogen sulphide. In developed countries, limits have already been prescribed for NO_x and SO_x in the kiln stack. However, in India only two states, namely Meghalaya and Gujarat have adopted such norms. The Central Pollution Control Board (CPCB) is reported to be contemplating fixing the emission limits for SO_x, and NO_x. The role of each of these gases as emission, and the role and impact of heavy metals in cement manufacture have been excellently explained in [3] and are summarised below.

6.1 Oxides of Nitrogen

The clinker burning process causes the formation of nitrogen oxides (NO_x) in the sintering zone as also in the low temperature calcining zone. In the sintering zone there is predominant formation of thermal NO_x from atmospheric nitrogen, partially overlaid by the formation of nitrogen oxides from the nitrogen in the fuel. In the calcining zone the NO_x is formed from nitrogen in fuel. The source

for NO_x emission has been compounded in the cement industry due to the compulsive use of lower grades of solid fuels as well as industrial wastes containing combustibles.

The statistical calculation of NO_x emission measurements at a large number of cement plants equipped with / preheater rotary kilns showed a mean value of 2.1 g N per kg of clinker, which corresponds to 1050 mg/Nm³ in the exhaust gases related to 10% oxygen. While NO_x emissions are not spiky and highly variable in specific plants there would be short or long term changes.

The ways of reducing the NO_x emission are classified broadly as primary and secondary. The primary methods are designed to act on the following influencing factors to minimise the generation of NO_x during the combustion process:

- (a) Flame shape and temperature
- (b) Combustion chamber temperature
- (a) Combustion air temperature
- (b) Excess air in the combustible gases
- (c) Residence time of fuel
- (d) Nitrogen content of fuel

The most important measure is to ensure an optimum and stable kiln operation with homogenised raw mix, uniformly dosed fuel, effective cooler operation, etc. It is claimed that certain low- NO_x burners also help in achieving lower emission. Designs of low- NO_x burners vary in detail but essentially the coal and air are injected into the kiln through 3 or 4 concentric tubes with only 6-10% of primary air. The general effectiveness of a low- NO_x burner reportedly is limited.

On the other hand, the secondary reduction measures reconvert the already formed NO_x back into elementary nitrogen by any of the following processes:

- (a) Selective non-catalytic reduction (SNCR)
- (b) Selective catalytic reduction (SCR)
- (c) Multistage burning (MSC)

For the SNCR process the basic principle is to reduce NO_2 with the help of ammonia injection through special nozzles into the kiln inlet zone. Ammonia disperses freely in the gas stream and the reduction reaction occurs in the temperature range of 900°-1100°C. The reaction obviously is dependent on the molar ratio of NH_3 to NO_2 . The SNCR technique has undergone year-long trials in a 2000 tpd cement kiln, in which the above molar ratio was maintained at about unity with NO_2 reduction rate of up to 80% without any escape of NH_3 . Data collected for 2 months from a good number of plants showed the efficacy of the SNCR technique of keeping the stack NO_x emission always below the limit despite wide fluctuations in the NO_x generation inside the kilns.

In the SCR technique the NO_x reduction process is carried out on a noble-metal loaded catalyst surface with NH_3 injection at a lower temperature of 350°C without any adverse effect on sulphur-bearing gases. The process is extensively used in the power sector but seems to be too expensive to be adopted in the cement industry.

The concept of MSC is also borrowed from the power industry and involves installation of burners at different stages of the pyroprocessing line to reduce NO_2 . In the Prepol MSC the kiln gases encounter a burner at the kiln inlet which produces a reducing atmosphere and decomposes a part of the nitrogen oxides generated in the sintering zone. Further in the precalcining stage the fuel is burnt with a quantity of tertiary air, producing a reducing atmosphere there. In the last combustion stage the remaining tertiary air is fed into the system as 'top air' for residual combustion. Thus, in this specific design there were four stages of combustion starting from the burning zone.

Based on similar concepts, a few other denitrating designs of precalciners have been developed and used, one being in India being DD-furnace of erstwhile Nihon Cements of Japan.

With all these developments in place, the statutory emission limit either in force or awaiting introduction in many countries is now 800 or 500 mg/Nm³ (10% O₂) which would correspond to 1.7 or 1.19 NO₂ per kg of clinker, although the World Bank Environmental Requirements demand a limit of 400 mg/Nm³ for stack emission and 100 µg. m³ of NO₂ as annual arithmetic mean for ambient air quality.

6.2 Sulphur Dioxide

It is well known that the source of SO₂ in the gaseous emissions is sulphur and its compounds appearing in fuel and raw materials. Unlike other industries such as steel and power, the cement industry has a unique inbuilt desulphurisation mechanism, by virtue of which the lime and alkali from the raw materials react with sulphur compounds and trap it in the clinker. Generally, it is observed that 70-90% of sulphur gets trapped this way and 10-30% would only appear in the stack gases.

The roller mills turns out to be the most effective machine for combined drying and grinding and consequently to utilise large quantities of kiln gases to treat raw materials containing up to 20% moisture. This mode of operation obviously allows maximum absorption of SO₂ from the kiln gases in the raw mill.

So far as the kiln systems are concerned the pattern of emission is influenced by the content and form of sulphur in raw materials and fuels and the sulphur cycle that develops in the kiln-preheater system. The precalciner kilns with high levels of free lime in the precalcined material behave as better absorbents of SO₂ into the kiln feed and consequently into the clinker.

On the whole the SO₂ emissions are highly variable in cement plants. Even from a particular kiln the emissions may fluctuate widely (10: 1 or greater).

The abatement of SO₂ emission is generally effected through the following approaches:

- (a) Process and plant modifications
- (b) On-line techniques
- (c) Off-line techniques

In the first approach the possibilities of minimizing the input of sulphur into the system are explored. The maintenance of oxidising conditions (O₂ > 2%) at the back end of the kiln and in the lower stages of the preheater is important to facilitate the faster reaction between CaO and SO₂. For the same reason reducing conditions are avoided at the gas outlet of the precalciners. In the raw mix design stage the stoichiometric balance between alkali and sulphate is attempted to ensure entrapment of sulphur in the clinker phases.

For on-line abatement plant-scale trials have been carried out with injection of hydrated lime into the riser duct between the two top preheater stages. This injection system consists of a storage silo for the hydrated lime, proportioning and conveying equipment and a pneumatic injection unit. The success depends on the uniform distribution of the hydrated lime in the gas stream for effective gas-solid reaction. Operating results have indicated that the SO₂ emission can be reduced by up to 70%, when the input of hydrated lime is highly over-stoichiometric. It may be relevant to mention here that these kinds of desulphurisation process (wet or dry) are expensive to install and mostly produce a waste product that may be difficult to recycle directly into the clinkering process. To overcome some of these problems one of the plant suppliers has attempted to install a pilot plant with a

travelling bed reactor which can absorb high SO₂ emissions into a medium that would serve to provide secondary gypsum for cement grinding.

So far as the off-line facilities are concerned, they relate to processes like wet-scrubbing or dry absorption of SO₂ and are required only when major reduction of SO₂ is called for. In wet scrubbing the gases are first passed through a heat exchanger and then reacted with limestone slurry in an absorber. The clean gas, after reheating, is released into the atmosphere. There are alternate routes like injection of slaked lime into a spray drying chamber or into an existing conditioning tower of the cement plant

A dry plant to absorb SO₂ has also been developed which uses a circulating fluidised bed of calcium hydroxide mixed with raw meal. This system has been operating in a Swiss plant. Another dry scrubber is based on activated coke as a filtering medium for the dirty gas and has been installed at another Swiss plant. This type of dry scrubber is capable of reducing not only the SO₂ emission but also other pollutants like NO_x and heavy metals.

The main problems of these offline systems are high capital and operating costs as well as recycling of effluents. So far as environmental regulations for SO₂ emissions are concerned, the norms vary from country to country in the range of 200 to 1000 mg/Nm³, the preferred range being 400-600 mg/Nm³ for normal raw materials. Many countries have kept special regulatory provisions up to 1800 mg/Nm³, if especially high-sulphur raw materials are used. The environmental requirements of World Bank for the cement plants have the following limits for SO₂:

Stack emission	400 mg/Nm ³
Ambient air quality	100 µg/m ³

However, the norms provide for some relaxation in the ambient air quality by permitting maximum 24-h peak value to touch 500 µg/m³ outside the plant fence and 1000 µg/m³ inside the plant.

6.3 Trace Elements and Metals

Since trace elements including alkaline, transition and heavy metals occur to some extent in all raw materials and fuels, their appearance in the cement manufacturing process is almost inevitable. Some trace elements tend to volatilise and move on with the kiln gases to form volatile cycles. On condensation on the dust stream these metals are principally incorporated in the clinker, although a small portion is carried out in the form of SPM. Generally the heavy metals are classified in 3 groups:

- I. Hg, Cd, TI
- II As, Co, No, Se, Te
- III. Sb, Pb, Cr, Cu, Mn, V, Sn Plus Zn

Generally the emissions of the first two groups of metals do not exceed 0.1 mg/Nm³ while the third group emission maintains at less than 0.3 mg/Nm³, unless the initial concentration of the trace elements in the raw materials and fuel is abnormally high. Hence in common practice these emissions do not pose any serious threats.

6.4 Carbon dioxide emissions

Carbon dioxide generated from the cement industry is the major contributor of GHG. For example, in producing a ton of Portland cement clinker, 0.87 to 1.00 ton of CO₂ gas is discharged from the calcination of limestone and combustion of fuel. Taking into account the global production of different varieties of Portland cement it is estimated that about 500 million tons of CO₂ emission per year is broadly attributable to the cement industry, which works out to be 2% of gross emissions of all industries.

The two processes from which CO₂ is emitted from cement manufacturing are (i) calcination and (ii) emission from fuel use. CO₂ is released from calcining the limestone in the raw mix. The quantity of CO₂ released is proportional to the calcium carbonate content of the limestone. Compilation of individual plant-wise quantity and quality limestone consumed for the studied years provides accurate assessment of the total CO₂ released:

The share of CaO in clinker usually amounts to 64-67%. The remaining part consists of **silica**, iron oxides and aluminum oxides in decreasing order. CaO content of clinker is a fairly accurate measure of CO₂ emission from limestone dissociation, unless the source of CaO is other than limestone. Such exceptions, e.g., plants using lime-sludge or partly (insignificantly) calcium silicate in crystalline limestone are known and are accounted for in the assessment. The specific process of calculating CO₂ emission from cement production depends on the ratio of clinker to cement. The ratio varies from 0.5 to 0.95, depending upon the type of cement produced.

The fuel in pyroprocessing for clinker making is primarily coal. Lignite has been marginally used by the industry, and only in a few regions in the proximity of lignite sources. The amount of CO₂ released during this process depends on the type of coal used and its ultimate analysis (coal, fuel oil, natural gas, petroleum coke, alternative fuels). The total CO₂ released depends on:

- Types of production process (efficiency of the process or sub-process)
- Fuel used – coal, lignite, natural gas
- Clinker/cement ratio

For the Indian cement industry, quality and quantity of coal supplied to plants under the linkage agreement between cement industry and Coal India Ltd. (the sole coal mining and supply authority since 1972) is well documented. CO₂ emission owing to coal burning in each year is therefore calculated on the basis of proximate analysis (fixed carbon and volatile matter content) and cross checked from the ultimate analysis.

As a common yardstick, total CO₂ emissions per ton of cement range between 0.85 to 1.15 tons, assuming clinker to cement ratio to be 0.95 [IPCC, 1996]. The approximate contributions of each of the 3 main sources of CO₂ emissions are:

Calcination	=	50 – 55%
Fuel Combustion	=	40 - 50%
Electricity	=	0 - 10%

Thus, for the year 2001, the average level of CO₂ Emission worked out for the Indian cement industry is found to be 50 million tons due to the process of calcination, 40 million tons from coal combustion, and 7.4 million tons from electricity consumption, using grid or captive power. Table 9A provides an estimate of CO₂ emission in million tons in different regions of the globe including India from process and energy related activities in cement manufacturing for the year 1994-95. For Indian cement industry, only major plants constituting more than 94% of capacity and production are considered (as most of world production of cement, except China is from large plants only). Table 9B shows the level of GHG emission from total cement manufacturing in India in the year 1994-95 in comparison to the world average. It is evident that the CO₂ emission level in India estimated at 1.102 tons per ton of cement is significantly higher than the world average of 0.746 tons. This situation at that time called for adopting measures for reduction of GHG emission by the Indian cement industry.

The contemporary dry process plants in India has been continuously adopting modernisation and technology upgradation measures for the obvious benefits of increasing productivity, lowering cost of production mainly through reduction of energy consumption. This has been providing the direct benefit of gradually reducing GHG emissions. Table 10A provides an estimate of energy consumption of dry process plants in course of the last decade, which clearly shows a decreasing trend. Table 10B gives some of the typical data on specific heat consumption, specific power consumption and corresponding CO₂ emission from some of the modern dry process plants in the country in the year 1999.

Table 10A. Reducing Energy Consumption by Dry Process Plants in the Last Decade

Year	Thermal (Kcal/kg of clinker)	Power (kwh/t of cement)
1989	876	120
1998	763	97
1999	750	91
2000	734	89

Source: [15]

CO₂ emission from the Indian cement industry for each calendar year for the period 1980 to 2000 has been estimated with relatively fair accuracy based on the following parameters:

- CO₂ emission in each year due to decarbonation of limestone measured from annual clinker production and cross-checked by annual plant-wise consumption of limestone (and its total carbonate content)
- CO₂ emission in each year from plant-wise coal and other substitute fuel consumption in clinkerisation process based on plant-wise annual fuel consumption and its total carbon content (in terms of fixed carbon and volatile matter).
- CO₂ emission in each year from plant-wise diesel consumption by Diesel generating (DG) sets and coal consumption by captive thermal power plants.
- CO₂ emission in each year from plant-wise limestone raising and cement packing related fuel and power consumption

For estimation purpose, parameters (b) and (c) have been combined to give the total CO₂ emission due to fossil fuel burning in the cement production process. Parameter (d) has not been dealt with in this paper as this is not directly involved with the cement manufacturing process. Besides, in the national GHG estimates, the limestone raising process is taken care of under the Head limestone mining.

Based on these assumptions the CO₂ emission from the cement industry for the years 1996 to 2001 for the process, fuel burning and other indirect sources is shown in Table 11 and Figure 4 indicates the trend of total emission of CO₂ from the Cement sector for the last two decades. As can be seen the emissions are increasing continuously. Figure 4 gives the total CO₂ emitted from the cement sector. The dashed line gives the production of cement and the bold line describes the CO₂ emission from this source.

Table 11. Computation of year-wise CO₂ emission by the Indian Cement Industry for the last five years

Year	Production (in Mn. T)		Emission of Carbon Dioxide (in Mn. T)						Grand Total (a+b)
	Cement	Clinker	Direct Source			Indirect Source			
			Calci- nation	Fuel Combus- tion	Total (a)	Power Consu- mption	Trans- port Activities	Total (b)	
2001 (83 plants)	93.52	83.82	42.70 (46.38)	38.06 (41.34)	80.76 (87.73)	8.97 (9.55)	2.33 (2.53)	11.30 (12.27)	92.06 (100)
2000 (83 plants)	94.21	85.18	43.39 (47.26)	37.54 (40.88)	80.93 (88.14)	8.54 (9.30)	2.35 (2.56)	10.89 (11.86)	91.82 (100)
1999 (81 plants)	81.76	72.23	36.79 (45.30)	34.72 (42.77)	71.51 (88.07)	7.65 9.42)	2.04 (2.51)	9.69 (11.93)	81.20 (100)
1998 (89 plants)	76.74	71.91	37.12 (44.00)	37.81 (44.81)	74.93 (88.81)	7.52 (8.91)	1.92 (2.27)	9.44 (11.19)	84.37 (100)
1997 (94 plants)	69.98	64.42	32.78 (39.52)	41.33 (49.83)	74.11 (89.35)	7.08 (8.54)	1.75 (2.11)	8.83 (10.65)	82.94 (100)
1996 (88 plants)	64.54	58.63	29.88 (38.80)	39.19 (50.88)	69.07 (89.68)	6.34 (8.23)	1.61 (2.09)	7.95 (10.32)	77.02 (100)

Figure 4. Annual CO₂ emission from the Indian Cement sector

The graph shows that CO₂ emission from the cement industry has increased progressively over the stated years, but the growth rate is much lower than the growth rate of production of cement in the country. This indicates that the cement industry has been continuously adopting energy conservation measures, as explained in Tables 10A and 10B. The various technological interventions over the years for improving efficiency has lead to an almost constant CO₂ emission from the year 2000 onwards.

Thus, although India emitted a total of about 778 million tons of CO₂ from all activities in 1995 and about 1000 million tons in 2000, the share of the cement industry to the total CO₂ emission has increased marginally from 4 to about 5% during these years.

7. GHG EMISSION PROJECTIONS

It is projected from the contemporary trend that CO₂ emission from the year 2002 onwards will remain almost static or will increase marginally during the next few years, despite 8 to 10% annual growth in production, if the technological interventions are continued at the present rate. This is because increase in production and capacity at present are based primarily on debottlenecking measures (95%) involving major energy conservation and insignificant greenfield capacity addition (5%), the last mentioned too is based on modern highly energy efficient technology. Thus if production increases with relatively much lower energy consumption, the overall impact will be that the average energy consumption will remain nearly the same. Correspondingly, CO₂ emission from cement manufacture will remain the same or will increase marginally for a few years.

However, in the long term projections the cement industry in India has to grow at a faster rate to match the increasing demand of the infrastructure development programmes. With growth in the infrastructure sector namely, roads, housing, power generation installations etc. the demand of cement will increase and more of Greenfield projects are bound to come up to bridge the gap. This will also compensate to some extent the very low per capita consumption of cement which is at present 96 kg in comparison to the world average of 269 kg [Cement in Japan, Japan Cement Association, 2002]. Such a quantum jump in growth of cement capacity much beyond the present 8-10% through Greenfield projects is bound to increase energy consumption by leaps and bounds, and therefore, its natural fallout will be increased GHG emission. One can therefore logically presume an increased GHG emission from the cement industry in the later part of the present decade and next decade. This will also open up the opportunity for carbon trading by the Indian Industry through adoption of CDM related technologies. A preliminary analysis of CO₂ reduction from the Indian Cement Industry by the year 2015 is shown in Table 12. The measures that are

likely to be used include energy efficiency with higher electrical energy efficiency and use of supplementary fuel, conversion of technologies using wet process to dry process; conservation of thermal energy by insulating brick lining and using of mineralisers; recycling industrial waste as fuel; raw mix optimization and use of co-generation power.

Table 12. Potential reduction of CO₂ from Indian Cement Industry by the year 2015

Areas for Improvement	Future Use (2015) (%)	Likely CO ₂ Reduction (%)
Production blended Cement (PPC-50%; PSC-15%)	75	22 - 24
Use of CNG as Fuel	20	8 - 9
Use of Waste Derived fuels	10	8 - 9
Use of Non-Conventional Energy Sources (Wind, Hydro)	8	2 - 3
Energy Efficiency Improvement	10	8 - 10
Total CO ₂ Reduction		48 - 55

8. THE FUTURE OUTLOOK

Quantitative assessment of GHG and pollutant emissions from the cement industry is the theme of this paper. Amongst all the emissions discussed in the above section, CO₂ is the major gas constituting more than 95% of total GHG emission from this source. Also, the change in technology over the years though has moved towards an efficient energy use, but the total emission from this source, both process based and due to fossil fuel consumption is still increasing (refer to Table 11 and 12 and Figure 4.) rising because of greater demand. The increasing demand for cement as a construction material means that in as little as a decade, world cement CO₂ emissions could equal 3,500 million tons including the share of the growing Indian cement industry. The effect of these CO₂ emissions on the world's fragile climate and global warming could be catastrophic. Therefore steps should be taken to reduce this emission.

There are various methods by which CO₂ can be reduced, one of the practical avenues being reduction of fuel consumption itself. Over the last two decades, the fuel consumption has been reduced to a level below 700 kcal/kg clinker as against the theoretical requirement of 425-450 kcal/kg clinker. Within the present state of technology it seems that there is not much scope for further significant reduction of fuel consumption for clinker making unless a break-through kind of technology comes to the forefront in the industry. It is also well known that an effective avenue for reduction of CO₂ emission is the production of blended cements by using cementitious and pozzolanic mineral admixtures at the time of grinding. It is obviously possible to bring down the clinker consumption in cement grinding through such routes, thus reducing the CO₂ emission in totality.

For many years the cement industry has been making a significant contribution to environmental case by burning a wide range of secondary fuels. The benefits include reduction in atmospheric emissions including CO₂, apart from energy recovery from waste materials and conservation of

nonrenewable fossil fuels. Another possibility that exists but still continues to be in the realm of research and development is to dovetail a facility to stabilise CO₂ through production of chemicals as an appurtenant to an existing cement plant (4).

For an energy intensive and energy efficient industry like cement, proposals are being considered in the industrialized countries to apply certain fiscal instruments for stabilization of CO₂ emission. There is also a parallel approach in countries like The Netherlands to adopt a voluntary measure to improve energy efficiency or to reduce or stabilise CO₂ emission. The German and French industries have recently developed the elements of an agreement on energy efficiency and CO₂ reduction. It appears that in near future the strategy of eco-trading may help in stabilising the CO₂ emission.

CEMENT CONFERENCES PRIOR TO THE “FIRST”

Ferenc D. Tamás (University of Veszprém, Hungary)

The "Historical Preface" of the Proceedings of the 3rd International Symposium on the Chemistry of Cements (London, 1952) mentions that the First Symposium, to deal solely with the chemistry of cement, was held during the first World War, on 14th January 1918, when the Faraday Society arranged a meeting in London to discuss "The setting of cements and plasters". This preface mentions that there had been former symposia too, organised by the International Association for Testing Materials (IATM) dealing, however, not only with cement, but also with other building materials. The first of them, as far as can be traced, was held in Stockholm, Sweden in 1897 and the next in Budapest, Hungary in 1901.

By searching libraries and archives, I was able to find out some data of the Stockholm and Budapest conferences, 106 and 102 years ago, respectively.

The Stockholm conference ^[1] was held on 23-25 August 1897. More than 250 experts attended, among them 93 from Germany, 51 from Sweden and 38 from France, and discussed problems in three categories: A./ Steel structures, B./ Natural and artificial stones (mostly cementitious materials) and C./ Other materials. The conference was opened by the mayor of Stockholm, and was followed by plenary papers and their discussion. The list of plenary papers in Section B./was:

1. Wahlberg, A. (Stockholm, Sweden): Testing of building materials in Sweden
2. Osmond (Paris, France): Methods of metal microscopy used for the investigation of clinker
3. Buess (Hamburg, Germany): Durability of natural stones
4. Gary (Berlin, Germany): Investigation of concrete tubes
5. Michaelis, W.: Hardening of calcium containing binding materials
6. Meyer, M. (Mallstatt, Germany): Quality testing of hydraulic binders
7. Eurich (Carlstadt, Germany): Setting disturbances of cements
8. Greil (Vienna, Austria) – Tetmayer (Zürich, Switzerland): Workability of cement paste when testing strength and density
9. DeShärengard (Louma, Sweden): Törnebohm's investigations on the petrography of clinkers

During this congress the President and the Steering Committee of the IATM were elected. L. Tetmajer (of ETH, Zürich) was re-elected as president, and 8 vice-presidents were also elected (one-each from Switzerland, Germany, France, Russia, Austria, Great Britain, Sweden and U.S.A.).

The Budapest conference, organised by IATM, was held on 9-14 September 1901, discussed problems in two sections: A. Steel structures, B. Cementitious materials. The venue of the conference was the Technical University (official name at this time: Royal Hungarian "József" Technical University); 380 participants, coming from 17 countries attended. (152/Hungary, 70/Germany, 41/Austria, 36/France, 26/Russia, 12/Italy, 10/Switzerland, 9/Denmark, 8/Netherlands, 5/Sweden, 4/UK, 3/Norway, 3/Belgium, 3/USA, 3/Spain, 1/Romania, 1/Serbia).

The opening ceremony was held in the Aula of the (at this time newly built) TU. The first speaker was the president of the IATM, professor L. Tetmayer (Zürich, Swiss Federal Polytechnic, the famous ETH), followed by addresses by the Hungarian government (Minister of Trade and Industry, Mr. S. Hegedüs) and several national and international celebrities. The Rector of TU Budapest (professor L. Illosvay) gave a short speech, followed by one from the chairman of the Hungarian organising committee, professor G. Czigler.

The work of the Organising Committee deserves great praise; they accomplished a great deal, even by today's standards. All printed material: information, agendas of the conference, preprints of the plenary papers, abstracts of others, etc. were given to attendees in four languages (English, German, French and Hungarian). Besides that a "Technical Guide-book of Budapest" was distributed too (again in four languages), which described showpieces of Budapest from an engineering point of view, with photos and technical sketches; many of which are nowadays an obvious part of tourists' itineraries, but were brand new a century ago: the cog-railway to Sváb-hill, the underground railway under the Andrásy street (actually, this was the first on the European continent, its only predecessor was the first underground line of London), the Elisabeth bridge over the Danube (not finished at this time), etc.

Ten plenary lectures were held in Section A., while 17 were given in Section B. (Cementitious Materials) of the conference.

The full list of plenary papers of Section B follows:

1. Considère (Paris, France): Studies on reinforced concrete
2. Feret (Boulogne, France): Adhesion of mortar and concrete
3. Feret (Boulogne, France): Calculation of reinforced concrete slabs
4. H. LeChatelier (Paris, France): Rapid methods for cement soundness testing
5. H. LeChatelier (Paris, France): Decomposition of cement in seawater
6. Deval (Paris, France): The role of calcium sulfates on cement
7. Deval (Paris, France): Composition of sulfo-aluminates in hydraulic lime
8. Foss (Copenhagen, Denmark): Determination of the breaking strength of cements by Feret's method
9. L. Tetmajer (Zürich, Switzerland): Effect of inorganic salts on the setting and hardening of cementitious materials
10. L. Tetmajer (Zürich, Switzerland): The swelling of cement
11. Leduc (Boulogne, France): Carbonation and decomposition of hydraulic binders
12. Zielinski and Zhuk (Budapest, Hungary): Investigation of Roman cements
13. Mercier (Paris, France): Flexural strength of cements
14. Maynard (Paris, France): Corrosion of cements in seawater
15. P. Siméon (Paris, France): Comparison of strength values of cylinders vs. cubes
16. M. Gary (Charlottenburg, Germany): Actual problems of cement testing in Germany
17. Cajo (Ancona, Italy): Corrosion of concrete by alkali sulfates

All this shows that important, almost "evergreen" topics of cement chemistry were discussed a century ago; at times when practically wet chemical analysis and optical microscopy were the only tools to study the chemistry of cements – when X-ray diffraction, electron microscopy, thermal analysis, EDX, etc., etc. had not yet been discovered. Abstracts of papers and details of discussions can be found in references 2 and 3.

Some names of expert notabilities of the time who attended: Wilhelm Michaelis (Berlin, Germany), Prince Gagarin (St. Petersburg, Russia), Sir William Bayley (Manchester, U.K.), Bertram Blount (London), Emil Svartz (Novorossiisk) and others.

Some technical excursions were included in the agenda of the congress. A special train was ordered for attendees to visit two factories: the Resica Steel Works (now in Romania) for participants of Section A., and the Cement Factory of Beocsin (now in Yugoslavia) for participants of Section B. Some factory visits in Budapest had been organised too, as well as one to the building site where the Elisabeth bridge was being erected.

The extracurricular activities were interesting too: a boat trip was made to see the Water and Sewage Works, with an on-board buffet. A committee organised several activities for the ladies, where the programme included visits to museums, galleries and also a fashion show.

The Conference Reception was held in the most luxurious hotel in Budapest at this time, the Hotel Royal. Here, obviously after a pledge to King Henry, LeChatelier gave the first toast, praising the international community of scientists and engineers. Dr. Wedding, a quarry consultant of Prussia complimented the work of the Ladies Committee, ending his German toast with the words "Three cheers for the ladies!", in Hungarian.

ABSTRACT

Pozzolanic and alkali-silica reactions open new opportunities for the future (1, 2). The inorganic polymeric materials called geopolymers are a result of this technology. This work presents a comparative study of fracture toughness of mortar composites, using a polysialate-siloxo (PSS) geopolymeric cement (3) with Si/Al = 3 ratio and a reference Portland cement (PC) as binders and natural wollastonite micro-fibers ($\text{Ca}[\text{SiO}_3]$) as reinforcement and stabilization elements. The values of K_{Ic}^s and $CTOD_c$ were determined and the G_I^s and R-curves were calculated. The results show that with 2% of fiber volume, there is an increase in maximum toughness. With high fiber volumes (3% and 5%), there is a decrease of fracture parameter values, probably caused by porosity elevation. The microstructural results show the occurrence of toughening mechanism such as debonding and fiber pullout, have been more common in PSS cement composites. The toughness difference between both PSS and PC cement pure matrices (0% of fibers) is of order of 100%, showing the high performance of these geopolymeric materials.

Keywords: Fracture toughness, geopolymer, reinforcement, wollastonite.

1. INTRODUCTION

The alkali-activation of granulated blast-furnace slags and pozzolanic materials opens new opportunities for development of high-performance structural materials [1-3]. Inorganic polymers based on aluminosilicates, obtained by alkali-silica reactions, called geopolymers [1-4], are a new generation of high-performance products that are classified within the domain of "advanced materials". In the fresh state, its viscosity is like that of organic resins. After polymerization, it develops ceramic properties, and in this way can create competition with the Portland cement and with other traditional materials, for various applications.

The geopolymer with Si/Al ratio between 2 and 3, is called poly(sialate-siloxo) or PSS and presents functional units composed by $\text{SiQ}_4(2\text{Al})$ tetrahedrons, with aluminum atoms in four-fold coordination numbers, generating cross-link polymeric chains. This three-dimensional arrangement forms an irregular structure of low mobility. The polycondensation reaction is not uniform in bulk material and mineral fillers are necessary for mechanical stabilization. In this case, the polycondensation reactional subproduct is water [1,4,5].

The addition of fibers as a reinforcement element is an efficient form for improvement of toughness in brittle and quasi-brittle materials. The fracture toughness is the relevant material property and shows the energy absorption capacity until rupture. The geopolymer studied presents quasi-brittle

material properties. Therefore, the concepts of Non-linear Fracture Mechanics (NLFM), developed to evaluate stones and concretes were applied. [6]. NLFM considers the inelastic response of structures caused by the presence of a fracture process zone (FPZ), an inelastic zone formed in the region of a crack tip around by stress concentration [7].

The RILEM Technical Committee 89 – Fracture Mechanics of Concrete – Test Methods[8], recommends the employment of the two-parameter fracture model (TPFM) based on the studies of Jenq and Shah [9] for determination of the fracture toughness of mortars and concretes. The model considers that elasto-plastic deformations occurred ahead of the tip of a macrocrack induced by a notch. The unloading compliance (C_u) measured from the unloading at 95% of the maximum load (post-peak load) in diagrams load versus CMOD (crack mouth opening displacement), allows the determination of the fracture properties of the material. Those properties are indicated by the critical stress intensity factor (K_{Ic}^s), the critical crack tip opening displacement ($CTOD_c$) and the critical crack effective extension ($\Delta a_c = a_c - a_0$). The compliance in the initial loading (C_i) gives the modulus of elasticity (E) of the composite. The parameters K_{Ic}^s and $CTOD_c$ were used to calculate the G_I^s and R -curves.

This work presents a study of the fracture toughness of a mortar composite of PSS cement matrix with ratio Si/Al = 3, reinforced with natural wollastonite ($Ca[SiO_3]$) micro-fibers, a natural mineral of high modulus of elasticity (120 GPa) and aspect ratio (10-20), employed in the ceramic industry as reinforcement and stabilization elements. The volumes of fibers studied were of $V_f = 0\%$ (pure matrix) to $V_f = 5\%$. The fracture parameters were measured and compared with the results obtained with the Portland cement mortar composites.

2. MATERIALS AND METHODS

For achieving the calcium, potassium and sodium poly(sialate-siloxo), Na,K,Ca-PSS requirements, the main source of aluminum and silicon was metakaolin, obtained by burning of kaolin originating from Rio Grande do Norte (RN), Northeast of Brazil. The time and temperature of burning were the subject of another study, because they depend on the purity and the degree of the kaolin crystallinity. Burning for 12 hours at 700 °C promotes the desidroxilation of the kaolinite and the conversion of aluminum coordination number from VI to IV, disordering the lattice [5]. Since the ratio between the silicon and the aluminum in the metakaolin is lower than 3, an extra source of silicon, a commercial alkaline polysilicate was used. In order to obtain a pH of 14, necessary to begin the polymerization, potassium hydroxide (Vetec P.A.) was also used as a complementary alkali source. The source of calcium was granulated blast furnace slag (GBFS) supplied by Belgo Mineira S.A.

The reference Portland cement was CPIIE-32 (type II of ASTM C 150), of Campeão/Mauá S.A. and the fine aggregate was river sand supplied by IPT S.A. (Normalized Brazilian sand). The proportion between binder and aggregate was 1:3, by weight for all the composites and the water/binder dry ratio was 0.48 for the Portland cement composites and 0.38 for the PSS composites. The consistency index (flow table - ASTM C 230) for both composites systems was of 165 ± 5 mm, with $V_f = 0\%$.

The wollastonite used was NYAD-G[®] grade (Figure 1) of Nyco Minerals Inc. (New York - USA). Table I shows the main characteristics of the raw materials used in this study.

The mixture of the basic constituents and the moldings of the specimens followed the procedures described in the NBR 7215 Brazilian standard. The wollastonite micro-fibers were dispersed in the water before mixture with others materials. In order to determine the fracture toughness, the procedures established by TC-89 FMT Draft Recommendations of RILEM were adopted as already

mentioned. The dimensions of the toughness test specimens and the experimental configuration are shown in the Figure 2. The Na,K,Ca-PSS cement (PSS) composites were cured in air at 25 ± 2 °C, and the Portland cement (PC) composites were cured immersed in water at 22 ± 2 °C until the test date.

Figure 1. Micrograph (SEM) of wollastonite micro-fibers used (500 X).

Table 1. Chemical composition and physical properties.

Materials	Chemical Composition (%)									L.O.I (%)	Specific Area Blaine (m ² .Kg ⁻¹)	Specific Weight (g .cm ⁻³)

% Retained in the sieve # 325 Tyler-Mesh = 12.35%.

Aspect ratio of wollastonite: 10 to 20.

CPIIE-32 – Bogue composition (ASTM C 150): 46,60% C₃S; 22,18% βC₂S; 10,54% C₃A; 4,87 C₄AF.

Figure 2. Dimensions of specimens and tests configuration. The maximum load (P_{max}), initial compliance (C_i) and unloading compliance (C_u) are obtained from the diagram and used as input for the TPFM.

The strain energy release rate, G_I^s , was calculated from relationship $G_{Ic}^s = (K_{Ic}^s)^2/E$ and the crack propagation resistance, R , was obtained using the model proposed by Ouyang and Shah [10]. The R-curve was obtained by solving of a linear differential equation with constant coefficients, written as

$$R = \sum_{n=1}^{\infty} \beta_n c^{d_n} \quad (1)$$

where the β_n are constants to be determined and the d_n are roots of the differential equation. If only terms up to $n = 2$ are considered, which indicates that G_I^s is approximated by a quadratic expression of crack length, the solution of Eq. (1) is:

$$R = \beta \psi (\Delta a)^{d2} \quad (2)$$

where

$$\psi = 1 - \frac{d2\alpha - \alpha + 1}{d1\alpha - \alpha + 1} \left(\frac{\alpha a_0 - a_0}{\Delta a} \right)^{d2-d1} \quad (3)$$

and

$$d1, d2 = \frac{1}{2} + \frac{\alpha - 1}{\alpha} \pm \left[\frac{1}{4} + \frac{\alpha - 1}{\alpha} - \left(\frac{\alpha - 1}{\alpha} \right)^2 \right]^{\frac{1}{2}} \quad (4)$$

The roots $d1$ and $d2$ represented in Eq. (4) are calculated taking the signal (+) to root $d1$ and (-) to root $d2$.

Using the critical conditions $R = G_{Ic}^s$, the parameters **a** and **b** can be determined as

$$\alpha = \mu + \sqrt{\mu^2 + 1} \quad (5)$$

and

$$\beta = \frac{(K_{Ic}^s)^2 (d1\alpha - \alpha + 1)}{E\alpha(d1 - d2)(\alpha a_0 - a_0)^{d2}} \quad (6)$$

where

$$\mu = \frac{\pi E^2 CTOD_c}{0.0195 a_0 (K_{Ic}^s)^2} \quad (7)$$

After determination of the fracture properties, samples were selected for scanning electron microscopy (SEM – Jeol 5800 LV) to determine the damage mechanisms. The fracture surfaces were observed by secondary electron imaging. Since the samples are not conducting, a gold deposition sputter coating was utilized.

3. RESULTS AND DISCUSSIONS

Figure 3 shows the values of K_{Ic}^s and $CTOD_c$ for PSS cement composites and PC composites. For PC composites, the $CTOD_c$ values decreased to fiber volumes up to 2%. The influence of fibers is governed by closing pressure on cracked surfaces that tends to close the crack tip. The presence of fibers provides a bridging effect and prevents the opening of the crack. This phenomenon causes an additional toughening on PC composites indicated by increase of K_{Ic}^s .

Figure 3. Variation of $CTOD_c$ and K_{lc}^s as function of fiber volume.

The PSS cement composites showed $CTOD_c$ values always peak, independent of wollastonite fiber volume. It is noted that in PSS composites, the fiber-matrix bond is more denser than in the PC composites. The toughness gain obtained without $CTOD_c$ decrease in PSS composites was caused by more active debonding and pullout fiber mechanisms (Figure 4). However, in the PC composites, the rupture of fiber in the crack plane is the principal mechanism in action (Figure 5). This indicates that because of the high porosity of PC matrix, the embedded length of wollastonite is smaller than the critical debonded length. Both composite matrices showed K_{lc}^s increase up to 2% of fiber volume. On other hand, for fiber volumes higher than 2%, a K_{lc}^s decrease occurs. Since the stress intensity factor is the driving force to open a crack, it can be supposed that the porosity increase has occurred due to the excess of fiber addition.

Figure 4. Micrograph (SEM) of PSS cement composite showing the pullout of wollastonite micro-fiber. (600 X)

Figure 5. Micrograph (SEM) of Portland cement composite showing details of wollastonite micro-fibers embedded in porous outer C-S-H products. (10000 X)

The strain energy release rate, G_I^s , calculate by relationship $G_{lc}^s = (K_{lc}^s)^2/E$, was plotted as Δa function, to both composites systems, as shown in Figures 6 to 8. The negative values of Δa are due to the interpolation form $a = a_0$ up to $a = 0$.

Figure 6. Variation of strain energy release rate, G_I^s , as function of effective crack extension, Δa , for the PSS cement composites with $V_f = 0$ to 5%.

Figure 7. Variation of strain energy release rate, G_I^s , as function of effective crack extension, Δa , for the Portland cement composites with $V_f = 0$ to 3%.

The performance of reinforcement was evaluated by G_I^s - Δa responses. It was noted that for certain Δa value, there was increase of G_I^s for volumes of fibers up to 2%. An identical behavior was presented by PC composites, however the PSS composites presented G_I^s values 100% higher than PC composites, showing the more efficiency of fiber reinforcement (Figure 8).

Figure 8. Comparison of G_I^s values between the both composites matrices, with $V_f = 2\%$.

The R -curves obtained show more clearly the toughness increase that occurred in each composite system. Again it is seen the positive contribution of fibers to fracture response (Figure 9 and 10). As $R = 0$ for $a < a_0$, the R -curves were plotted for positive values of Δa . An increase in R -value to unstable crack propagation (its maximum value) was observed of order of 34% to PSS composite and 20% to PC composite with 2% of fibers in relation to its pure matrices (0% of fibers).

The results confirm the efficiency and compatibility of wollastonite micro-fibers as stabilizer and as the reinforcement element to the composites systems studied. The fracture toughness measurements indicate that the PSS cement is tougher than PC, and totally adequate for structural applications.

Figure 9. R -curves to PSS cement composites with different fiber volumes. $V_f = 0$ to 5%.

Figure 10. Comparison of R -curves between both composite matrices with $V_f = 2\%$.

4. CONCLUSIONS

The necessity of stabilization of a PSS matrix and the opportunity to improve its fracture toughness were successfully achieved by use of the wollastonite micro-fibers. The two-parameter fracture model permitted an evaluation of the influence of fiber addition in the fracture behavior of composites. Better values of K_{Ic}^S and $CTOD_c$ were obtained with 2% of fiber volume, to both composite systems. The microstructural analyses showed that the fiber-matrix bonds in PSS cement composites are more efficient and this provides the actuation of debonding and pullout mechanisms. The G and R -curves showed a maximum relative toughness increase of the order of 34% to PSS cement composites and of 20% to PC cement composites. The comparison between PSS cement and PC pure matrices, shows the high performance of PSS cement matrix. The difference in toughness is about 100% higher than the PC matrix. These results indicate that the PSS cement is perfectly viable for structural applications.

ACKNOWLEDGEMENTS

The authors thank to CETEM for the chemical analyses and to Belgo Mineira S.A. for the GBFS supply. F. J. Silva should like thanks to CAPES for the financial support.

ABSTRACT

The influence of acrylate superplasticizers on the rheological properties of cement pastes has been studied. It is shown that the copolymers belonging to the same group influence the rheological properties of cement pastes in a different way, depending on qualitative and quantitative composition of mer segments in a macromolecule. In the case of the superplasticizers examined, the increase in content of oxyethylene groups in the copolymer as well as the decrease in the content of hydrophobic methyl acrylate segments result in a significant increase in yield value and plastic viscosity of the cement paste.

1. INTRODUCTION

The technology of state-of-the-art composite materials, including composites based on reactive powders and self-compacting concrete, requires addition of more efficient plasticizers compared with those used in the 80's. In those days, the plasticizers based on water-soluble polymers containing sulfo groups (SMF, SNF) were mostly used [1].

In the last decade a new kind of more efficient superplasticizer based on acrylic copolymers (AP) has been introduced [2, 3]. The mechanism of their action, consisting in dispersion of cement grains, is related to the effect of steric hindrance caused by the presence of long branched chains. It differs significantly from the mechanism of action of the SMF and SNF-type superplasticizers. Acrylic copolymers include various compounds that differ in the structure of particular blocks and their sequence. Therefore their influence on the degree of fluidization of suspensions based on cement may be different.

Modern superplasticizers belong to the class of multifunctional copolymers of a regular and/or block sequence of mers in the macromolecules. The state-of-the-art superplasticizers are most frequently tri-block and tetra-block copolymers of different properties depending on the kind of mer blocks and their contents in macromolecules [4, 5]. Identical blocks of mers form the so-called segments showing similar properties, thus reacting on particular external stimuli such as temperature, acidity (pH) or ionic strength (salt content). Non-polar segments of copolymers, such as aliphatic hydrocarbon chains or aromatic rings increase hydrophobicity of superplasticizers and decrease their solubility in water. Polar segments, including mainly hydroxyl and carboxyl groups as well as ionic salts cause hydrophilic character. The increased content of hydrophilic segments in a copolymer results in better water solubility [6, 7]. Oxyethylene or trialkylamine segments make the superplasticizers sensitive to temperature and the changes in ionic strength of the solution. All superplasticizers contain both hydrophilic and hydrophobic groups; hence they are amphiphilic. The

ratio of hydrophilic segments to the hydrophobic ones determines the water solubility of the superplasticizers. If this ratio increases, the water solubility rises and *vice versa*. The properties of superplasticizers may be controlled through the careful selection of the kind and amount of comonomers in the process of polymerization. The study of the influence of the kind and amount of segments of mers in the chemical structure of superplasticizers on the rheological properties of cement pastes was found to be interesting.

The influence of two commercially used superplasticizers based on acrylates on the rheological properties of cement pastes has been studied. Since the composition and chemical structure of the superplasticizers studied was not known, the qualitative and quantitative analysis of these compounds was carried out by means of Fourier-Transform Infrared Spectroscopy (FTIR).

2. EXPERIMENTAL

2.1. Materials

The tests were performed using cement pastes obtained from cement prepared in the laboratory by milling commercial clinker with the addition of 5 wt. % of gypsum dihydrate. Chemical and phase composition of clinker is shown in Table 1.

Table 1. Chemical and phase composition of clinker

Component	% by wt.
Loss on ignition	0,57
Insoluble residue	0,19
SiO ₂	20,23
Fe ₂ O ₃	3,53
Al ₂ O ₃	6,64
CaO	66,05
MgO	1,42
SO ₃	0,53
Na ₂ O	0,19
K ₂ O	0,85
CaO free	1,46
C ₃ S	58,75
C ₂ S	13,40
C ₃ A	11,60
C ₄ AF	10,74

Blaine specific surface of the cement was 318.6 m²/kg.

Rheological studies were carried out using two acrylate superplasticizers, denoted as A and B, used as 20 % water solutions. Superplasticizers were introduced into batch water in the amount of 1 wt. % of solution, keeping the water cement ratio at 0.25 and 0.3.

2.2. Methods

2.2.1. Infrared studies

Qualitative analysis

The qualitative analysis of A and B superplasticizers was carried out by means of absorption spectrometry in the region of middle infrared. The samples in the form of pellets contained 1–2 mg of the superplasticizer and 600 mg of potassium bromide.

The absorption spectra of the samples were recorded using Philips Analytical PU 9804 FTIR spectrometer with the constant spectral resolution of 2 cm^{-1} . Ten scans for each pellet were recorded in the full region of $4000\text{--}400\text{ cm}^{-1}$ using EAGLE v.4.31 computer program. The characteristic frequencies of absorption bands were assigned to the appropriate functional groups of copolymers which were present in plasticizers. The interpretation is partially shown in the appropriate spectra. Full interpretation is presented in the tables. The structural segments of copolymers were determined on the grounds of functional groups detected.

Quantitative analysis

On the grounds of FTIR spectra the relative absorption of the following bands was determined:

- ester band at 1724 cm^{-1} (A), 1735 cm^{-1} (B), $\text{STRC=O}_{\text{ES}}$ of hydrophobic segments,
- carboxylic salt band at 585 cm^{-1} , STRCOO- of hydrophilic as well as pH-sensitive segments, and
- ether band at 1108 cm^{-1} , STRC-O-C of oxyethylene chains as hydrophilic segments which are sensitive to temperature and presence of salts in the solution. The absorption at 2873 cm^{-1} STRCH_2 (A) and 2874 cm^{-1} STRCH_2 (B) was chosen as an internal reference. The contribution of absorption bands of ester, carboxylic and oxyethylene segments for both A and B superplasticizers was determined on the grounds of relative absorption of appropriate bands. This was the measure of content of particular segments in the copolymers.

2.2.2. Rheological tests

The rheological measurements were carried out using the rotative viscosimeter type Rheotest RV-2.1, with the modified surfaces of both cylinders. The tests were performed at a constant temperature 21°C . Measurements started 10 minutes after mixing with water. The rheological properties of cement pastes were determined from the flow curves, at growing and reduced rates of shearing in the range from 0 to 146 s^{-1} and the course of stress changes in time at constant shear rate ($\dot{\gamma} = 46\text{ s}^{-1}$ for 60 minutes). The yield value and plastic viscosity were determined from the descending part of flow curve, according to Bingham's model.

3. RESULTS AND DISCUSSION

3.1. Quantitative and qualitative spectral analysis of the A and B superplasticizers

The FTIR spectra of the A and B superplasticizers are shown in Figures 1 and 2, respectively.

Figure 1. FTIR spectrum of the A superplasticizer

Figure 2. FTIR spectrum of the B superplasticizer

The wavenumbers corresponding to the characteristic absorption minima were determined using the EAGLE v.5.31 computer program. The appropriate types of vibrations were determined and the functional groups present in the macromolecules of superplasticizers were assigned. Full specification of characteristic frequencies together with the corresponding types of vibrations and kinds of functional groups is shown in Table 1 (for the A superplasticizer) and Table 2 (for the B superplasticizer).

Table 2. Characteristic FTIR frequencies for the sample of the A superplasticizer.

Wavenumber, cm ⁻¹	Type of vibrations	Structural fragments
2948	STR/A CH ₃	Methyl group on the chain R
2917	STR/A CH ₂	Methyl group in the chain
2873	STR/S CH ₃	Methylene group in the chain
1724	STR C=O ES, KET	Ester or ketone carbonyl group
1585	STR/A COO ⁻ SALT	Carboxyl group of the metal salt
1468	DEF CH ₂	Methylene group in the chain R
1454	DEF CH ₂	Methylene group adjacent to a heteroatom (O, N)
1400	STR/S COO SALT	Carboxylic group of the metal salt
1351	SCI CH ₂	Methylene group adjacent to the O atom
1251	STR/A C–C–O ES	C–C–O ester group
1108	STR/A COC ET	Aliphatic ether group R–O–R
950	RK CH ₃ (C)	Methyl group adjacent to the C atom
853	RK CH ₃ (O)	Methyl group adjacent to the O atom

Table 3. Characteristic FTIR frequencies for the sample of the B superplasticizer.

Wavenumber, cm ⁻¹	Type of vibrations	Structural fragments
2948	STR/A CH ₃	Methyl group on the chain R
2918	STR/A CH ₂	Methyl group in the chain
2874	STR/S CH ₃	Methylene group in the chain
1735	STR C=O ES.	Ester carbonyl group
1585	STR/A COO ⁻ SALT	Carboxyl group of the metal salt
1451	DEF CH ₂	Methylene group adjacent to a heteroatom (O, N)
~1400	STR/S COO SALT	Carboxylic group of the metal salt
1351	SCI CH ₂	Methylene group adjacent to the O atom
1252	STR/A C–C–O ES	C–C–O ester group
1108	STR/A C–O–C ET	Aliphatic ether group R–O–R
948	RK CH ₃ (C)	Methyl group adjacent to the C atom
853	RK CH ₃ (O)	Methyl group adjacent to the O atom

The descriptions of FTIR spectra contain the following abbreviations:

STR... – stretching vibrations
 STR/A... – asymmetric stretching vibrations
 STR/S... – symmetric stretching vibrations
 DEF... – deformation vibrations
 SCI... – scissoring in-plane vibrations
 RK... – rocking in-plane vibrations
 WAG... – wagging in-plane vibrations
 TWI... – twisting out-of-plane vibrations
 ADJ... – vibrations of adjacent atoms
 ...AL – aliphatic hydrocarbon chain
 ...AR – aromatic ring
 ...ALC – alcohol, hydroxyl functional group
 ...AC – acid; carboxyl functional group
 ...SALT – salt; carboxyl functional group
 ...ES – ester, ester functional group
 ...ET – ether; ether functional group
 ...KET – ketone; ketone carbonyl group

The conclusion based on the data presented in Tables 2 and 3 is that the A and B superplasticizers do not contain aromatic rings because the FTIR spectra do not show characteristic bands corresponding to the following vibrations: STRCH_{AR}, STRCC_{AR}, WAGCCC_{AR}, DEFCH and ADJH_{AR}.

The A superplasticizer (table 2) contains the following functional groups:

- aliphatic groups: methyl CH₃, methylene CH₂, methine CH,
- aliphatic ester groups O=C–O–R,
- carboxyl groups of sodium salt O=C–O⁻Na⁺
- n-oxyethylene groups (–CH₂–CH₂–O–)_n.

The logical reasoning indicates that the A superplasticizer is a regular or block copolymer (probably block copolymer, taking into account the costs of synthesis), containing segments of alkyl, sodium and oxyethylene acrylates and/or methacrylates and/or maleates of the following structure (according to the methacrylate blocks):

alkyl (meth)acrylate

where: R = H, CH₃
R' = CH₃, C₂H₅

hydrophobic segment
decreasing solubility

sodium (meth)acrylate

where: R = H, CH₃

hydrophilic segment
ion and pH-sensitive

n-oxyethylene (meth)acrylate

where: R = H, CH₃

hydrophilic segment
ion and temperature-sensitive

Therefore, the A superplasticizer contains the following fragments:

- ester fragments which make the superplasticizer more hydrophobic and lower its solubility in water,
- carboxylic salts which make the superplasticizer more hydrophilic and increase its solubility in water as well as sensitivity to presence of ionic salts and pH of solution,
- oxyethylene fragments which increase hydrophilicity of the superplasticizer and its sensitivity to ambient temperature as well as presence of salts in solution.

Unfortunately, it is impossible to determine the sequence of particular segments in the macromolecule and to decide whether the segments are alternating regularly or irregularly by means of FTIR. It is also impossible to determine the average molecular mass and molecular mass distribution, i.e. the parameters which also influence water solubility of the superplasticizer as well as its properties in solution.

Comparison of both FTIR spectra and spectral data of the A and B superplasticizers leads to a conclusion that both superplasticizers contain identical functional groups, structural elements and segments. Therefore both superplasticizers are qualitatively identical. The only quantitative difference relates to the size of ester, carboxyl and oxyethylene segments in the copolymer. It is possible that the sequence of segments might also be different, but this cannot be solved using FTIR spectroscopy.

The results of quantitative analysis of the A and B superplasticizers, including determination of absolute and relative absorption of the ester band at 1724 cm⁻¹ (A), 1735 cm⁻¹ (B), carboxylic salt band at 1585 cm⁻¹ and ether band of oxyethylene groups at 1108 cm⁻¹ together with their contribution to the total absorption are shown in Table 4.

Table 4. The results of quantitative analysis of A and B superplasticizers.

Superplasticizer	Absolute absorption of a band				Relative absorption of a band			Absorption fraction		
	standard A ²⁸⁷⁴	ester A ¹⁷³⁰	salts A ¹⁵⁸⁵	ethers A ¹¹⁰⁸	esters A ¹⁷³⁰ A ²⁸⁷⁴	salts A ¹⁵⁸⁵ A ²⁸⁷⁴	ethers A ¹¹⁰⁸ A ²⁸⁷⁴	esters %	salts %	ethers %
A	0.8046	0.4205	0.6673	1.3711	0.5226	0.8293	1.7041	17.1	27.1	55.8
B	0.7038	0.5484	0.7495	1.1590	0.7794	1.0649	1.6467	22.3	30.5	47.2

The data presented above indicate that the absorption of the A superplasticizer, which is related to the ether groups deriving from n-oxyethylene acrylate, is 8.6 % greater comparing with the B superplasticizer. It corresponds to the content of oxyethylene groups, which is greater by 18 wt. %.

On the other hand, the absorption of ester groups deriving from methyl (or ethyl) acrylate in the B plasticizer is 5.2 % greater and the absorption of carboxyl groups deriving from sodium acrylate is 3.4 % greater. It corresponds to the content of ester groups which is 30 wt. % greater and content of carboxyl groups which is 12 wt. % greater in the B superplasticizer comparing with the A superplasticizer. Therefore, the A superplasticizer shows better solubility in water and higher sensitivity to temperature compared with the B superplasticizer. The B superplasticizer shows lower water solubility (greater content of hydrophobic ester segments) and higher sensitivity to pH of solutions comparing with the A superplasticizer.

The differences in IR absorption of functionally different elements of the structure of both copolymers indicate different content of particular mers in the macromolecule as well as different size of segments (blocks) in microchains. It is obvious that the structural differences result in different physicochemical properties, including rheological properties of cement pastes.

3.2. Rheological study

The influence of the A and B superplasticizers on the rheological properties of cement pastes was determined on the grounds of rheological measurements carried out for pastes with the addition of these superplasticizers. The results of the rheological study are shown in Figures 3, 4 and Table 5.

Figure 3. Flow curves of cement paste containing A or B superplasticizer

Figure 4. Stress growth for cement paste containing A or B superplasticizer

Table 5. Yield value and plastic viscosity of cement paste containing A or B superplasticizer

superplasticizer	w/c	yield value τ_o [Pa]	plastic viscosity η_{pl} [Pa · s]
A	0,25	lack	0,25
	0,30	lack	0,18
B	0,25	250	0,79
	0,30	44	0,36

It can be stated that the cement pastes containing equal amounts of the A or B superplasticizers, which belong to the same group of acrylate plasticizers and are built of qualitatively identical structural segments and differ only in the size (and possibly the sequence) of these segments, show different rheological properties.

The A superplasticizer, which contains 20 wt. % more n-oxyethylene acrylate segments, or the same amount of acrylate segments $(-\text{CH}_2\text{CH}_2\text{O}-)_n$ but containing oxyethylene chains longer by 20 % and also less hydrophobic methyl acrylate segments by ca. 20 wt. % compared with the structure of the B superplasticizer, shows significantly better efficiency. Cement pastes with the addition of the A superplasticizer show the properties of Newtonian liquid at the w/c ratio of both 0.3 and 0.25. With the presence of the B superplasticizer, analogous pastes show the properties of viscoplastic liquid. At the w/c equal 0.25 the yield value of paste reaches a huge value of 250 Pa at the plastic viscosity of 0.79 Pa·s. The dependence of shear stress on time (Figure 4) indicates better efficiency of the A superplasticizer as well. The paste with the addition of the A superplasticizer shows very low values of shear stress and its negligible increase within one hour compared to the paste containing the B superplasticizer.

4. CONCLUSIONS

On the grounds of the rheological study carried out, it has been shown that the superplasticizers which belong to the same group of copolymers may influence the rheological properties of cement pastes in a different way, depending on the qualitative and quantitative composition of mers in the copolymer macromolecules.

The FTIR analysis of the A and B superplasticizers carried out indicates that both superplasticizers belong to the same group of acrylate copolymers, probably of a block microstructure. They are composed of qualitatively identical segments of three kinds of acrylate mers of different properties. These segments play different parts in water solutions of plasticizers.

On the grounds of the detailed FTIR analysis it has been established that both superplasticizers consist of the following segments of acrylate and/or methacrylate mers: methyl/ethyl (co)acrylate, sodium (co)acrylate and n-oxyethylene (co)acrylate.

The efficiency of superplasticizers which belong to the same group of copolymers and show identical qualitative composition of mer segments depends to a great extent on the quantitative composition of particular segments as well as their size in the macromolecules. For the acrylate superplasticizers examined, the increase in content of oxyethylene groups as well as the decrease in the content of hydrophobic methyl acrylate segments lead to the increase in water solubility of the superplasticizer, as well as increased values of rheological parameters (yield value and plastic viscosity) of the cement suspension.

The results of the study lead to the conclusion that the controlled synthesis of acrylate superplasticizers of particular properties may be carried out through the appropriate selection of comonomers and their amount in the process of polymerization.

SUPERCLASSIFIED PFA FOR SELF-COMPACTING CONCRETE

S.D. Fossey, E.A. Byars and H.Y. Zhu

Centre for Cement and Concrete, University of Sheffield, UK. E-mail: DrByars@aol.com

ABSTRACT

In recent years the demand for Self-Compacting Concrete (SCC) has grown significantly due to the tightening health and safety regulations and good concrete practice. However, the high cement contents and volumes of expensive admixtures necessary for satisfactory SCC make it largely uneconomical. This paper reports on the use of ultra fine super-classified PFA (SPFA) to achieve the required workability and cohesion for SCC with low cement contents and no need for specialist admixtures. Initial tests show self-compacting SPFA concrete displays both high workability and stability with w/c ratio as low as 0.2 and that SPFA SCC is significantly more economical than other forms of SCC.

Keywords: Self-Compacting Concrete, Super-classified PFA, Admixtures, Strength, Absorption

1. INTRODUCTION

In the 1980's a chronic skills shortage in the Japanese construction industry was partially solved by using high-workability mixes that could be consolidated without vibration^[1]. This type of concrete became known as Self-Compacting Concrete (SCC). An additional advantage of SCC was found to be the ability of the concrete to flow into complex formwork, but with increasing variety and usage of SCC, some problems with excessive bleeding and segregation have emerged requiring additional expensive admixtures[2].

A major driving force encouraging the use of SCC is the impending European Health and Safety Directive covering hand-arm vibration [3]. However, SCC also has implications for traditional large concrete pours and post-tensioning placement where its uniform strength development may benefit the stressing procedure and reduce cracking. In addition, with SCC the associated reduction in labour and plant reduces cost and improves QA procedures as the sample test cubes are more representative of in-situ concrete than vibrated normal workability concrete cubes [2].

2. AIMS AND OBJECTIVES

The aims of this project were to optimise SPFA concrete mixes to maximise workability and cohesion and achieve self-compaction at low water cement ratios. Several objectives were defined as follows:

1. To assess the effects of SPFA on water demand of concrete.
2. To optimise the aggregate gradings used in combination with flowing cement paste to create cohesive flowing SPFA concrete.
3. To minimise the cement content used in very high performance self-compacting SPFA mixes.

4. To measure the compressive and tensile strength development, absorption and UPV of the self-compacting SPFA concrete mixes.
5. To compare the economy and performance of SPFA self-compacting concrete mixes with concrete made with other materials of equal mix proportions.

3. MATERIALS

3.1 Materials properties

Selected physical and chemical properties of all cementitious materials used are given in Table 1.

Table 1. Typical physical and chemical properties of the materials used in this project

PARAMETER	OPC	PFA	GGBS	MS	SPFA
Surface Area (m ² /kg)	350	350	400	20000	13000
Specific Gravity	3.2	2.1	2.9	2.2	2.3
Particle Range (μm)	5–100	1-150	3-100	0.01–0.5	0.25–25
SiO ₂ (%)	20.8	48.0	35.8	92.9	53.5
Al ₂ O ₃ (%)	5.0	28.0	14.0	0.6	34.3
Fe ₂ O ₃ (%)	3.2	9.0	0.5	0.9	3.6
CaO (%)	63.7	3.0	39.7	0.4	4.4
MgO (%)	2.6	2.5	8.6	1.58	1.0

3.2 Cements

Blue Circle OPC to BS12 [4] was used throughout the experimental program.

3.3 SPFA

The SPFA used throughout the research was a Class F PFA to ASTM 311[5] with a mean particle size of 6μm [6], compared to 1-200μm for Class 1 PFA[7]. The water requirement of the SPFA is shown plotted in Figure 1[6].

3.4 Pulverized-Fuel Ash (PFA)

The PFA used for this research conformed to BS3892: Part 1[8].

3.5 Ground Granulated Blast furnace Slag (GGBS)

The GGBS used complied with BS6699 [9].

3.6 Micro-Silica (MS)

The MS used was in a 50/50 ($\pm 2\%$) aqueous slurry form and complied with ASTM C 1240[10].

3.7 Superplasticizer

A single polycarboxylate polymer water-reducing admixture to ASTM C494 ^[11] and BS5075[12] was used.

3.8 Aggregates

The grading of the aggregates used is described in Table 2. The coarse aggregate was a continuously-graded well-rounded aggregate with a nominal particle size of 5-10mm. The fine aggregate used was well graded concrete sand to BS812 [13].

Figure 1. Water requirement of SPFA

Table 2. Aggregate Sieve Analysis

SIEVE SIZE (mm)	% PASSING BY MASS	
	10-5mm	Sand
28	100	100

4. TEST METHODS

4.1 Rheology

Three methods were employed to test the fresh concrete rheology.

4.1.1 Slump Test

The slump test [14] was used on stiffer mixes.

4.1.2 Slump Flow Test

Where the concrete displayed a significant fluidity it was tested using the slump flow test [15]. A 600mm spread was taken to be the lower boundary for SCC. Mixes displaying excessive segregation or bleeding at this stage were rejected.

4.1.3 SSCI Test

The third test method, the ‘Sheffield Self-Compactability Index (SSCI) test, Figure 2, was developed as part of the project. The top funnel section of the apparatus is filled with concrete then a gate removed, which allows the concrete to flow down a shallow slope through a throat which is heavily congested with rebar. A comparison of the results obtained using the slump flow test and

the SCCI test led to the conclusion that Self-Compactability (600mm flow) corresponded to the concrete flowing to touch all four corners of the lower reservoir when the SSCI apparatus was inclined at 15° to the horizontal. However, the SSCI was found to be more sensitive to lack of cohesion in SCC mixes than slump flow. Visual observation showed aggregates “balling” in the SSCI throat in some instances, and therefore a further restriction on SCC acceptability was imposed: zero segregation in the SSCI test.

Figure 2. The SSCI test apparatus

4.2 Hardened Properties of Concrete

For each of the final mixes described in Table 3, the appropriate numbers of 100mm cube samples were made ^[16]. Where the concrete was self-compacting, no vibration was used. Half of the cubes were cured in water at 20°C to BS1881 ^[17] and half in air at 20°C and 65% RH. Further tests were carried out at appropriate ages as shown in Figure 3.

Figure 3. Testing Flow Chart

4.2.1 Compressive Strength

Cubes were tested for compressive strength at 7 and 28 days to BS1881 ^[18]. The air-cured cubes were saturated prior to test by immersion in a water tank for 24 hours (7 day test) or 48 hours (28 day test).

4.2.2 Tensile Strength

The indirect tensile strength of the cylinders was tested ^[19] at 7 and 28 days, with the air-cured cylinders being saturated as per the compression test samples.

4.2.3 Surface Absorption

Absorption tests were carried out on both the water and air cured samples after 28 days ^[20]. Cubes were preconditioned by oven drying for 72 hours, or until the % mass change in 24 hours was $\geq 0.2\%$.

4.2.4 Ultrasonic Pulse Velocity (UPV)

The UPV test was carried out on a full size element (a column measuring $1.5 \times 0.2 \times 0.2 \text{ m}$ cast from SCC1) and tested to BS1881: Part 203 ^[21].

4.3 Mix Development

From previous studies carried out at the CCC [6], it was decided to use SPFA at a 30% replacement for cement and a w/b ratio of 0.45 for the initial trials. The influence of fine aggregate content on the concrete stability and the ratio of coarse to fine aggregate was carefully monitored during a series of trials and particular attention was given to cementitious material and superplasticizer minimisation, as shown in Table 4. Mixes were proportioned on a trial and error basis to assess the influence of changes and the rheology assessed using the slump flow test, Table 4. If the flow equalled or exceeded 600mm, the mixes were also tested using the SSCI test to assess cohesiveness.

Table 4. Summary of the Mix Proportions used during the development of SCC with SPFA

MIX CODE	MIX PROPORTIONS (Kg/m³)								Flow (mm)	SSCI TEST	
	OPC	SPFA	WATER	W/B	AGGREGATE			SP (%Cem)			TOTAL
					10mm	Fines	Total				
TRIAL 1	218	93	140	0.45	1179	786	1965	1	2416	510	×

SPFA1	249	107	160	0.45	1029	842	1871	0.3	2387	650	✓

Instability and segregation were found to be the greatest hurdles during trial mixing and required significant manipulation of the fines content of the concrete mixes.

The SPFA concrete mix that was adopted as self-compacting had a Coarse: Fines (C: F) ratio of 55:45, Table 4. Trial 13 was almost self-compacting (580mm slump flow) and had an excellent aggregate distribution with no sign of segregation, Figure 4, suggesting that the mix had excellent cohesivity.

4.4 Full Scale Trial

A full-scale sample column was cast in the lab to study self-compactability at full scale. The element, measuring 1.5m x 0.2m x 0.2m, was cast in one pour using mix SPFA1, then cured overnight in a humid environment in accordance with BS1881 [17]. At 28 days the sample was tested with UPV [21] to establish any variation of density with depth.

Extending from the data of the 0.45w/b trials, a 0.2w/b ratio mix (SPFA2) was developed as shown in Table 5.

Table 5. Summary of the mix proportions used to develop mix SPFA2

MIX CODE	MIX PROPORTIONS (kg/m3)								FLOW (mm)	SSCI TEST	
	OPC	SPFA	WATER	W/B	Aggregate		SP (%Cem)	Total			
					10mm	Fines					Total

5. RESULTS

5.1 Rheology

Table 6 summarises the rheology test results measured on the five final mixes. It can be seen that the workability of the two mixes containing SPFA is far superior to the other mixes despite the mix proportions being identical.

Table 6. Rheology results

TEST	SPFA1	GGBS	MS	PFA	SPFA2
SSCI	PASS	FAIL	FAIL	FAIL	PASS
Slump Flow (mm)	650	-	-	-	710
Slump (mm)	-	220	50	210	-

Observations were made with reference to the stability of the mix throughout the testing procedure and it was noted during rheology testing that SPFA displayed an excellent degree of cohesion as shown in Figure 5. Cutting through a cylinder of SPFA1 confirmed the cohesivity of the mix, which showed excellent aggregate distribution throughout the sample and no bleeding or laitance.

Figure 5. Mix SPFA1 following a slump flow test and the aggregate distribution in a hardened sample

5.2 Effect of alternative replacement materials

It was found that only SPFA produced fluid, cohesive, self-compacting concrete mixes using the minimum cementitious materials and low water content of SPFA1. To produce a high fluidity concrete using other cement replacement materials requires greater volumes of water, cementitious materials and admixtures. The implications on cost mean that whilst generally the use of SCC can be expensive, the inclusion of SPFA can reduce costs to a competitive level, (see Figure 7).

5.3 Hardened Properties

5.3.1 Compressive Strength

The compressive strength results of the water and air cured samples are shown plotted in ure 6. It is clear from these that the SPFA1 concrete, whilst in this set of tests having slightly lower compressive strength than other comparable mixes, develops greater strength with time in both water and air-curing environments.

Figure 6. Compressive strength development for air and water cured samples

5.3.2 Tensile Strength

The tensile strength trends, Table 7, are similar to those observed for compressive strength development. The SPFA1 mix initially has a slightly lower tensile strength than other mixes, but this increases relatively with time.

Table 7. Tensile strength results

MIX CODE	Water Cured (N/mm ²)		Air Cured (N/mm ²)	
	Age (Days)		Age (Days)	
	7	28	7	28
SPFA1	3.7	5.6	2.5	4.6
GGBS	4.2	5.7	3.1	4.3
MS	4.9	6.4	4.0	5.1
PFA	3.9	5.4	2.9	4.4
SPFA2	4.9	7.1	4.2	6.4

5.3.3 Water Absorption

The results from the water absorption test, Table 8, show that the SPFA mixes have significantly lower absorption than other mixes. All air-cured samples showed greater absorption than water-cured ones, yet it is clear from these results that the SPFA mixes are significantly less affected by air curing than similar mixes made at the same w/b ratio with other materials. This is of particular note when one compares the strength results of the SPFA1 and MS concrete mixes, the latter developing considerably higher strength at the age of 28 days, when the absorption tests were conducted. The differences between the SPFA and the PFA concrete absorption is also very well defined with air-curing, which suggests an unexpectedly high level of pore refinement with SPFA.

Table 8. Water Absorption Results

MIX CODE	PRECONDITIONING MASS (kg)				SATURATED MASS (kg)	WATER ABSORPTION (%)
	Age (hours)					
	0	24	48	72		
Water Curing						
SPFA1	2.356	2.341	2.326	2.322	2.341	0.80
GGBS	2.275	2.261	2.252	2.249	2.277	1.27
MS	2.359	2.350	2.346	2.343	2.362	0.83
PFA	2.392	2.381	2.373	2.370	2.392	0.93
SPFA2	2.386	2.385	2.383	2.382	2.397	0.63
Air Curing						
SPFA1	2.286	2.284	2.282	2.282	2.324	1.84
GGBS	2.194	2.194	2.192	2.191	2.294	4.70
MS	2.247	2.245	2.244	2.242	2.310	3.01
PFA	2.306	2.305	2.304	2.302	2.405	4.45
SPFA2	2.365	2.365	2.364	2.364	2.407	1.40

5.3.4 Full Scale Trial

A 1.5×0.3×0.3m column of SPFA1 concrete was cast and tested using UPV at 28 days to establish if there was any variation in density with depth, which could identify segregation. Readings were taken over the full height of the column and are shown in Table 9.

Table 9. UPV Test Results

Height Above Ground (m)	Time Reading (μ s)
1.5	46.0
1.2	45.3
0.9	45.0
0.6	45.3
0.3	44.3
0.0	45.4

The minimal difference in the readings suggests that the concrete is of constant density and that no significant degree of segregation has taken place, which implies that the SPFA1 concrete mix developed in this study has the potential to be used for full-scale works.

6. DISCUSSION

The SPFA used in this study has proved to be extremely effective for making self-compacting concrete. Indeed, when the total binder contents used in this study to make 0.45 w/b ratio SCC are compared with those from other studies, it can be seen that the use of SPFA results in SCC with a binder content of 105-270 kg/m^3 lower than used in comparable studies around the world [22], Figure 7.

Figure 7. Comparison between total binder contents used in this research and leading projects worldwide.

The explanation for this lies with the nature and properties of the SPFA particles. As a Bingham fluid, in order to maximise the ability of concrete to deform under its own self-weight, the internal yield stress must be minimised. This can be achieved by preventing the formation of Van der Waals bonds between adjacent cement particles as they flocculate in the cement paste. Generally, this is achieved via the addition of expensive admixtures, which adhere to the cement particles and impart a charge, causing repulsion. This deflocculation improves the dispersion of free water throughout the mix thereby increasing the workability of the concrete. PFA can work in the same

way, coating the surface of the cement particles and giving them a charge[23]. SPFA will similarly adsorb to the surface of cement particles however due to the smaller particle size, SPFA does this more effectively. Further, in common with PFA, SPFA is hydrophilic in nature and introduces additional water entrainment into the mix thereby giving more consistent dispersion of free water and in turn reducing the tendency for bleeding and segregation and increasing cohesion due to the higher number of interparticular contact points associated with the smaller SPFA particles.

The research on this new area of concrete and ash technology is continuing at the CCC to develop a complete range of SCC mixes using SPFA at various levels and at staged water-binder ratios, in addition to ultra-high strength, compactable concrete for flexible architectural solutions.

7. CONCLUSIONS

1. Superclassified PFA (SPFA) has been shown to be suitable for making low cementitious content, extremely cohesive, self-compacting concrete at water-binder ratios between 0.2 and 0.45.
2. A 30% replacement of SPFA for cement has been found to be the optimum replacement level.
3. When SPFA is used to make SCC, the cementitious content is markedly lower (up to 280kg/m³) than other SCC concretes made with conventional materials.
4. Virtually zero segregation or bleeding and extremely high cohesiveness and flow characteristics are observed in SCC made with SPFA.
5. The SSCI test has been shown to be more sensitive to the tendency for SCC mixes to segregate than the slump-flow test and has been adopted as a second check on SCC developed at Sheffield University.
6. Self-compacting SPFA concrete mixes may be considerably more durable than similarly-proportioned concrete mixes made with other alternative cement replacement materials, as shown by their significantly lower absorption, which indicates a better resistance to physical penetration of aggressive ionic species.
7. In a large-scale trial, the SPFA SCC cast as a column exhibited no signs that segregation of any description had taken place over its height.

ACKNOWLEDGEMENT

The authors are grateful for the support and materials received from Sphere-Fill (Pty) Ltd that allowed the research work leading to this paper to be carried out.

IMPORTANCE OF MINOR PHASE INCLUSION IN THE RIETVELD ANALYSIS OF CEMENT CLINKER

ABSTRACT

The effect of minor phases on the quantitative phase analysis of cement clinker by the Rietveld method was investigated. Simulated laboratory x-ray data-sets were constructed from set quantities of cement clinker components that approximated a known clinker, with differing counting statistics. These simulated data-sets were then refined with and without prior knowledge of the phases present. In half of the refinements the smallest weight percentage phase, the rhombohedral tricalcium silicate phase, was not included in the refinement. Comparison of the phase quantification results obtained from these different strategies showed that in the refinements from the high count data-set, the phase quantities were not significantly disturbed by not including the minor phase, whereas the refinements using the low count data-set showed a large variation in phase quantification results. This has implications for the interpretation of quantitative phase analysis results from low count data such as obtained from on-line cement analysis.

1. INTRODUCTION

There has been an increase in the use of Rietveld refinement of powder diffraction data for the quantitative phase analysis of cement and analysis of cement components in recent years [1]. The complex nature of cement clinker components and structural modifications of each phase makes phase quantification of cement clinker difficult. Although Rietveld provides the most consistent results for even the interstitial phases, overlapping phase peaks from the multiphase system in diffraction patterns further complicated phase analysis by this method.

Major phases present in clinker are tricalcium silicate (Ca_3SiO_5), dicalcium silicate (Ca_2SiO_4), tricalcium aluminate ($\text{Ca}_3\text{Al}_2\text{O}_6$), and tetracalcium aluminoferrite ($\text{Ca}_2(\text{Al}_2\text{O}_3)_x(\text{Fe}_2\text{O}_3)_{1-x}$). Clinker composition is complicated by the crystal modification of some of these phases. The solid solution of tricalcium silicate in cement is called alite. Three structural models are commonly used in the Rietveld analysis of cement clinkers, including a triclinic, a monoclinic and a rhombohedral model. Only one of the dicalcium silicate polymorphs has been shown likely to be present in cement clinkers, the monoclinic β -type. Tricalcium aluminate exists in three modifications, a monoclinic, an orthorhombic, and a cubic type, through ion substitution. The cubic and orthorhombic modifications of this phase are likely to be present in clinker. Tetracalcium aluminoferrite appears in one form, with a varying Al:Fe ratio.

Rietveld analysis techniques are currently applied to on-line powder diffraction data from cement clinker directly from the kiln. A common practise is to refine until a good figure of merit is achieved. One of the problems with the Rietveld analysis of cement clinkers is the existence of

multiple small weight percentage phases. Often these smaller phases can exist below the detectable limit for Rietveld methods, which is dependent on the size and complexity of the unit cell being modelled. The compounded effect of multiple missing phases in the Rietveld model means that if the fit of the model to the data is still good despite multiple missing phases, then the model is compensating for these missing phases which could generate incorrect results. If the Rietveld analysis model is being used for phase quantification purposes, the effect of missing phases could result in incorrect quantitative phase analysis of the clinker material.

2. EXPERIMENTAL

Simulated data was used as a tool for investigating the effect of minor phases on Rietveld analysis of data with differing counting statistics. Cement clinker powder diffraction data-sets were simulated using the Rietveld program Rietica [2]. Typical counting intensities were modelled from real data collected using Cu K α radiation on the Scintag x-ray diffractometer at the Australian Nuclear Science and Technology Organisation (Scintag X1, Scintag Instruments, U.S.A.). Data were simulated over the range $2\theta = 2.00 - 90.00^\circ$ with a stepping of 0.02° . A single-term 5th order polynomial function was used to model the background, and peak shape parameters were based on real cement clinker sample data taken from the instrument that was simulated. Rietveld scale factors were calculated from weight percentages based on real clinker compositions using the ZMV relationship [3], where Z is the number of formula units per unit cell, M is the mass of the formula unit and V is the unit cell volume. Instrumental noise was simulated using a random number generator with a normal distribution. Two data-sets were generated, one known as the high count data-set, where counting statistics resulted in the most intense peak from the pattern having an intensity of around 3000 counts, the other known as the low count data-set, where this peak had an intensity of around 600 counts. The background term used in the low count data-set was 1/5th of that used in the high count data-set. Modelled phase compositions were based on a real ordinary Portland cement clinker composition. The model constitution is outlined in Table 1.

Table 1. Component structures and composition used in data simulation

Phase	Structural reference	Wt. % from ZMV
Alite	-	61.14
Tricalcium silicate triclinic	T ₁ [4]	19.84
Tricalcium silicate monoclinic	M ₃ [5]	38.86
Tricalcium silicate rhombohedral	R [6]	2.44
Dicalcium silicate	β [7]	17.07
Tricalcium aluminate	Orthorhombic [8]	9.21
Tetracalcium aluminoferrite	Orthorhombic [9]	12.58

Each data-set was at first refined with a new refinement data file, and approached with prior knowledge of all phases present, but without knowledge of peak shapes, scale factors, or any refinable parameters. This was known as refinement strategy number 1. The next refinement was performed in the same manner as the first, but approached as a blind data-set refinement, without prior knowledge of the phases present. This was known as refinement strategy number 2. Refinements were deemed finished when no further significant improvement in fit could be made.

3. RESULTS AND DISCUSSION

Table 2 shows the ZMV calculated or “ideal” phase quantities, as well as the phase quantification results for the two refinements made for each data-set. The Rietveld figures of merit R_p and Goodness Of Fit (GOF) are listed in Table 3. In the first column of Table 3, the figures of merit are based on fits of the ideal input to the simulated data without refinement of any parameter. In the case of refinement strategy 2 of both data-sets, the fits of the model to the data were deemed good

enough to not to continue searching for any further phases. The approach to Rietveld refinement of a cement clinker data-set often involves the search for one polymorph of tricalcium silicate at a time. As the rhombohedral modification of tricalcium silicate is usually present in much lower quantities than all other polymorphs, if at all, it is usual to include this as a final step of phase identification. Hence refinements using strategy number 2 did not include the search for this phase. Inspection of the difference line did not yield visual clues to the possibility of a missing phase. The intensity of the largest reflection from this phase was observed as approximately 135 counts in the low count data-set, and 675 counts in the high count data-set.

In Figures 1-4, crosses represent the observed data, and the solid line through the observed data is the result of the Rietveld fit. The line below the markers represents the residual or difference line.

Figures 1 and 2 represent refinements of the high count data-set, and Figures 3 and 4 represent refinements of the low count data-set. The short vertical bars mark the positions of the Bragg reflections of each phase. Figures 1 and 3 represent refinements with all phases present, and peak markers from top to bottom represent the phases triclinic tricalcium silicate, rhombohedral tricalcium silicate, dicalcium silicate, monoclinic tricalcium silicate, tricalcium aluminate and tetracalcium aluminoferrite respectively. Figures 2 and 4 represent refinements without the rhombohedral tricalcium silicate phase present, and peak markers from top to bottom represent the phases triclinic tricalcium silicate, dicalcium silicate, monoclinic tricalcium silicate, tricalcium aluminate and tetracalcium aluminoferrite respectively.

Figure 1. High count data-set refinement with all phases.

Figure 2. High count data-set refinement not including rhombohedral tricalcium silicate

Figure 3. Low count data-set refinement with all phases

Figure 4. Low count data-set refinement not including rhombohedral tricalcium silicate

Table 2. Phase quantification results from refinements of the low and high count data-sets

	Wt. % "Ideal"	Wt. % 6 phases	Wt. % 5 phases	Wt. % 6 phases	Wt. % 5 phases
Phase/Refinement		1 (High count)	2 (High count)	1 (Low count)	2 (Low count)
Alite	61.1	61.4(5)	61.5(3)	62.4(9)	72.1(7)
Ca ₃ SiO ₅ T ₁	19.8	20.0(3)	20.1(2)	20.0(6)	69(1)
Ca ₃ SiO ₅ M ₃	38.9	39.1(5)	41.9(3)	41(1)	2.8(4)
Ca ₃ SiO ₅ R	2.4	2.4(3)	Not inc.	1.71(6)	Not inc.
Ca ₂ SiO ₄	17.1	16.8(2)	16.9(2)	16.0(5)	4.9(5)
Ca ₃ Al ₂ O ₃	9.2	9.2(1)	9.1(1)	9.0(3)	9.8(4)
Ca ₂ FeAlO ₅	12.58	12.63(9)	12.56(7)	12.6(2)	13.3(2)

Table 3. Figures of merit for refinements of the low and high count data-sets

Figures of merit/Refinement	"Ideal"	Refinement 1 6 phases	Refinement 2 5 phases
GOF (High count)	1.031	1.030	1.051
R _p (High count)	3.002	2.993	3.027
GOF (Low count)	1.036	1.022	2.266
R _p (Low count)	6.653	6.662	9.913

As expected, Rietveld figures of merit were generally better for the refinements of the high count data-set than for those of the low count data-set, although refinement strategy number 1 of the low count data-set resulted in an unusually good GOF, even when compared to the "ideal" GOF. This result was not reflected in the R_p value. In both data-sets, refinement with all phases (refinement

strategy number 1) resulted in better Rietveld figures of merit than were obtained from using refinement strategy number 2, where a phase was missing from each model.

Refinement using strategy number 1 of both data-sets, where all phases were used, yielded phase quantification results near to the “ideal” amounts. Refinement strategy number 2, where the rhombohedral modification of tricalcium silicate was not modelled, yielded similar results to the “ideal” amounts from the high count data-set, but the low count data-set exhibited some large phase quantification variations. The most significant differences in results between the two data-sets using the refinement strategy number 2 was the weight percentages of tricalcium silicate and dicalcium silicate phases. Using refinement strategy number 2 and the high count data-set, an amount of dicalcium silicate and tricalcium silicate polymorphs (both the triclinic and monoclinic forms) similar to the ideal quantity was found. The corresponding refinement of the low count data-set however, resulted in approximately 71wt. % less dicalcium silicate, 245 wt. % more triclinic tricalcium silicate, 93 wt. % less monoclinic tricalcium silicate, and 18 wt. % more total alite than was found using refinement strategy number 1. This result is alarming, as the incorrect result is not reflected in the figure of merit, which is still reasonably good. The amounts of tricalcium aluminate and tetracalcium aluminoferrite phases found using refinement strategies 1 and 2 were not notably different.

Rietveld packages specifically designed to give phase quantification results of cement clinker are being increasingly used in industry, and although they represent the best routine analysis methods available, they are limited by the statistics available from the data count rates. The tricalcium and dicalcium silicate phase in cement powder diffraction patterns are heavily overlapped and the effect of this can be detrimental to phase quantification results from Rietveld analysis, especially at lower count rates when resolution becomes an issue. As the powder patterns for the polymorphs of tricalcium silicate are similar, it is difficult to locate which polymorphs are present in clinker, although it is important that care be taken to look for all polymorphs. Low count data appears to be more prone to false refinement minima during Rietveld analysis than the high count data.

THE DEVELOPMENT OF AN AFFORDABLE K GALAGADI SAND BUILDING BLOCK (KSBB) – A POSITION PAPER

Esau U. Masuku¹ and Botshelo H. Maedza²

² Member of Botswana Institution of Engineers (MBIE), E-mail: har709@botec.bw

ABSTRACT

About three-quarters of Botswana is covered by Kgalagadi Sands (KS). KS are invariably closely graded, consist of medium to fine sub-rounded particles and contain insignificant amounts of silty and clayey fractions. As a result of these physical and chemical properties, KS lack packing and therefore compactibility, have very high voids ratios and are cohesionless. Consequently, the wet and dry strengths (compressive, shear and flexural), dimensional stability, durability and aesthetics of building blocks moulded with KS alone, in the very rare cases where they occur with silts and clays of the right quantities and quality, are well below acceptable values.

This position paper describes the extensive experimental work currently underway at Botswana's major multi-disciplinary Research and Development (R&D) Centre – Botswana Technology Centre. The work seeks to render this immensely abundant and widely available, but hitherto unusable resource, utilizable in construction. The affordability of the resultant KSBB shall derive from the local availability of KS as a raw material, usage of locally manufactured equipment and exploitation of local, largely unskilled labour force under supervision by semi-skilled artisans.

Keywords: Acceptable values (of KSBB properties), medium to fine particles (of KS), packing (of KS)

1. INTRODUCTION

Utilisation of a given soil as a building material implies a fundamental choice between three options. The first case involves using the soil available on site as it is. Under such circumstances the properties of the soil have to be accommodated in the project design process. In other words, the project has to be adapted as much as possible to the quality of the soil. The second option is to import soil with the desirable properties. Such a soil would be one with properties more suited to the requirements of the project. Finally, the soil may be improved by imparting to it the desirable properties. The locally available soil is modified so that it is better suited to the requirements of the project.

Kgalagadi sands are invariably characterised by a narrow medium to fine particle size distribution and insignificant silt and clay contents. They thus lack packing and therefore compactibility. They also lack cohesiveness. Compactibility and cohesiveness of the soil are the two major factors that account for the strength, durability and finish of a soil block. It is thus quite apparent that soil-block making cannot be adapted to Kgalagadi sands as they naturally occur. About $\frac{3}{4}$ of Botswana is covered by Kgalagadi sands. Therefore, the option of importing soils more suited to the requirements of soil-block making is quite clearly not cost-effective. That leaves open only the third option. The abundantly available Kgalagadi sands must be modified so that they are suited to the

requirement of building block making. Improving a given soil by imparting to it purpose-specific properties is generally termed soil stabilisation.

This paper presents a methodology for stabilising Kgalagadi sands. The methodology is based on improving both the compactibility and cohesiveness of the Kgalagadi sands. The compactibility of a given Kgalagadi sand is enhanced by “widening” its particle size distribution. Cohesiveness is imparted to the given Kgalagadi sand through the introduction of a three dimensional matrix that binds Kgalagadi sand particles together. Cement is the key determinant of the strength and durability of the matrix. Therefore, the chemistry of cement is of pivotal importance in developing the methodology for stabilizing Kgalagadi sands. In adherence to the subject of the Conference, this paper will focus on the chemistry of cement as a stabiliser for Kgalagadi sands.

2. CEMENT AS A STABILISER FOR KGALAGADI SANDS

Soil stabilisation is not necessarily cost-effective, at least immediately. Experience shows that it can involve considerable extra costs ranging from 30 to 50% of the final cost of the building materials [1]. On that account, the cost implications of soil stabilization have a direct bearing on the development of the methodology for imparting the desirable properties to a given soil.

Being narrowly graded and consisting of medium ($0.20 < \phi \leq 0.60\text{mm}$)¹ to fine ($0.06 < \phi \leq 0.2\text{mm}$)¹ subrounded grains, Kgalagadi sands are characterized by very high voids ratios ranging from 48 to 72 % by volume [2]. A combination of such high voids ratios and cohesionlessness of Kgalagadi sands significantly increases cement paste demand in the KSBB. Consumption of cement, by far the most energy-intensive and therefore most expensive component in the KSBB, increases correspondingly. It thus makes economic sense to use a pozzolan – a much less expensive substance to substitute in part the cement content in the KSBB. In Botswana, the only readily available pozzolan is fly ash produced by the Morupule Thermal Power Station. Therefore, the strength and durability of the three-dimensional matrix binding Kgalagadi sand particles together is determined by three major factors. They are the type of cement used, the type of pozzolan used and the cement + fly ash : Kgalagadi sand : water, ratio by mass.

2.1 Choice of cement for stabilising Kgalagadi sands

The selection of a cement for stabilising Kgalagadi sands is dependent on the set of indicators identified and analysed below.

2.1.1 Lime content of Morupule flyash

Given that only Morupule flyash is readily available as the potential cement extender, the choice of cement for stabilising Kgalagadi sands depends on the lime (CaO) content of this artificial pozzolan. Table 1 below shows that Morupule flyash is a low lime flyash. Since the CaO content in Morupule flyash is less than 10%, the latter is classified as a Class F flyash.

¹ Jackson, N.Ravindra, K.D. (Editors). Civil Engineering Materials 4th Edition

Table 1. Content of oxides in Morupule flyash

No.	Oxide	Content, % by mass				Range
		B.K. Sahu ²	BPC	SIRDC ³	T. Kudo	
1	SiO ₂	41.20	40.80	43.00	53.70	40.80 – 53.70
2	Al ₂ O ₃	33.60	34.70	33.50	23.20	23.20 – 34.70
3	Fe ₂ O ₃	5.08	8.80	5.20	2.80	2.80 – 8.80
4	MgO	3.00	3.50	3.30	2.90	2.90 – 3.50
5	CaO	6.45	8.70	8.10	9.70	6.45 – 9.70

11	MnO	-	-	-	0.07	-

* While the % oxide content in the first three columns were sources from B.K. Sahu, BPC & SIRDC, they in fact were all determined from SACAA laboratories. T. Kudo's results were obtained in Japan on our request. Therefore, the sharp differences in values could be ascribed to the methods of testing used at the two facilities. To a lesser extent, that could be due to the variability of flyash properties – a normal phenomenon. A re-run of the analysis has been requested.

The hardened cement paste (hcp) based on cement + Morupule flyash as the cementitious component has very low early age strength. This is because the production of tricalcium disilicate hydrate (C₃S₂H₃) by the pozzolanic reaction (1) is secondary to the production of the same chemical compound by hydration of cement, represented by reactions (2) and (3).

where: S – SiO₂, CH – Ca(OH)₂, C₃S₂H₃ – 3CaO.2SiO₂.3H₂O, C₃S – 3CaO. SiO₂,
H – H₂O, C₂S – 2CaO.SiO₂.

The calcium hydroxide (CH) that takes part in the pozzolanic reaction would have been produced by reactions (2) and (3) in the process of hydration of cement. The tricalcium disilicate hydrate produced by the pozzolanic reaction starts to appear at about the time of initial set, when the ettringite [Ca₆Al₂(SO₄)₃(OH)₁₂.26H₂O] from adjacent cement particles starts to develop.

On the basis of the above characterisation of Morupule flyash, cement for stabilising Kgalagadi sands must be of high early strength class.

2.1.2 Water content of KSBB mix.

There are three major determinants of KSBB strength. In order of significance, they are : the strength of the transition zone between the hcp and the aggregate (Kgalagadi sand particles), the

² Unconfined Compressive Strength of Fly ash stabilised Sandy Soil (Proceedings of the Kgalagadi Sand Building Block Workshop, 18-19 March, 1999, Gaborone Botswana)

³ History and properties of South African Flyash and Portland flyash cements. The South African Coal Ash Association (SACAA).

strength of the hcp and the strength of the aggregate. The first two factors are inversely proportional to the water/cementitious ratio. In the case of the hcp, the relationship to the W/C ratio is through porosity. Porosity is directly proportional to the W/C ratio. In a nutshell, the lower the W/C ratio (the “drier” the mix), the stronger the KSBB, provided that the mix is adequately compacted.

It follows from the above analysis of the influence of the W/C ratio on KSBB strength that the binder for stabilising Kgalagadi sands must have a of minimal water demand. Figure 1 below illustrates the influence of the W/C ratio on strength development of OPC + pozzolan concrete.

Figure1. Influence of W/C ratio on strength development of OPC + pozzolan concrete (after Blanks and Kennedy, 1955).

2.1.3 Rate of hydration

Ordinary Portland cement (OPC) generates considerable heat of hydration in its early age. The resultant heating/cooling cycle aggravates thermal shrinkage and therefore cracking of the cement product. Partial replacement of OPC with flyash can significantly reduce or even completely eliminate cracking due to early age heat of hydration-induced alternate heating and cooling.

Therefore, cement for stabilising Kgalagadi sands does not have to be of low early age heat of hydration.

2.1.4 Alkalinity

OPC exhibits significant levels of alkalinity. Alkalinity may lead to the disruptive alkali-silica reaction (ASR). Experiment shows that although a flyash may contain high total alkali ($K_2O + Na_2O$) levels, the extent to which this contributes to the total alkalinity of the total pore water appears to be insignificant when the flyash is combined with high alkalinity cement. The effective total alkalinity is reduced. Substitution of OPC by at least 25% of flyash has been observed to limit

the total alkali content of concrete, to less than 3.0kg/m^3 . That is less than the threshold of $3.5 - 4.0\text{kg/m}^3$, below which no disruption will occur, even with reactive aggregates.

As a consequence of the effect fly ash has on high alkalinity cements, cement for stabilising Kgalagadi sands need not be of low alkalinity.

The analysis given above shows that a cement for stabilising Kgalagadi sands must preferably be of high early strength and of low water demand. Furthermore, that cement does not have to satisfy the requirements of low heat of hydration or low alkalinity. In other words, it is of no consequence that the cement is of high heat of hydration and/or high alkalinity. The significance of this analysis is that the choice of cements for stabilising Kgalagadi sands is widened. Table 2 below gives preferred cements, selected on the basis of the four indicators outlined above.

Table 2. Selected cements for stabilising Kgalagadi sands

No.	Standard	Class/Type	Description
1	SABS ENV 197 – 1:1992	32.5 R	High early – strength
2	“	42.5 R	“
3	“	52.5 R	“
4	ASTM C150	I	Normal, general purpose
5	“	IA	Normal, air - entraining
6	“	III	High early – strength
7	“	IIIA	High early – strength, air - entraining

3. SUITABILITY OF MORUPULE FLYASH FOR USE AS CEMENT EXTENDER

According to Sersale (1980), flyash suitable for use as a cement extender must have a chemical composition such that the following conditions are satisfied:

$$\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3 \geq 70\%, \text{ by mass} \quad (4)$$

$$2.5\% < \text{SO}_3 < 5\%, \text{ by mass} \quad (5)$$

$$\text{MgO} \leq 5\%, \text{ by mass} \quad (6)$$

$$(\text{K}_2\text{O} + \text{Na}_2\text{O}) \leq 1.5\%, \text{ by mass} \quad (7)$$

$$\text{LOI} \leq 12\%, \text{ by mass} \quad (8)$$

The total alkali content ($\text{K}_2\text{O} + \text{Na}_2\text{O}$) generally exceeds the 1.5% by mass limit. This will not pose a problem as long as the alkali available for reaction is below the stipulated limit of $(\text{K}_2\text{O} + \text{Na}_2\text{O}) \leq 1.5\%$, by mass.

The Loss on ignition (LOI) is related to the carbon content of the ash. The presence of carbon does not, as such, influence the pozzolanic reaction. Its limitation has to do with discoloration of the KSBB. Table 3 below shows that Morupule flyash satisfies all but one requirements stipulated by Sersale.

Table 3. Suitability of Morupule flyash for use as a cement extender according to the Sersale criteria

No.	Property	% content, by mass			
		B.K. Sahu	BPC	SIRDC	T. Kudo
1	Si + Al + Fe	79.88>70	84.30>70	81.70>70	79.70>70
2	SO ₃	-	-	-	0.90<5
3	MgO	3.00<5	3.50<5	3.30<5	2.90<5
4	K ₂ O + Na ₂ O	0.54<1.5	0.50<1.5	-	0.03<1.5
5	LOI	-	-	-	3.50<12

The requirement that sulphur tri-oxide (SO₃) must be greater than 2.5%, by mass is unacceptable. It actually contradicts the requirement that utilisation of flyash as a cement extender should not result in creating an acidic medium in the cement paste. In this case the acidic medium would be a result of the formation of either the unstable weak sulphurous acid (H₂SO₃) or the stable highly corrosive sulphuric acid (H₂SO₄).

It is noteworthy that the chemical composition of a pozzolan is not a reliable criterion for its reactivity. Furthermore, chemical tests to evaluate reactivity may indicate the presence of a pozzolanic reaction. However, that would not indicate the strength characteristics of the OPC + pozzolan hcp. The only safe way to determine the suitability of a given pozzolan for use as a cement extender is to test it in product mixes. It is generally accepted that strength tests are the most suitable method of evaluating the activity of a pozzolan. Compressive strength is normally used as a measure of strength and cube specimens are preferable to cylinders because the latter require some form of capping to ensure that the ends are plane and parallel.

4. OPC + MORUPULE FLYASH : KGALAGADI SAND : WATER, RATIO

Determination of the above ratio is the ultimate goal of the methodology for stabilising Kgalagadi sands. Figure 2 shows that cost-effectiveness of the final product (KSBB) serves as the measure for optimal mix design.

Figure 2. Connectivity between soil and KSBB properties

As pointed out in 2.0, the cement component is by far the most expensive ingredient of the KSBB. Therefore, the cost-effectiveness of the final product will be greatly enhanced by a significant reduction in the cement content of the KSBB. In other words aggregate packing must be improved. This can be achieved by widening the very narrow grading of Kgalagadi sands (see Figure 3 below) through mixing them with coarser aggregates from readily available calcretes.

Figure 3. Particle size distribution of Kgalagadi sands

Figure 4 condenses the methodology for stabilising Kgalagadi sands:

Figure 4. Flowchart of purpose-specific experiments

N.B. For brevity, the expression “calcrete &/or sintered FA” is abbreviated to “cal &/or sFA”; “Dry Density” to “D.D.”; “Compressive Strength” to C.S.”; Moisture Content” to M.C. & “Compacting Effort” to “C.E.”.

5. CONCLUSIONS

Cement holds the key to the exploitation of the abundant Kgalagadi sands as a viable raw material for building block production. The built-environment needs of such a developing country like Botswana can be catered for by the use of cement as a stabiliser for Kgalagadi sands provided that it is cost-effective. Therefore, cement, an expensive product, must be extended through blending it with a readily available pozzolan – Morupule flyash. The chemistry of the interaction of cement with, among other constituents of the KSBB, flyash, must be focused upon. This will provide for the development of a strong, durable, aesthetically acceptable and affordable KSBB with predictable chemical, physical and mechanical properties.

THE LONG-TERM PERFORMANCE OF CEMENTITIOUS MATERIALS IN UNDEGROUND REPOSITORIES FOR NUCLEAR WASTE

Thorsten Meyer and Horst-Jürgen Herbert

Gesellschaft für Anlagen- und Reaktorsicherheit (GRS) mbH, Braunschweig. E-mail: met@grs.de

ABSTRACT

The long-term behavior of cemented fly ashes in high saline brines has been investigated by means of a time accelerating leaching experiment and by the geochemical modeling of the observed reactions. The investigated materials, cemented hard coal fly ash (SFA) and brown coal fly ash (BFA), were mixtures of fly ashes, blast furnace cement, halite and saturated NaCl solution. The leaching fluids were a saturated NaCl-CaSO₄ solution and an IP21 solution, likely to occur in salt and potash mines, used in Germany as repositories for radioactive and hazardous chemical wastes. The employed leaching experiment was developed at GRS specifically for the boundary conditions of underground repositories. The experimentally observed reaction path was modeled using the computer code EQ3/6. In a second step the laboratory-scale and modeled results were compared with results of a full-scale experiment in the Asse salt mine.

The results of a 10-year leaching experiment with cemented fly ashes are in good agreement with the reaction path obtained by the time accelerating cascade experiment and geochemical modeling. Thus we can demonstrate that the experimental and modeling tools employed have proved suitable for the evaluation of the long-term behavior of cementitious materials in repositories in salt formations. It can be concluded that the investigated cementitious materials in Mg-rich brine will be less stable than in NaCl-CaSO₄ solution.

1. INTRODUCTION

In the German concept cements and cement based systems are proposed as technical barriers like dams and backfill materials for the final disposal of radioactive and hazardous wastes in salt formations. Cemented waste forms can represent a significant part of the inventory material, based on cements and fly ashes. Additionally, fly ashes can also be used as backfill material in the final disposal of radioactive and hazardous wastes. The long history of cementitious materials in this area is founded on the durability and persistence under environmental conditions. They have chemical and physical retention potential for nuclear waste and are resistant to many solutions and materials.

In contact with high saline solutions cementitious materials can show a significant change in their structure. Therefore the safety assessment of the repository system implies detailed knowledge of the geochemical behavior of cement and concrete systems in the salt environment. In case of a brine intrusion in the repository, significant changes of the structure, the chemical and themineralogical composition can be expected. Dissolution and precipitation processes will result in changes of the brine composition and pH. All these changes have a high impact on the long-term performance of the technical barriers but also on the solubilities of radionuclides and toxic heavy metals in the repository.

2. CASCADE EXPERIMENTS

In order to understand the complex interactions in the leaching and corrosion processes, a special laboratory scale experiment was developed, which leads in several steps (cascades) towards the thermodynamic equilibrium. It is a fast experimental method for the investigation of the reaction path of the fluid-solid interactions.

In a cascade experiment a weighed mass of the ground material is reacted with a certain mass of solution (first cascade). After 2-3 days of equilibration under continuous rotation of the reaction vessel at 25°C, the solution is extruded through a pressure filter onto unreacted material (second cascade). While these steps are repeated, the effective solid-solution ratio increases. The number of steps in the experiment ranges from 10 to 20. The number of steps is limited by the continuously decreasing volume of leachate. For each cascade the solution as well as the solid material are analyzed by ICP-MS and ICP-OES, in addition the mineral phases of the solids are analyzed by XRD. Further experimental details are given in [1].

The results of this laboratory experiment are compared with the results of geochemical modeling and with results of a full-scale in-situ experiment in the Asse salt mine.

3. GEOCHEMICAL MODELING

The Gibbs enthalpy for the formation of a solid phase from an aqueous solution consisting of species i is given by the following expression:

$$\Delta G = \Delta G^0 + RT \ln \prod_i a_i^{v_i} \quad (1)$$

At equilibrium, $\Delta G = 0$ and the product of activities becomes K , the equilibrium constant:

$$\Delta G^0 = -RT \ln K \quad (2)$$

The activities are a product of the molalities m_i and the activity coefficient γ_i of the species:

$$K = \prod_i a_i^{v_i} = \prod_i m_i^{v_i} \gamma_i^{v_i} \quad (3)$$

The theory of Debye and Hückel is based on the assumption that strong electrolytes are completely dissociated in solution. Following the theoretical considerations of Debye and Hückel the activity coefficient of a strong electrolyte is a function of the solution's ionic strength. For Debye-Hückel the activity coefficient can be expressed:

$$\ln \gamma_i = -A z_i^2 \sqrt{I}; \quad I = \frac{1}{2} \sum_i m_i z_i^2 \quad (4)$$

A : Debye-Hückel coefficient; z_i : ion charge; m_i : molalities of the species

The Debye-Hückel-Theory is valid only for ionic strength less than 10^{-2} - 10^{-3} M. Several extended equations have been established (Güntelberg, Davies). Pitzer and Co-workers developed a model which extends the Debye-Hückel expression for the calculation of ion activity coefficients in terms of the specific interactions between two or three ions.

The Pitzer formalism extends the Debye-Hückel expression with a virial expansion to account for binary and ternary ionic interactions between ions of like and opposite charge:

$$\ln \gamma_i = f(I) + \sum_j \lambda_{i,j}(I)m_j + \sum_j \sum_k \mu_{i,j,k} m_j m_k \quad (5)$$

$f(I)$: Debye-Hückel expression; $m_{j,k}$: molalities of the species; λ, μ : interaction coefficients

The Pitzer expression includes specific parameters which have to be determined for each individual ionic interaction.

The experimentally observed reaction path was modeled using the computer code EQ3/6 [2-3], release 7.2a, and the thermodynamic database for the seawater system of Harvie, Møller and Weare [4], extended by Pitzer coefficients for Al and Si estimated by Reardon [5]. The solubility data used for cement phases (Table 1) were those published by Revertegat et al. [6], Berner [7] and NEA data listed by Glasser et al. [8].

Table 1. Solubility data of cement and mineral phases.

Phase	Formula	log K _{sp}	Phase	Formula	log K _{sp}

A = Al₂O₃, C = CaO, Cs=CaSO₄, Cc=CaCl₂, H=H₂O, M = MgO, S = SiO₂

The chemical composition of the cemented materials for the main components to be modeled are listed in Table 2. The cemented BFA contains 54 wt-% of rock salt (94 wt-% of halite and 6% of anhydrite). The water cement ratio of cemented SFA is w/c = 0.4, that of cemented BFA w/c = 1.8.

The initial composition of the IP21 and NaCl-CaSO₄ solutions are given in Table 3. The solutions were first computed via an EQNR3 run. The reaction path of the material interaction with the different solutions were modeled in an EQ6 run using the titration model. The steps of the EQ3/6 run (z_i) correspond to the reaction i.e. the corrosion progress.

Table 2. Main components of the investigated materials.

Element	BFA	Cemented BFA	Cemented SFA
	[mg/kg]	[mg/kg]	[mg/kg]

In order to simulate the corrosion of cementitious materials, the dissolution of portlandite, a main component in cement systems, can be used in a first attempt to predict the solution composition [9-11]. For the prediction of the reaction of complex systems like cementitious materials in contact to saline solutions special reactants were defined by using the chemical composition of the material.

4. RESULTS AND DISCUSSION

The comparison of the experimental results of the dissolution of the cemented hard coal fly ash with the modeled dissolution of the special reactant shows a good agreement for the ions Mg^{2+} , Na^+ , Cl^- and SO_4^{2-} in solution. Figure 1 shows the experimental and calculated development of the elements in solution during the leaching process of cemented coal fly ash (SFA). The strong decrease of Mg^{2+} in solution is very similar to that of portlandite dissolution [11]. This decrease is due to the precipitation of the mineral phase brucite ($\text{Mg}(\text{OH})_2$). Parallel to this process an increase of Ca^{2+} was found up to 2.1 mol/kg H_2O in the third cascade. After the third cascade a reduction of Ca^{2+} in solution could be observed accompanied by the precipitation of newly formed CSH and CSAH phases.

The modeling with the special reactant reflects the decrease of Ca^{2+} in solution according to the experimental results after the third cascade. K^+ stays nearly constant in the experiment, in the modeling K^+ increases. Due to the high concentration of NaCl in the cemented SFA Na^+ increased, whereas Cl^- slightly decreased. These results were observed in the experiment as well as in the modeling. During the first cascade SO_4^{2-} decreased to an amount of $< 10^{-4}$ mol/kg H_2O in solution (Figure 4). The sulfate ions were fixed in the newly formed phase gypsum, which could be identified in the XRD spectrum of the solid material after the first cascade. The pH rose stepwise from 5.8 to 12.4.

Brucite is formed during the first four cascades in rather large quantities. The formation of this phase is controlled by the amount of Mg^{2+} in solution. Brucite precipitates as a gel-like phase. This gel was observed macroscopically but it could not be detected by XRD as it is not in a crystalline state immediately after precipitation. It controls the pH during the first four cascades. After the consumption of all Mg^{2+} brucite precipitation ceases and the pH increases stepwise up to 12.4. The minerals detected in the cascade experiment partially correspond to those found in the geochemical modeling. In addition the modeling indicates that further minerals like chrysotile may be involved in the reaction. Talc occurs as an intermediate phase which becomes stable at a certain step of the reaction path and disappears later. Halite is also present in the system in large quantities and therefore not shown in Figure 1.

The reaction of BFA (Figure 2) and cemented BFA in contact to IP21 solution resulted in very similar solution compositions and precipitated mineral phases. These reactions will be discussed together and compared with the reaction of SFA in contact with IP21 solution. Similar to the reaction of cemented SFA, an increase of Ca^{2+} in solution was found as well as a decrease of Mg^{2+} . The decrease of the leaching fluid terminated the cascade experiment at an early step of the reaction path. The calculated reaction path indicates that Mg^{2+} will be precipitated in the phase talc. In the further progress of the reaction the Ca^{2+} will, similar to the reaction of SFA, decrease. The experimentally observed and the calculated Na^+ concentration keeps constant for the different solid/solution ratios. The K^+ and Cl^- increases slightly in the cascade experiment as well as in the modeling of the considered reaction. In addition, the SO_4^{2-} decreases during the first three cascades. The pH stayed at about 8.5. Similar to the SFA reaction, the precipitation of anhydrite/gypsum was observed and brucite was responsible for the Mg^{2+} decrease in solution. The modeled phases are given in Figure 2. According to the modeling of SFA in contact with IP21 solution, gibbsite was calculated. Si was computed as SiO_2 .

The modeled results and the experimentally obtained data for the reaction of cemented BFA in contact with NaCl- CaSO_4 solution are displayed in Figure 3. The comparison of the experimental results of the dissolution of the cemented BFA with the modeled dissolution of the special reactant shows a good correspondence for the ions Na^+ , K^+ , Ca^{2+} , Cl^- and SO_4^{2-} in solution. There was a slight decrease of Cl^- and increase of Na^+ observed in the cascade experiments as well as in the

chemical modeling. Ca^{2+} slightly decreases during the first cascades, limited by precipitation of anhydrite in the modeling.

Figure 1. Reaction path of the dissolution of cemented hard coal fly ash (SFA) in a Mg-rich high saline solution (IP21); upper part: evolution of the solution composition, symbols mark the experimental data and lines the calculated results; lower part: calculated dissolved and newly formed phases.

Figure 2. Reaction path of the dissolution of brown coal fly ash (BFA) in a Mg-rich high saline solution (IP21); upper part: evolution of the solution composition, symbols mark the experimental data and lines the calculated results; lower part: calculated dissolved and newly formed phases.

Figure 3. Reaction path of the dissolution of cemented brown coal fly ash (SFA) in a high saline solution (NaCl-CaSO₄); upper part: evolution of the solution composition, symbols mark the experimental data and lines the calculated results; lower part: calculated dissolved and newly formed phases.

Besides halite the phases SiO₂, chabazit and syngenite were computed by EQ3/6. Equal to the reaction with IP21 solution the phases anhydrite, talc and gibbsite were calculated. The reaction of

cemented BFA in contact to saturated NaCl-CaSO₄ solution is similar to that of pure BFA with the exception of SO₄²⁻ in solution. During the reaction of BFA in contact with NaCl-CaSO₄ solution SO₄²⁻ increases to an amount of 0.8 mol/kg H₂O.

A good agreement between the prediction of the modeled and the calculated solution composition for all five systems was obtained. Further attempts to improve the database for the cement phases will advance the prediction ability. The cascade experiment is a time accelerating experiment. Under in-situ conditions these reactions take several hundred years. Comparing the full scale with the laboratory scale experiments a rough estimate of the reaction time under in-situ conditions until the thermodynamic equilibrium suggests that the investigated materials could have long-term stabilities of several hundred years.

5. COMPARISON OF THE LABORATORY EXPERIMENT WITH FULL-SCALE IN-SITU EXPERIMENT IN THE ASSE SALT MINE

In the Asse salt mine 200 liter forms of cemented waste were leached in IP21 solution over a period of about 10 years [12]. The inactive simulated waste samples for intermediate-level waste (ILW) were fabricated by filling the unhydrated product into drums. After complete hydration of the product, the samples were removed out of the drums and stored at the Asse salt mine exposed to the ambient temperature of $28 \pm 1^\circ\text{C}$ at the 490-m level. Sampling was done periodically at a higher frequency during the initial period and only once a year after a few years of reaction.

Figure 4. Comparison of the Mg²⁺, SO₄²⁻ and the pH in solution in the corrosion experiments in the Asse salt mine and the laboratory GRS cascade experiment; symbols mark the experimental data (cascade and dark red the Asse experiment) and lines the calculated results.

A comparison of the results of the laboratory-scale cascade experiment with the full-scale in-situ experiment in the Asse salt mine shows a good agreement. The concentrations observed in the

leaching solution after 10 years in the Asse experiment correspond to the concentrations between the second and third cascade of the laboratory scale leaching experiment (Figure 4).

6. CONCLUSIONS

Considering the good agreement between the long lasting full-scale in-situ experiment and the time accelerating laboratory-scale cascade experiments, we conclude that it is possible to predict the chemical behavior of cementitious materials in salt solutions. The cascade experiment is a fast method that enables the prediction of the chemical changes in solution during the cement corrosion processes. For the investigated materials in contact with brines, a good agreement between the experimental data and the modeling results was obtained.

The existing thermodynamic database for the geochemical modeling however is still incomplete. Solubility data and dissolution models for CSH phases are incomplete or missing. The Pitzer coefficients of Si and Al still need to be determined more accurately. However the present state of the geochemical modeling with the existing database allows a valuable insight into the processes taking place along the reaction path in the extremely complex system. The experimental and modeling tools employed have proved to be suitable for a prediction of the long-term chemical behavior of cementitious materials.

ABSTRACT

Although several experimental studies have related the peculiar mechanical properties of macro-defect-free (MDF) polymer-cement composites to the existence of a crosslinking of the polymer chains by Al or Ca ions coming from the hydration reactions of the cement, the importance of the crosslinking effects on the MDF properties is still debated. In the present study, the results of previous and present theoretical investigations on the existence and the strength of crosslinking in four different MDF materials are analysed. The combination of two different polymers, polyvinyl alcohol (PVA) and polyacrylic acid (PAA), and two different cements, high-alumina and Portland cements have been considered, that correspond to the Al-PVA, Al-PAA, Ca-PVA, and Ca-PAA ion-polymer systems. The results suggest the following relative strengths of the polymer-chain crosslinking: Al-PVA > Al-PAA > Ca-PAA > Ca-PVA. This scale of relative strength is consistent with the different mechanical properties observed in the case of high-alumina cement and Portland cement MDFs, thus suggesting that crosslinking can significantly affect the MDFs properties.

1. INTRODUCTION

The flexural strength of high-alumina and Portland cement-based materials can be increased dramatically by incorporating a polymer component (e.g., polyvinyl alcohol - PVA) in the cement paste under high shear and subsequent molding under pressure at 80°C [1-4]. The polymer acts as a rheological aid facilitating particle packing as well as a filling agent reducing the material porosity [2]. These modified cements were called Macro-Defect-Free (MDF) cements, referring to the absence of the relatively large voids or defects which are usually present in cement pastes [1, 3].

Several experimental studies have then clarified that a "new" composite material is produced by the incorporation of the polymer in the cement paste, the microstructure of which is characterized by grains of partially hydrated cement particles embedded in a matrix of polymer [5, 6]. Interphase regions coat the individual cement grains. In the case of high-alumina cement (HAC) MDFs, these regions consist of an amorphous phase of Al(OH)₃ and PVA inside of which are dispersed fine crystallites of hydration products. The peculiar mechanical properties of the HAC-MDF materials were initially related to the reduced density of defects in the final cement paste [2, 3]. Further studies have shown that the mechanical behavior of the interphase regions play an important role during the fracture of the MDF materials. Thus, it has been suggested that the mechanical strength of the MDFs can be related to chemical reactions occurring between the polymer and the inorganic ions produced by the cement constituents dissolved in water. More specifically, the existence of a crosslinking of the PVA chains by Al ions has been suggested, i.e., the formation of O-Al-O bonds

where an Al atom is bonded to the O atoms of two different PVA chains [7, 8]. The crosslinking of the polymer chains may have significant effects on the mechanical properties of the MDF materials. Metallic ions may link polymer chains together as well as polymer chains to O atoms of the inorganic matrix, thus strengthening both the network of the polymer chains around the cement grains and the organic-inorganic interfaces. Moreover, crosslinking may favor an intimate mixing of the cement and the polymer as well as the formation of the interphase regions. On the other hand, an excessive networking of the polymer chains induced by crosslinking may damage the interphase regions and hinder the achievement of a workable paste during the material processing. Thus, crosslinking may influence the peculiar strength attained by the MDF materials in two different ways: it may strengthen the organic-inorganic interfaces as well as affect the development of the cement-polymer paste, which in turn affects the final microstructure and the mechanical properties of the MDF materials. Only indirect evidence of a linkage of the polymer chains by ions released by the cement has been found by experiments [5, 6, 9].

Experimental investigations of crosslinking are difficult due to the complex structure of the MDF materials, to the fact that crosslinking is likely localized at the organic-inorganic interfaces, and to a possible interplay between crosslinking effects and material processing. For what concerns the last point, in the case of the HAC-PVA material, it has been suggested that crosslinking reactions are induced by the mechanical work performed during the mixing process [10]. On the other hand, in the case of Portland cements and PVA, it results difficult to obtain a workable paste, possibly because of crosslinking effects given by the Ca ions released by calcium silicates (the main components of Portland cements). The final microstructure and the mechanical properties of the MDFs can also be affected by a post-processing curing of the MDF materials [11].

In conclusion, the mechanical properties attained by an MDF material are likely affected by a complex interplay between crosslinking, processing effects and post-processing treatments. In this scenario, a systematic, theoretical investigation has been started on the existence and the strength of the crosslinking of different polymer chains by different metallic ions. In detail, the crosslinking of two different polymers, i.e., PVA and PAA (polyacrylic acid in anionic form), has been investigated in two different cements: HAC, where Al ions come from the hydration of the cement constituents, and Portland cements, where Ca ions come from the hydration of calcium silicates. Objectives of that investigation were: i) to estimate the potential effects of crosslinking on the material properties by separating them from the processing or post-processing effects; ii) to evaluate the relative strength of crosslinking in different MDF materials. This strength can be directly related to the flexural strength of the MDFs if the processing or post-processing conditions can be arranged to obtain materials with a similar microstructure, i.e., with similar density and type of defects. Further, the results of a theoretical investigation of crosslinking can give suggestions on possible effects of crosslinking on the material processing.

Previous theoretical studies have investigated the ion-polymer interaction in the Al-PVA, [12] Ca-PAA, [13] and Ca-PVA[14] systems. In the present study, some preliminary results achieved in the case of the Al-PAA system are reported. This system completes the possible combinations between the ions coming from the HAC and Portland cements and the PVA and PAA polymers. Present and previous theoretical results are then analysed together to clarify the effects of crosslinking on the properties of the HAC-PVA, HAC-PAA, Portland-PAA and Portland-PVA MDF materials. These results support the existence of crosslinking in all the above MDFs and show that the characteristics of crosslinking in the systems investigated can explain why the mechanical properties of Al-PVA MDFs are better than those of the Al-PAA MDFs and why the properties of the Portland-cement MDFs improve when the PVA polymer is replaced by the PAA polymer [15-17]. Furthermore, they give suggestions about the effects of crosslinking on the material processing.

Previous and present theoretical results have been obtained by performing ab initio calculations using the Car-Parrinello approach [18]. This method has been employed to investigate the equilibrium geometries, the total energy and the dissociation energy of model systems where an Al or a Ca ion is bonded with the O atoms of polymer chains.

2. COMPUTATIONAL METHODS

In the Car-Parrinello (CP) method, the interatomic forces are computed from the instantaneous quantum-mechanical electronic ground state in the Born-Oppenheimer approximation. The electronic ground state corresponding to a given atomic geometry is obtained within the density-functional theory. The exchange-correlation function used in the calculations includes gradient corrections to the local density approximation in the form proposed by Becke and Perdew. Only the valence electrons are taken into account in a pseudopotential approach. The single-particle Kohn-Sham wavefunctions are expanded on a plane-wave basis-set, thus implying the use of periodic boundary conditions (PBC). In the present calculations, the PBC have been applied to a supercell (i.e., the simulation box) containing fragments of a PVA or a PAA chain aligned with one side of the cell. As an example, in the calculations, the fragments of the PVA chains shown in Figure 1(a) are repeated along the chain axis in order to simulate chains of infinite length. This approach allows us to describe a PVA chain as a system with full translational periodicity in one dimension. CP calculations have been successfully performed in the investigation of structural and electronic properties of complex organic molecules. Further tests have been performed here in order to verify the convergence of the calculations with respect to the kinetic energy cutoff (which controls the number of planewaves used in the calculations) as well as to check the methods in the case of simple molecules. As far as the kinetic energy cutoff is concerned, convergence has been achieved by using a value of 22 Ry. Details on the methods and further references are given in Ref. 14.

Figure 1. Al-PVA model systems: (a) structure of the $[\text{PVA}](\text{O})_2\text{Al}(\text{OH})_2^-$ model, (b) structure of the $(2[\text{PVA}](\text{O})_2)\text{Al}^-$ model. The Al, C, O, and H atoms are identified by the colours cyan, green, red, and blue, respectively

3. RESULTS AND DISCUSSION

A number of model systems have been considered in order to investigate four different cases of crosslinking: i) linkage of PVA chains by Al ions, ii) linkage of PAA chains by Al ions, iii) linkage of PVA chains by Ca ions, and iv) linkage of PAA chains by Ca ions. These cases correspond to crosslinking of polymer chains in the MDF materials formed by: i) PVA and HAC, ii) PAA and HAC, iii) PVA and Portland cements, and iv) PAA and Portland cements, respectively. The model

systems corresponding to the linkage of PVA chains by Al ions are shown in Figure 1. These systems may be produced by polycondensation reactions occurring between the PVA polymer and the $\text{Al}(\text{OH})_4^-$ complex coming from the hydrated cement. In the Al-PVA systems of Figure 1, the Al^{3+} ions form two different tetrahedral AlO_4 complexes. In the former complex, two oxygen atoms belong to a PVA chain and two further O atoms belong to hydroxyl groups, thus giving rise to an intrachain linkage, see Figure 1(a). In the latter complex, the O atoms belong to two PVA chains, thus giving rise to an interchain linkage (i.e., a crosslinking of the polymer chains), see Figure 1(b). The polymer fragment with two O atoms interacting with the Al ion will be designated as $[\text{PVA}](\text{O})_2^{2-}$ to stress the number of $-\text{O}^-$ groups of the fragment involved in the ion-polymer bonding (the $-\text{O}^-$ groups come from ionized $-\text{OH}$ groups of the chain). Within this convention, the systems of Figure 1 and a fragment of the PVA chain will be designated as $[\text{PVA}](\text{O})_2 \text{Al}(\text{OH})_2^-$, $(2[\text{PVA}](\text{O})_2)\text{Al}^-$ and $[\text{PVA}](\text{OH})_2$, respectively. The geometries of the above systems and of the $\text{Al}(\text{OH})_4^-$ complex have been optimized by following the atomic forces and by minimizing the total energies. A stable configuration has been found for each system. The strength of the Al-O bonds in the AlO_4 complexes has been then investigated by considering hypothetical reactions of dissociation where the Al-O bonds are broken by producing Al^{3+} and negative ions, e.g.:

The corresponding dissociation energies (D) have been evaluated by differences of total energies (E) of the involved species, e.g.:

$$D = E[\text{Al}^{3+}] + 4E[\text{OH}^-] - E[\text{Al}(\text{OH})_4^-] \quad (2)$$

There are no experimental counterparts for the above reactions of dissociation. Notwithstanding, these reactions have been considered here because they lead to the formation of similar ionic species, thus permitting a comparison of the strength of the Al-O bonds formed in different systems, see Table 1. In the table, negative values of the dissociation energy D indicate endothermic reactions. The dissociation energy per Al-O bond is referred to as D_b .

Table 1. Dissociation energy values, D, calculated for reactions involving molecules and Al-PVA model systems investigated in the present work. D_b is the dissociation energy per Al-O bond. An endothermic reaction is identified by negative values of D and D_b . All values are given in eV

Reaction of dissociation	D	D_b
$\text{Al}(\text{OH})_4^- \longrightarrow \text{Al}^{3+} + 4\text{OH}^-$	-61.0	-15.4
$[\text{PVA}](\text{O})_2\text{Al}(\text{OH})_2^- \longrightarrow \text{Al}^{3+} + [\text{PVA}](\text{O})_2^{2-} + 2\text{OH}^-$	-60.0	-15.0
$(2[\text{PVA}](\text{O})_2)\text{Al}^- \longrightarrow \text{Al}^{3+} + 2[\text{PVA}](\text{O})_2^{2-}$	-60.4	-15.1

The results obtained show that the AlO_4 fragments have quite similar geometries in the $\text{Al}(\text{OH})_4^-$ complex and in the Al-PVA systems. The D and D_b values of Table 1 show that the strength of the Al-O bonds in the Al-PVA systems is comparable to that of the corresponding bonds in the stable $\text{Al}(\text{OH})_4^-$ complex. In particular, the D and D_b values indicate that Al-O bonds of comparable strength are formed in the cases of intrachain and interchain linkages.

Figure 2. Ca-PAA model systems: (a) and (b) show the structure of the $[PAA](COO)Ca-OH^{3-}$ system at the beginning and at the end of a geometry-optimization procedure, respectively (see text); (c) intrachain linking in the $[PAA](COO)_2CA^{2-}$ (two Ox.) system; (d) interchain crosslinking in the $(2[PAA](COO)_2)CA^{6-}$ system (a Ca ion is bonded to four O atoms of two PAA chains). The Ca, C, O, and H atoms are identified by the colours yellow, green, red, and blue, respectively

The formation of the above Al-PVA systems has also been investigated by evaluating the energy released in polycondensation reactions involving the $Al(OH)_4^-$ complex and one or two PVA chains. These energies are given by:

$$\Delta E_1 = E\{[PVA](O)_2Al(OH)_2^-\} + 2E\{H_2O\} - E\{[PVA](OH)_2\} - E\{Al(OH)_4^-\} \quad (3)$$

and

$$\Delta E_2 = E\{(2[PVA](O)_2)Al\} + 4E\{H_2O\} - 2E\{[PVA](OH)_2\} - E\{Al(OH)_4^-\} \quad (4)$$

The values calculated for ΔE_1 and ΔE_2 , -0.28 eV and -1.16 eV, respectively, clearly indicate that an interchain linkage is favored. Thus, the above results strongly support the existence of a crosslinking of the PVA chains by the Al ions.

A similar investigation has been performed in Al-PAA model systems. In this case, a fragment of the polymer chain of the poly(acrylic acid) in anionic form is represented by $[PAA](COO)_2^{4-}$ to stress the number of $-COO^-$ groups of the fragment involved in the ion-polymer bonding (actually, the fragment carries four $-COO^-$ groups). PAA fragments in Ca-PAA model systems are shown in

Figure 2. In the case of the Al-PAA systems, the intrachain and interchain linkages have been simulated by considering the $[\text{PAA}](\text{COO})_2\text{Al}(\text{OH})_2^{3-}$ and the $(2[\text{PAA}](\text{COO})_2)\text{Al}^{5-}$ systems, respectively. In the former system, the Al^{3+} ion is bonded to two O atoms of a $[\text{PAA}]^{4-}$ fragment and to two hydroxyl groups in an atomic arrangement similar to that of Figure 1(a). In the latter system, the Al^{3+} ion is tetrahedrally bonded to the four O atoms of two PAA chains, thus giving rise to an atomic arrangement similar to that of Figure 1(b). The dissociation energies evaluated for these two Al-PAA systems are given in Table 2. In both systems, the D and D_b values are smaller than those found for the Al-PVA systems. Furthermore, they slightly favor an intrachain linkage with respect to the interchain one. These results indicate that a linking of the PAA chains should be produced by the Al ions. However, this crosslinking is expected to be less strong than that produced in the case of the Al-PVA systems.

The interaction of Ca ions with PVA or PAA polymer chains may give rise to more complex atomic arrangements with respect to those found in the Al-PVA and Al-PAA systems. This is related to the tendency of Ca and O atoms to give rise to complexes where a Ca ion coordinates a different number of O atoms also in excess of six. Thus, different configurations of the Ca-PVA and Ca-PAA systems have been investigated, where the number of the coordinated O atoms has been varied by locating several hydroxyl groups close to the Ca ion. For example, D values are reported in Table 3 for the $\text{Ca}(\text{OH})_2$ molecule and two $\text{Ca}(\text{OH})_4^{2-}$ complexes. In the case of the Ca-PVA systems, the intrachain linkage has been investigated by considering three different models. In the first model, the Ca ion is simply bonded to an O atom of a PVA chain and to an hydroxyl group. The geometry of this system is similar to that shown in Figure 2(a) for the corresponding Ca-PAA system. In the second model, the Ca ion is tetrahedrally bonded to two O atoms of a PVA chain and to two hydroxyl groups. Within the convention used for the Al-PVA systems, the above Ca-PVA systems are designated by $[\text{PVA}](\text{O})\text{Ca}-\text{OH}$ and $[\text{PVA}](\text{O})_2\text{Ca}(\text{OH})_2^{2-}$, respectively. Two further hydroxyl groups have been located close to the Ca ion of the $[\text{PVA}](\text{O})_2\text{Ca}(\text{OH})_2^{2-}$ system in order to reach a sixfold coordination for this ion. However, this last model is unstable.

Table 2. Dissociation energy values, D, calculated for reactions involving the Al-PAA model systems investigated in the present work. D_b is the dissociation energy per Al-O bond. An endothermic reaction is identified by negative values of D and D_b . All values are given in eV

Reaction of dissociation	D	D_b
$[\text{PAA}](\text{COO})_2\text{Al}(\text{OH})_2^{3-} \longrightarrow \text{Al}^{3+} + [\text{PAA}](\text{COO})_2^{4-} + 2\text{OH}^-$	-58.3	-14.6
$(2[\text{PAA}](\text{COO})_2)\text{Al}^{5-} \longrightarrow \text{Al}^{3+} + 2[\text{PAA}](\text{COO})_2^{4-}$	-55.8	-13.9

An intrachain linkage can also be recognized in a third model, the $[\text{PVA}](\text{O})_2\text{Ca}$ model, where the Ca ion is bonded to two O of the same PVA chain, as shown in Figure 2(c) for a similar Ca-PAA model. The interchain linkage has been investigated by considering a $(2[\text{PVA}](\text{O}))\text{Ca}$ model, where two Ca-O bonds are formed by involving two PVA chains, and a $(2[\text{PVA}](\text{O}))\text{Ca}(\text{OH})_2^-$ model which involves two PVA chains and two hydroxyl groups bonded to the Ca ion. In detail, the geometry of the $(2[\text{PVA}](\text{O}))\text{Ca}(\text{OH})_2^-$ system is characterized by an almost planar CaO_4 fragment where two O atoms are provided by the PVA chains and two further O atoms belong to hydroxyl groups. Even in the case of interchain linkages, model systems where the Ca ion is coordinated, sixfold are unstable.

The dissociation energies of the above model systems are reported in Table 3. The D values reported in the table show a general tendency of the Ca ion to bind four O atoms. The D value corresponding to the intrachain linkage recognized in the $[\text{PVA}](\text{O})_2\text{Ca}(\text{OH})_2^{2-}$ model is close to the D values of the $\text{Ca}(\text{OH})_4^{2-}$ complexes and larger than the values estimated for the interchain systems, i.e., the $(2[\text{PVA}](\text{O}))\text{Ca}$ and $(2[\text{PVA}](\text{O}))\text{Ca}(\text{OH})_2^{2-}$ systems. Furthermore, the D_b values

indicate that the more stable Ca-O bonds are formed when the Ca ion is bonded to only two O atoms. In that case, the D_b values of the Ca-PVA systems approach the value estimated for the bonds in the $\text{Ca}(\text{OH})_2$ molecule. All the above results indicate that the models realizing a crosslinking of the PVA chains must compete with a more stable intrachain Ca-PVA system and the $\text{Ca}(\text{OH})_4^{2-}$ complexes. It is expected, therefore, that the crosslinking of PVA chains by Ca ions is less efficient than that realized by Al^{3+} ions.

Finally, the results achieved for the Ca-PAA model systems are reported in Table 4. In the first system investigated, $[\text{PAA}](\text{COO})\text{Ca}-\text{OH}^{3-}$, a Ca^{2+} ion is bonded to an O atom of the $[\text{PAA}](\text{COO})_4^{2-}$ fragment and to an OH^- group. Figure 2(a) and 2(b) show the geometry of this system at the beginning and at the end of the geometry-optimization calculation, respectively. These figures show, once more, a tendency of the Ca ion to bind four O atoms. In a second system, $[\text{PAA}](\text{COO})_2\text{Ca}^{2-}$ (two Ox.), the Ca ion is bonded to two O atoms belonging to the carboxylate anions of a same PAA chain, thus realizing an intrachain O-Ca-O linking, see Figure 2(c). In the third model system, $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$, the Ca atom is bonded to four O atoms of two PAA chains, thus realizing an interchain $\text{O}_2\text{-Ca-O}_2$ linkage, see Figure 2(d). In this system, the relative positions of the two polymer chains have been chosen to permit the interaction of the Ca ions with more than two O atoms. At the beginning of the geometry-optimization procedure the Ca atom is bonded to two O atoms only, which belong to different PAA chains. As the geometry of the system is fully relaxed by following the atomic forces, two further O atoms move toward the Ca atom, thus leading to the formation of a CaO_4 fragment. Further model systems have been investigated to analyze the effects of OH^- ions and higher coordination numbers of the Ca atom on the stability of the intrachain and interchain linking. In the case of intrachain linking, the $[\text{PAA}](\text{COO})_2\text{Ca}(\text{OH})_2^{4-}$ system has been considered, which can be derived from the $[\text{PAA}](\text{COO})_2\text{Ca}^{2-}$ (two Ox.) system of Figure 2(c) when two OH^- ions are bonded to the Ca ion. In the case of the interchain linking, a $(2[\text{PAA}](\text{COO})_2)\text{Ca}(\text{OH})_2^{8-}$ system has been also investigated which derives from the $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$ system of Figure 2(d) when two OH^- ions are bonded to the Ca ion. The optimized geometry of this system presents a distorted octahedral configuration for a CaO_6 complex where the four O atoms of the PAA chains form the square basis of the octahedron and the O atoms of the OH^- ions occupy the two remaining vertexes of the octahedron. It is worth noting that the $(2[\text{PAA}](\text{COO})_2)\text{Ca}(\text{OH})_2^{8-}$ system is metastable with respect to the $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$ system, as shown by the reaction of dissociation

which results to be exothermic with a D value of +1.4 eV.

Table 3. Dissociation energy values, D, calculated for reactions involving molecules and Ca-PVA model systems investigated in the present work. D_b is the dissociation energy per Ca-O bond. An endothermic reaction is identified by negative values of D and D_b . All values are given in eV

Reaction of dissociation	D	D_b
$\text{Ca}(\text{OH})_2 \longrightarrow \text{Ca}^{2+} + 2\text{OH}^-$	-16.7	-8.4
$\text{Ca}(\text{OH})_4^{2-} (\text{planar}) \longrightarrow \text{Ca}^{2+} + 4\text{OH}^-$	-20.4	-5.1
$\text{Ca}(\text{OH})_4^{2-} (\text{tetr.}) \longrightarrow \text{Ca}^{2+} + 4\text{OH}^-$	-20.4	-5.1
$[\text{PVA}](\text{O})\text{Ca}-\text{OH} \longrightarrow \text{Ca}^{2+} + [\text{PVA}](\text{O})^{1-} + \text{OH}^-$	-15.4	-7.7
$[\text{PVA}](\text{O})_2[\text{PVA}](\text{OH})_2^{2-} \longrightarrow \text{Ca}^{2+} + [\text{PVA}](\text{O})_2^{2-} + 2\text{OH}^-$	-20.1	-5.0
$[\text{PVA}](\text{O})_2\text{Ca} \longrightarrow \text{Ca}^{2+} + [\text{PVA}](\text{O})_2^{2-}$	-14.5	-7.3
$(2[\text{PVA}](\text{O}))\text{Ca} \longrightarrow \text{Ca}^{2+} + 2[\text{PVA}](\text{O})^-$	-13.9	-6.9
$(2([\text{PVA}](\text{O}))\text{Ca}(\text{OH})_2^{2-} \longrightarrow \text{Ca}^{2+} + 2[\text{PVA}](\text{O})^- + 2\text{OH}^-$	-18.8	-4.7

For what concerns the stability of the above Ca-PAA systems, in the case of intrachain linking the tendency of the Ca ion to coordinate more than two O atoms, already shown by the evolution of the $[\text{PAA}](\text{COO})\text{Ca}-\text{OH}^{3-}$ geometry, is confirmed by the large negative D value of the $[\text{PAA}](\text{COO})_2\text{Ca}(\text{OH})_2^{4-}$ system. On the other hand, an analysis of the D_b values corresponding to the above systems shows that the $[\text{PAA}](\text{COO})_2\text{Ca}^{2-}$ (two Ox.) system of Figure 2(c) has the most stable Ca-O bonds, that is, this system is quite stable once it is formed. For what concerns the interchain linking, the $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$ system has the larger negative D and D_b values with respect to the $(2[\text{PAA}](\text{COO})_2)\text{Ca}(\text{OH})_2^{8-}$ system. An overall analysis of the results given in Table 4 shows that the D value corresponding to the $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$ system is the largest negative value, thus indicating that the formation of this system is favored with respect to the other systems involving PAA chains and the molecular complexes formed by Ca and hydroxyl ions (see Table 3). In particular, the interchain O-Ca-O linking results to be more stable than the intrachain linking. The above results support therefore the existence of a crosslinking of PAA chains by Ca ions. Further support comes from a detailed analysis of the D_b values of Table 4. Although these values indicate that each Ca-O bond formed in the $(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-}$ system ($D_b = -5.6$ eV) is weaker than a single Ca-O bond formed in the $\text{Ca}(\text{OH})_2$ molecule ($D_b = -8.4$ eV) or in the $[\text{PAA}](\text{COO})_2\text{Ca}^{2-}$ (two Ox.) system ($D_b = -7.3$ eV), the breaking of the crosslink between two polymer chains implies (at least) the breaking of two Ca-O bonds because the Ca ion is anchored to four points of two PAA chains (two points for each chain), see Figure 2(d). This process requires an energy of -11.2 eV, thus stabilizing the crosslinking of the PAA chains.

Table 4. Dissociation energy values, D, calculated for reactions involving different Ca-PAA model systems investigated in the present work. D_b is the dissociation energy per Ca-O bond. An endothermic reaction is identified by negative values of D and D_b . All values are given in eV

Reaction of dissociation	D	D_b
$[\text{PAA}](\text{COO})\text{Ca}-\text{OH}^{3-} \longrightarrow \text{Ca}^{2+} + [\text{PAA}](\text{COO})_2^{4-} + \text{OH}^-$	-18.6	-4.6
$[\text{PAA}](\text{COO})_2\text{Ca}^{2-}$ (two ox.) $\longrightarrow \text{Ca}^{2+} + [\text{PAA}](\text{COO})_2^{4-} + 2\text{OH}^-$	-14.7	-7.3
$[\text{PAA}](\text{COO})_2\text{Ca}(\text{OH})_2^{4-} \longrightarrow \text{Ca}^{2+} + [\text{PAA}](\text{COO})_2^{4-} + 2\text{OH}^-$	-19.2	-4.8
$(2[\text{PAA}](\text{COO})_2)\text{Ca}^{6-} \longrightarrow \text{Ca}^{2+} + 2[\text{PAA}](\text{COO})_2^{4-}$	-22.4	-5.6
$(2[\text{PAA}](\text{COO})_2)\text{Ca}(\text{OH})_2^{8-} \longrightarrow \text{Ca}^{2+} + 2[\text{PAA}](\text{COO})_2^{4-} + 2\text{OH}^-$	-21.0	-3.5

4. CONCLUSIONS

An analysis of the D and D_b values calculated for all the model systems investigated in the present study indicates that the Al ions realize stronger crosslinking than the Ca ions with both PVA and PAA chains. This result agrees with the general properties of the Al and Ca elements. It reflects indeed the different strength of the Al-O and Ca-O bonds as shown, e.g., by the different D values estimated in the case of the $\text{Al}(\text{OH})_4$ and $\text{Ca}(\text{OH})_2$ molecules. Moreover, present results show that the potential capability of the Ca ion to reach higher coordination numbers with respect to the Al ion does not affect the relative strength of the bonds formed by the two ions with the O atoms, in the systems investigated. The Al-PVA crosslinking is also stronger than the Al-PAA one. In the case of Ca-polymer systems, the PAA crosslinking results are stronger than the PVA crosslinking. The above results suggest the following relative strengths of the polymer-chain crosslinking: $\text{Al-PVA} > \text{Al-PAA} > \text{Ca-PAA} > \text{Ca-PVA}$. This theoretical estimate of the strength of polymer-chain crosslinking is consistent with the different mechanical properties observed in the cases of high-alumina cement and Portland cement MDFs formed with PVA and PAA polymers, thus suggesting that crosslinking plays a significant role in the realization of MDFs materials with peculiar mechanical properties. Furthermore, the different strength of the Al-O and Ca-O bonds may account for the differences observed in the material processing of HAC-PVA and Portland-PAA

MDFs. In the former case, high activation energy is expected for the crosslinking reactions. This agrees with the fact that crosslinking is realized only in presence of the mechanical work performed during the mixing process. In the latter case, lower activation energies should be required for the crosslinking reactions, thus inducing a fast crosslinking of the polymer chains. This can explain the difficulties experienced in obtaining a workable paste during material processing.

MINERALOGICAL COMPOSITION OF CLINKER BY BOGUE AND RIETVELD METHOD: THE EFFECT OF MINOR ELEMENTS

Umberto Costa^{1*} and Maurizio Marchi¹

¹CTG – Italcementi Group, Via G. Camozzi, 124, 24121 Bergamo, Italy. E-mail: u.costa@itcgr.net

ABSTRACT

Quantitative phase analysis by means of X-ray powder diffraction performed using the Rietveld method (hereinafter QXPA) has been applied to a large number of industrial clinkers produced at different plants. The results have been compared with those obtained by calculation methods based on chemical analysis, such as the Bogue method. QXPA usually gives higher C_3S and lower C_2S values than those derived by Bogue. Regarding the composition of the aluminate phases, when only cubic C_3A is present, QXPA values are lower than Bogue values; the opposite is observed when also C_3A orthorhombic polymorph is found. In those samples having a high C_3A content, the C_4AF content is lower than the one calculated by Bogue. Differences between the mineralogical composition obtained by QXPA and by the calculation methods seem to be strongly dependent on the alkali and sulfate contents in the clinker. Moreover, a good correlation has been found between the sulfate module and the C_3S/C_2S and C_3A/C_4AF content ratios obtained by QXPA.

1. INTRODUCTION

Knowledge of the mineralogical composition of clinker is necessary to predict and justify clinker performances. In the cement industry, the most currently used method to estimate the mineralogical composition of clinker is the Bogue calculation [1] based on chemical analysis. It has been stated that the Bogue calculation gives approximate results because equilibrium is not reached during clinker cooling. In addition, the four major phases contain foreign ions, and in such a way, the compositions assumed for the phases are inaccurate [2,3]. Optical microscopy, either by visual linear analysis [4] or by point counting, is the most widely adopted experimental method for the quantitative determination of the mineralogical composition of clinker. This method has however some disadvantages. It is time-consuming (at least a thousand points need to be considered) and operator-dependent, and some difficulties may arise when determining the aluminate phases (C_3A , C_4AF). Actually, since their micro-crystallinity may sometimes make them insufficiently resolved, the aluminate phases are usually quantified as a group and reported as “interstitial phase”.

In recent years the alternative use of X-ray powder diffraction associated with the Rietveld method has gained ground.

The Rietveld method [5] is a full-profile fitting method, basically consisting of calculating a theoretical diffraction pattern starting from the crystallographic information gained from the existing phases (space groups, cell parameters, atomic co-ordinates, thermal parameters) and from instrumental information. The calculated pattern is then optimized through an iterative calculation procedure in order to obtain the best possible fit to the experimental diffraction pattern.

Originally conceived for structural analysis, the method has been applied by Bish and Howard [6] to the quantitative phase analysis by means of X-ray powder diffraction (QXPA).

Compared to traditional methods, this technique presents a host of advantages: internal standards or calibration curves are not required and the severe peak overlapping and preferred orientation problem don't affect the results.

Moreover, additional information – cell parameters for example - are available, which can provide useful indications of possible atomic substitutions in the crystalline phases caused by the formation of solid solutions.

The Commission on Powder Diffraction of IUCr [7] has recently promoted a round robin test for the purpose of comparing various methods known as “full profile fitting” and obtaining analytical uncertainty data.

Several examples of QXPA application to determine the mineralogical composition of cements [8,9,10,11,12] are available in the literature. Differences between the composition obtained by QXPA and that calculated according to Bogue have always been found.

The present study was carried out on a large number of clinkers and provided important information on aluminate phase composition of industrial clinkers produced in different plants with a large variability of raw materials and fuels.

2. EXPERIMENTAL

Diffraction patterns have been collected using a SIEMENS D-5000 diffractometer with the instrumental Bragg-Brentano geometry equipped with a Cu-tube (λ 1.5456 Å) and a graphite monochromator on the diffracted beam.

The experimental conditions were: tube power of 40KV, 40mA, fixed divergence and anti-scattering slits equal to 1°, receiving slit aperture of 0.1 mm, sample holder spinning of 30 rpm. Diffraction patterns were collected from 10 to 70° 2 θ , at a scanning step of 0.02° 2 θ and counting time of 12 s/step.

Clinker samples were finely ground to pass the 45- μ m sieve and loaded on an aluminum sample holder, devised for side loading, for the purpose of minimizing preferred orientation effects. Rietveld refinements were carried out using TOPAS software from Bruker AXS [13]. The phase structural models used to perform the refinements are summarized in table 1.

Table 1. Crystallographic data of the main clinker phases used in refining operations

Name	Space Group	References
C ₃ S M1/M3	Monoclinic, C m	[14]
C ₃ S M3	Monoclinic, C m	[15]
β -C ₂ S	Monoclinic, P 2 ₁ /n	[16]
C ₄ AF	Orthorhombic, I bm2	[17]
C ₃ A	Cubic, P a3	[18]
Na-C ₃ A	Orthorhombic, P bca	[19]

The background was modeled by a Chebyshev polynomial with six refinable coefficients; the 2 θ zero shift and the unit cell parameters, crystallite size and scale factors for all phases were simultaneously refined. The preferred orientation of alite in all samples was also considered by using spherical harmonic correction [20]. For the ferrite phase, also the aluminum and iron phase

fractions in the octahedral and tetrahedral sites were refined in the final step, using soft constraints to maintain the sum in each site equal to one.

3. RESULTS

To better recognize the ranges within which the chemical composition of the clinkers is found to vary, table 2 indicates average, maximum, and minimum values of some of the main compositional parameters.

Table 2. Variability of chemical parameters of clinkers

SR			AR			LSF			Msulf		
MIN	MAX	Mean	MIN	MAX	Mean	MIN	MAX	Mean	MIN	MAX	Mean
2.0	4.1	2.6	0.9	2.7	1.6	88.3	100.5	96.4	0.1	2.9	1.2

SR= silica ratio; AR= alumina ratio; LSF= lime saturation factor; M_{sulf} = sulfate modulus

Tables 3 and 4 summarize the silicate and aluminate contents as derived from Bogue and Newkirk calculations [21] and by QXPA. Compared to Bogue, the Newkirk method is an attempt to refine the calculation of the aluminate phase composition, by distinguishing the cubic and orthorhombic polymorphs of C_3A , the latter designated by the NC_8A_3 formula.

By taking the results obtained by Rietveld method as a reference, the following statements can be made in comparison to Bogue calculations:

- The C_3S content obtained by QXPA is on average 5% greater, with 14 cases for which the deviation is greater than the average (as high as 12%). Only 5 samples evidenced C_3S -Bogue values overestimated with respect to QXPA.
- The C_2S content, as is logical, is correspondingly on average 3% lower than Bogue.
- The C_3A content is generally underestimated by around 2-3% except if orthorhombic C_3A occurs, in which case the Rietveld method identifies C_3A contents greater than 3%.
- The C_4AF content is more or less in good agreement with the calculated one, except in those samples having a high C_3A content, where lower values were found.

As a whole, the contents in C_3S and C_2S calculated after Newkirk reproduce the same results as those obtained with Bogue. Concerning C_3A , no better agreement with the QXPA results was observed.

4. CORRELATION STUDY

A correlation analysis between minor element contents (mainly alkalis and sulfur) and mineralogical composition obtained by QXPA has been tried.

For this investigation, the parameter considered was the sulfate module (M_{sulf}), calculated according to the formula:

$$M_{\text{sulf}} = \text{SO}_3 / (1.29\text{Na}_2\text{O} + 0.85\text{K}_2\text{O}) \quad (1)$$

$M_{\text{sulf}} \geq 1$ immediately indicates the potential combination of the alkalis occurring in the clinker as sulfates. On the other hand, values smaller than one would indicate stoichiometric alkali excess with respect to SO_3 becoming available for the formation of solid solutions in the clinker phases.

The replacement of calcium ions by alkalis in the crystalline lattice of C_3A may be very wide and lead to structural modifications [19]. Beyond a certain replacement limit, the cubic structure of C_3A becomes orthorhombic. This transition is easily detected by X-Ray diffraction, which is also capable of distinguishing between the two forms when they coexist.

The formation of orthorhombic C_3A , whenever availability of alkalis occurs, is confirmed by the results of the quantitative analysis performed on the clinkers. Figure 1 gives the contents in orthorhombic C_3A as determined by QXPA on clinkers, whose sulfate module varies within a wide range (0.2-2.9). As can be observed, the presence of orthorhombic C_3A is efficaciously detected when the sulfate module is smaller than one. It is also apparent how this C_3A polymorph progressively increases as the sulfate module decreases.

Figure 1. Trend of orthorhombic C_3A content as a function of the sulfate module

The relatively wide range within which the C_3A content is found to vary at equal sulfate module may be due to the influence exerted by AR, which is not constant across the different samples.

In fact, considering the three clinkers marked in red on the chart, and having a M_{sulf} equal to 0.6, it can be observed how the orthorhombic C_3A content may vary from 4.5 to 8.3 and AR from 1.29 to 1.76.

With a view to thoroughly understand how the sulfate module affects the mineralogical composition of the clinker, we should more opportunely consider clinkers characterized by compositions falling

within narrow ranges; for this purpose in the correlation study, we have considered only clinkers showing an AR of 1.7-1.8 and a LSF of 95-96.

The charts given in figures 2 and 3 illustrate the phase composition as identified by QXPA and expressed as weight ratios of C_3A/C_4AF and C_3S/C_2S respectively versus the sulfate module. The same charts show a horizontal line, which corresponds to the theoretical ratios according to Bogue calculation for clinkers having AR and LSF falling in the selected range.

Figure 2. Trend of the C_3A/C_4AF weight ratio obtained by QXPA as a function of the sulfate module

Figure 3. Trend of the C_3S/C_2S weight ratio obtained by QXPA as a function of the sulfate module

Figure 2 shows that, compared to a theoretical C_3A/C_4AF weight ratio of 0.97 that corresponds to an AR of 1.75, the experimental ratios tend to increase as the sulfate module decreases. If M_{sulf} is greater than one, then the C_3A/C_4AF ratio is lower than the theoretical ratio. If M_{sulf} is smaller than one, the C_3A/C_4AF ratio increases progressively until it becomes 2.5 times greater than the theoretical one. The curve that interpolates the experimental data intersects the reference line when M_{sulf} is about one.

The increase in the aluminate/ferrite ratio is linked to the formation of orthorhombic C_3A , which is probably promoted by thermodynamic effect.

The increase in C_3A content also affects the Al/Fe molar ratio of the ferritic phase. Figure 4 shows that for clinkers with a sulfate module smaller than 1, Al in the ferritic phase is less than in the C_4AF composition normally assumed in the Bogue calculation. This may be explained by the Al input that is needed for the formation of a larger amount of orthorhombic C_3A .

The opposite occurs when the sulfate module is greater than one, that is – as previously seen – when the amount of C_3A formed is less than expected.

Figure 4. Trend of Al/Fe molar ratio as determined by Rietveld refinement in C_4AF as a function of the sulfate module

The C_3S/C_2S ratio seems to be possibly affected by the sulfate module, too (figure 3). In clinkers characterized by a sulfate module smaller than 1, the C_3S/C_2S ratio takes on values being approximately equal to or greater than the theoretical one, i.e. 5.6. The C_3S/C_2S ratio is definitely lower (between 2 and 3) in clinkers with a sulfate module greater than 1.

In this case, experimental data turn out to be more scattered around the correlation curve compared to what was observed for C_3A . This might be because alite and belite contents as determined by QXPA are affected by a greater error than those found in the aluminate phases. However, the downward trend of the C_3S/C_2S ratio is rather clear when the sulfate module is greater than one. This statement is in agreement with Strunge's observation [22] according to which an increase in the SO_3 content in the clinker corresponds to a decrease in alite and an increase in belite content. This statement is also in agreement with Uda et al. [23]: when investigating the influence of SO_3 on the $CaO-SiO_2-Al_2O_3-Fe_2O_3$ equilibrium diagram, they found that an increase in SO_3 causes the stability field of alite to narrow.

5. CONCLUSIONS

Differences found between mineralogical composition of clinkers obtained by QXPA and Bogue are consistent with the findings of other authors, who applied this type of analysis on a smaller series of clinker samples.

The application of the Rietveld method to a wide series of industrial clinkers provided very interesting information about the influence exerted by alkali and SO_3 contents on the mineralogical composition of clinkers with particular regard to the aluminate phases.

It has been found that when alkalis are balanced by sulfates (sulfate module = 1), the contents in C_3A (in the cubic form) and ferrite are in good agreement with those calculated by traditional methods.

When alkalis exceed sulfates (sulfate module <1), orthorhombic C_3A is formed. In this case, the total C_3A content turns out to be greater than the one derived from calculations. Consequently, also a lower Al/Fe ratio in the ferritic phase has been found.

In clinkers where SO_3 is in excess with respect to alkalis, the $\text{C}_3\text{A}/\text{C}_4\text{AF}$ and $\text{C}_3\text{S}/\text{C}_2\text{S}$ weight ratios tend to be lower than the values as calculated. These results are in good agreement with the assumptions put forward in those studies concerned with the influence of SO_3 on the phase equilibria of a quaternary system.

The above observations let us assume that alkalis in excess with respect to SO_3 modify the phase equilibria in the system $\text{CaO-SiO}_2\text{-Al}_2\text{O}_3\text{-Fe}_2\text{O}_3$ on which the Bogue calculations are based.

For the time being, there are no recent theoretical investigations regarding the influence of alkalis on the phase equilibria within the quaternary system supporting the above assumption.

ABSTRACT

In the European Union, national regulations regarding the quality of drinkable water are based on numerous EEC directives, synthesized by the council directive 98/83/EC (1998) [1] on the quality of water intended for human consumption. With respect to the low tolerable concentration levels of toxic metals, each possible source of pollution has to be identified. Cementitious materials may be of concern, especially cement pipes used for water transport, because this man-made material may contain toxic metals. Industrial clinker contains amounts of heavy metals usually in the 20 to 100 mg/kg range and sometimes higher (up to 300 mg/kg) [2]. Metals in industrial clinker could come from: i) raw materials and fossil fuels and ii) co-incinerated wastes such as used tyres, tars, heavy oils etc. During the industrial process, some metals (e.g.: Cr, Cu, Ni, V, Zn and a fraction of Pb) are mainly incorporated in the clinker itself [2, 5, 7]. Other metals (e.g.: Hg, Cd, Tl) are mostly carried out by the gas flows and fixed in the kiln-dust collected in bag filters [2-4, 6].

Recently, using "environmental-like" experimental conditions for studying the long-term leaching of toxic trace metals from Portland cement concrete, Hillier and al. [8] concluded that "well cured Portland cement concrete released no detectable concentrations of the toxic metals outlined in directive 80/778/EEC water fit for human consumption". They only noticed detectable concentrations of vanadium released from poorly cured samples.

Different conclusions were obtained from former studies detecting trace toxic metals in the leachates so that clearly, the "soft" experimental conditions used by Hillier and al. (semi-dynamic leaching test method, no agitation throughout the test, no artificially aggressive leachants) represent at best usual interactions between water and cementitious materials, but are difficult to extrapolate to model long-term leaching, because of the purely empirical character of their study.

In order to address metal behavior during water-cement interaction, two experimental methods have been followed: i) the investigation of the composition of leachates, fitted on a kinetic law [9] and ii) the characterization of the distribution of toxic metals within the "leached layer" of a cement paste. Only, this last approach is presented in this article.

1. MATERIALS

A way to understand metal behavior during the leaching of cement pastes is to use a special clinker, enhanced by the addition of extra heavy metals well beyond usual contents in industrial products

[10, 16]. However, at elevated concentrations, the phase repartition of metals may differ from what occurs in industrial clinkers. Accordingly, non-doped cements were studied.

The Portland cement sample (n° 4440A) presented here, was made of pure clinker with gypsum addition of about 5wt% (CEM I 52.5N type following the EN 197-1 European norm of cements). Its chemical composition and trace metals content are given in tables 1 and 2

Table 1. Chemical composition of OPC samples.

Sample	Ig. Loss	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	SO ₃	Na ₂ O	K ₂ O
N°4440A (%)	0.93	20.62	4.61	2.85	63.77	3.38	2.66	0.15	0.78

Table 2. Trace metals content of OPC sample.

Sample	Cr	Cu	Ni	Pb	V	Zn
n°4440A (mg/kg)	74	23	60	18	215	69

2. SPECIMEN PREPARATION AND CHARACTERIZATION

The paste specimens used during leaching runs were cylinders of 90 mm in diameter and 100 mm in height whose upper and lower 25 mm had been cut off with a diamond saw for characterization. The water to cement ratio was 0.5; specimens were cured for 28 days, under a relative humidity of 100%. Samples have portlandite contents of 19.5% (determined by TGA). Mercury Intrusion Porosimetry indicates a total porosity of 27%, with 11.5% micropores (diameter lower than 25 nm) and 15.5% capillary pores

3. DYNAMIC LEACHING DEVICE PRINCIPLE

The CTG-LEACHCRETE (Figure 1) [11] device used for leaching runs is based on a modified version of the Soxhlet extractor.

Figure 1. CTG-LEACHCRETE device principle

It is mainly composed of a reactor (leaching cell) containing the cylinder of cement paste and of a boiler concentrating the leachates and producing recycled water vapor. In this device, the sample

cell is temperature and pH controlled, CO₂ free and separated from the boiler cell which produces the distilled water. In fact, the escaped vapor from the boiler cell is condensed by a cooling coil and the sample cell is continuously refilled by a constant water flow. At the output of the reactor, an overflow tube maintains a constant volume of water in contact with the cement paste sample. Then the overflow tube refills the boiler. Periodically, aliquots of solution are sampled in the boiler for analyses, an equivalent volume of water being added.

The reactor temperature may be regulated between 20°C and 40°C with a thermostatic bath. Pure N₂ is flowing through the leaching cell to limit the carbonation of the sample surface layer. Acidity in the reactor is regulated to pH = 5 +/- 0.2, using progressive additions of diluted HNO₃ (1 M). Nitric acid has been used because nitrate ions do not disturb cement hydration [19]. Literature shows that nitrate ions do not have an oxidizing [20, 21] or a complexing [22, 23] action on metals present in the interstitial solution ions (Cr(+VI), Cu(+II), Ni(+II), Pb(+II), V(+V) and Zn(+II)). Finally, using nitric acid accelerates the leaching process only by increasing the pH gradient between leachate and interstitial solution.

As an example of kinetic results, the Cumulate Fractions Leached (C.F.L) of Chromium have been plotted vs time on graphic 1 for three different runs at 20°C of about 1000 hours using specimens of cement n°4440 A. Although C.F.L are lower than 0.5%, the reproducibility is very good.

Graphic 1. Reproducibility of the Chromium release kinetic measurements for three different runs (O.P.C n°4440A) of dynamic leaching experiments with the CTG-LEACHCRETE device at 20°C and pH=5.

4. RESULTS AND DISCUSSION

4.1 Evidences of a Fe-Rich surface after leaching

After about 2 weeks of leaching, an irregular brown-ochre layer appears at the surface of paste specimens. From SEM-EDS studies, this layer is Fe-enriched and Ca-depleted with respect to the original paste [9]. No toxic metal has been detected, however EDS sensitivity is poor (about 0.5%). After sampling by delicate brushing, this brown-ochre layer has been analyzed by XRD. Quartz,

calcite, vaterite and, more surprisingly, anhydrous C_4AF (brownmillerite) have been detected. A large diffusion halo is indicative of the presence of an amorphous material.

The study of this layer has been complemented by GIXD (Grazing Incidence X-ray Diffraction) at 0.5° and 1° incidences, but directly on the surface of a leached cement paste sample. The same phases with additional hydrotalcite have been detected; the diffusion halo has disappeared and an extra-peak at $2\theta = 17.96^\circ$ attributed to oriented feroxyhyte [9] was found. Following the above data and the hydration equation of brownmillerite given by Fortune and Coey [12], the brown-ochre colour could result from the presence of iron oxyhydroxydes (feroxyhyte and poorly crystallized ferrihydrite) and of ferric hydrogarnets.

4.2 Characterization of the Ca-depleted layer

After about 1000 hour runs, sections of the leached specimens sawn perpendicularly to cylinder axis, have been enclosed in a resin and then diamond-polished. EDS profiles of Ca (Graphic 2) reveal that in the unleached core the CaO concentration fluctuates around the mean value of the anhydrous cement composition; On the other hand, near the surface a significant decrease appears.

For example, a thickness of $1350\ \mu\text{m}$ of a Ca-depleted layer is determined on a specimen of cement n°4440 A, after 1025 hours of leaching at 20°C and $\text{pH}=5$.

Graphic 2. SEM-EDS profile of CaO content in the cement paste sample after 1025 hours of dynamic leaching at 20°C and $\text{pH}=5$ in the CTG-LEACHCRETE device.

On the same sample, EDS "chemical cartographies" of Ca, Al, Si, Fe, Mg and S were made. The most interesting distributions (Photographs 1-3) are relative to:

- Ca, with a steep concentration decrease towards the surface;
- Si with a enrichment increase towards the surface,
- S which is presented a clear front in the degraded layer very close to the unleached paste from the core.

Photographs 1, 2, and 3.

From chemical distribution of Ca, Si and S, one may conclude that cement paste/leachant interaction resulted in portlandite dissolution, formation of a surface silica rich zone and precipitation of secondary ettringite. These conclusions are supported by an XRD investigation on a local scale.

Local XRD leads to identification of the distribution of mineral phases within a solid. Experiments were performed in Trento University (Italy), in the Department of Material Engineering. Analytical conditions are given elsewhere [9,15]. A total of 12 diffractograms have been made, from 2.75 mm beneath the surface to the surface itself, by successive steps of 0.25 mm. Areas of selected peaks, respectively representative of portlandite, calcite and ettringite, and of the diffusion halo corresponding to amorphous phases, have been measured. The relative variation from step to step of these areas is a quantitative indication of the spatial distribution of the different phases (Figure 2).

Figure 2. Evolution of the concentrations of portlandite, ettringite, calcite and amorphous phases in the leached layer, from the unleached core (2.5 mm) to the surface of the sample (0.0 mm)

This approach permitted the identification of:

- The solubility front of portlandite, i.e. the beginning of the leached zone
- The precipitation of secondary ettringite at the bottom of the leached zone
- The precipitation of calcite within the leached zone which indicates a residual CO_2 presence in the device despite the N_2 flow
- The formation of an amorphous silica gel at surface related to the CSH incongruent dissolution

The "spatial" characterization data of hydrates is relevant for an interpretation of the localization of trace metals in leached cement paste, especially the distribution of secondary ettringite and the presence of a calcite front.

4.3 Localization of trace heavy metals within the leached layer using ICP-MS analysis with laser ablation

Inductively Coupled Plasma Mass Spectrometry is a sensitive technique for trace element analysis. Applications to in situ solid analyses result from the "pulverization-vaporization" of the solid at the impact of a powerful laser ray (about 10^{10} watts/cm²) with the creation of a local microplasma [13] taken off to the ICP-MS system by an argon flow and finally analyzed. Usually, samples are moved while the laser ray remains fixed; this results in the formation of a crater, whose width result depends on laser power and solid properties (e.g.: hardness); typical values scatter in the 20 to 100 micrometer range. As determined by SEM examination, craters are about 20 micrometers large in the present investigation (Photograph 4).

Studied samples were polished sections cut perpendicularly to the axis of cylinder-shaped paste specimens. Analyses have been performed in the "Laboratoire d'analyses Radiochimiques et Chimiques" of the French Atomic Energy Commission (CEA) at Cadarache (Southern France). An ICP-MS spectrometer P.O.E.M.S (Thermo-Jarrell-Ash) and a laser ablation system LSX-100 (CETAC Technologies) have been used. Analyzed elements were 6 trace metals (Cr, Cu, Ni, Pb, V and Zn) and Si. Analytical conditions have been given elsewhere [9].

Photograph 4. Laser-Ablation crater on a pure cement paste sample (n°4440A) studied after a leaching run.

Only intensity profiles of characteristic mass/charge ratios (e.g. 29 for Si) are presented and discussed below, even if in the constant non altered zone, intensity profiles directly reflect concentration gradients. Indeed, the microstructural heterogeneity of the leached layer, precludes any quantitative determinations of trace metal concentration profiles. Accordingly, we choose to compare the different profiles of the various metals with the silicon profile, bearing in mind mineralogical variations with depth observed by local XRD within the leached layer.

Graphic 3-8 – ICP-MS Laser Ablation profiles of trace heavy metals in the leached layer

From an inspection of the graphics 3 to 8, the following comments can be made:

- ◆ In the pristine zone, the Si profile is roughly constant, with expected variations reflecting size and composition of the components of the cement paste.
- ◆ In the pristine zone, profiles of the different metals are either parallel or discordant with silicium. Good fits, including simultaneous fluctuations of metal and Si, are observed in the case of Cu, Pb, V and Zn. This correlation strongly suggests metal localization within a range of silicate phases. Misfits are noticed with Cr and mostly with Ni whose concentration is disturbed by an isobaric interference.
- ◆ In the altered zone, a decreasing fit between metal and silicium is observed, ranging from an excellent concordance for Pb to good parallelism for Cu, Ni and V. These data suggest a unique trapping of Pb in CSH phases and a major control of Cu, Ni and V by these phases. In contrast, misfits are noticed with Zn and mostly Cr.
- ◆ In the altered zone, the succession of mineralogical zones may be expected to be similar to that deduced on theoretical bases [14], complemented by data from figure 2. With respect to this distribution and graphics 3 and 8, one may suggest that secondary ettringite is the major hosting phase for Cr under CrO_4^{2-} substituting to SO_4^{2-} and suggest a significant trapping of Zn by calcite.

5. CONCLUSIONS

By comparing the particular hydrates' distribution and the trace metals' profiles within the leached layer, we can propose the following trace metals trapping mechanisms:

- Vanadium and chromium are present under their oxy-anionic forms in our experimental conditions. However, they are not hosted by the same major phase in the leached layer: Local XRD, SEM-EDS and local ICP-MS data are compatible with the hypothesis of CrO_4^{2-} substituting to SO_4^{2-} in the structure of secondary ettringite, while VO_4^- localization is clearly distinct.
- Secondary calcite probably plays a part for Zn trapping, because calcite and Zn display their maximum values in the median zone of the leached layer
- CSH of the altered zone appear to be significant host phase for Cu, Ni, Pb, and V. Adsorption and ionic substitutions to Ca^{2+} of these divalent cations Cu^{2+} , Ni^{2+} , Pb^{2+} may be advocated [16], [17], [18]. Concerning VO_4^- , the adsorption on the CSH surface seems to be the major mechanism.

Thus, these results obtained from measurements on hardened cement pastes are closely correlated with the kinetics of trace metal releases measured in the liquid phase [9] using the CTG-LEACHCRETE dynamic leaching device.

ABSTRACT

In the present work, the dimensional changes of several water-saturated concrete specimens during freeze/thaw cycles were continuously monitored using dilatometric equipment. Many concrete mixes were characterised by the presence or absence of air entraining agents, by different types and classes of cement and by various w/c ratios. Moreover, for most of the aforementioned concretes, the correlation between the results obtained with a standardized test method and the method presented herein is shown.

The main aims of the work were the study of the phenomena associated with water freezing in concrete specimens and the setting up of a differential dilatometer able to continuously monitor the length changes of specimens.

The results have shown that after a few freeze/thaw cycles it is possible to evaluate the frost susceptibility of concretes. Moreover, the results obtained are in good agreement with the results obtained by means of UNI 7087 which has been proven to furnish results comparable with those given by ASTM C 666.

1. INTRODUCTION

The frost deterioration of concrete, whether with or without de-icing salts, results from different coupled phenomena such as mass transport (water and/or vapour transport, ion diffusion, etc.) [1-4], ice formation in the porous structure of concrete [5], and osmotic pressure arising from different ionic concentrations [6]. When the water content in the porous structure of concrete is greater than a critical value [7], the deterioration of concrete may in some cases result from cumulative damage phenomena due to freeze/thaw cycles.

In order to prevent frost from damaging the concrete structures, the design of concrete mixes and the checking of their conformity to freeze resistance requirements should be carried out before the scheduled casting operations.

In this context, a test method able to quickly evaluate the frost sensitivity of concrete may be a useful tool for verifying the performance of the designed concrete mixes.

The main objective of this work is to develop an instrument able to provide frost judgement about concrete frost susceptibility.

2. EXISTING STANDARD TEST METHODS

Current test methods concern the evaluation of the internal damage of concrete (e.g. in absence of de-icing salts) and the assessment of surface damage due to de-icing salts and freeze/thaw cycles.

Despite the common aim of all the standard test methods, the procedures differ with respect to:

- size and shape of the specimens;
- freeze/thaw cycle (temperature limits, cooling and heating rate);
- cooling and heating fluid (water, air, kerosene, etc.);
- measurement technique to evaluate internal damage.

Accepting that it is not easy and not advisable to compare results obtained according to different standards, due to the differences related to the items a), b) and c), some comments can be made on the prescribed measurement techniques (item d).

An in-depth analysis of the standard test methods [8] allows observing that:

- ♦ the test duration can range from some weeks to some months;
- ♦ discontinuous measurements are time-consuming because there is the necessity to stop the test and to condition the specimens; moreover the conditioning period can lead to losing some information related to specimen damage;
- ♦ manual measurements may be more subject to error than automatic measurements;

3. EXPERIMENTAL

3.1 Equipment

The testing apparatus consists of an INVAR frame, in which the specimen and a reference INVAR rod are located (Figure 1). Two INVAR pins are constrained to the top and base of the specimen and the invar rod; in such a way the length changes can be transmitted to the outside of the frame. Two external gauges are mounted on INVAR rods, which are constrained to the measuring frame as well (see details on Figure 1). This testing arrangement was specifically designed in order to minimise errors due to spurious length changes introduced by thermal displacements of the equipment [9].

Figure 1. INVAR frame for differential measurements

Moreover, to reduce spurious displacements further, the length change values detected on the concrete specimens during a freeze/thaw cycle are referred to the dimensional variations measured on the reference INVAR rod. In this way, the actual length changes of specimens are provided by the following relationship:

$$\Delta L_{cls} = L_1 - L_2 + \alpha_{INVAR} \Delta T L_0 \quad (1)$$

where:

L_1 = displacement measured by LVDT on the concrete specimen;

L_2 = displacement measured by LVDT on the INVAR reference specimen;

α_{INVAR} = thermal dilation coefficient of INVAR by [10];

ΔT = temperature variation;

L_0 = reference length of INVAR rod at laboratory temperature ($20 \pm 2^\circ\text{C}$).

The testing frame is submerged into a diathermal oil bath contained in a cylindrical stainless steel vessel where freeze/thaw cycles are performed by circulating a primary diathermal oil coming from a heat/freeze source into a copper coil. The freeze/thaw cycle is realised by controlling the flow rate of primary diathermal oil with a proportional valve operated by a command signal coming from a programmable controller. The control loop is closed by the feed-back signal coming from a temperature gauge (Pt 100) immersed in the secondary diathermal oil up to mid-plane of the bath. A pneumatic rotating mixer stirs the secondary diathermal oil.

The displacements are detected by a measuring chain composed of two LVDT (Linear Variable Differential Transformers) that are connected to two amplifiers/conditioners of the signal.

The temperature data are detected with different gauges as indicated in Table 1.

Table 1. Placement and technical data of the adopted temperature gauges

Gauge type	Placement	Uncertainty
Pt100	Secondary oil bath	0.3 °C
Surface thermoresistance	On specimen surface	0.4 °C
Thermocouple	Inside the specimens	0.4 °C

3.2 Freeze/thaw cycles

In order to evaluate the sensitivity of the test method to the cooling/heating rate, the nominal thermal cycles described in Table 2 were applied. For temperature values and time intervals, a tolerance of $\pm 2^\circ\text{C}$ and $\pm 15'$ respectively has been considered acceptable.

Table 2. Thermal cycles adopted.

	Cooling/heating rate		
	Slow [1.5°C/h]	Medium [5°C/h]	Fast [10°C/h]
Phase	Duration [h]		
Storing at $+5^\circ\text{C}$	4	3	3
Cooling from 5°C to -25°C	20	6	3
Storing at -25°C	4	3	2
Heating from -25°C to $+5^\circ\text{C}$	20	6	3
Total time	48	18	11

3.3 Equipment calibration

All the measuring gauges were in calibration at the time of testing; the calibration of the equipment was carried out by fast cycles.

The performance of the dilatometer was verified in terms of:

- 1) deviation of bath temperature from the reference value of the set temperature cycle;
- 2) agreement between the measured temperature displacement relationship and the corresponding reference relationship provided by [10] for the reference specimens;
- 3) repeatability.

Commercially available rods ($\varnothing=12$ mm; $h=200$ mm) made of aluminium (97% Al) and electrolytic copper were used as reference specimens. Figure 2 shows the temperature profile (fast cycle) imposed to the oil bath compared with the measured temperature (feed-back quantity).

Figure 2. Comparison between the thermal cycle imposed to the oil bath and the measured temperature in the oil bath.

In Figure 3a and 3b the temperature/strain relationships for reference materials are compared. For both copper and aluminium specimens, a good agreement with the relationships given by [10] and shown in Table 3 was found.

Table 3. Temperature/strain relationships for aluminium and copper (reference materials)

$Strain = \alpha \cdot T + \beta \cdot (T)^2$ [$T=Temperature$]		
Material	α	β
Aluminium	2.2×10^{-5}	0.09×10^{-7}
Copper	1.61×10^{-5}	0.040×10^{-7}

(a)

(b)

Figure 3. Comparison between the measured temperature/strain relationships and those given by [10]

The mean deviation of the measured thermal strain from the reference values is less than $25 \mu\epsilon$ for both the reference materials.

As regards aluminium reference specimens, repeatability tests were carried out by detecting six times the temperature/displacement relationship. The slope of the best fitting straight line of the temperature/displacement relationship has been calculated and the results are shown in Table 4; the

same table shows the mean value, the standard deviation and the variation coefficient of the slope (α) of the best fitting straight line. The good repeatability performance was highlighted by the low value of the coefficient of variation

Table 4. Repeatability tests for aluminium rod

Slope (α) of the best fitting straight line									
Test No.	1	2	3	4	5	6	Mean	σ	CV [%]
α [ϵ $^{\circ}\text{C}^{-1}$]	2.35E-5	2.34E-5	2.36E-5	2.34E-5	2.35E-5	2.34E-5	2.35E-5	5.67E-8	0.24

Moreover, the thermal gradient in the mass of a cylindrical specimen ($\varnothing=100$ mm; $h=200$ mm) was detected in order to evaluate the distribution of temperature in its middle plane. The results, shown in Figure 4, highlighted that the temperature was in the range whose upper and lower limits are defined in § 3.2.

Figure 4. Temperature distribution in a concrete specimen during a freeze/thaw cycle

3.4 Concrete mixes

The experimental program has been set up to evaluate the frost behaviour of concrete with respect to the type, class and content of cement, the w/c ratio, and the type and content of admixture. The cement content was 350 kg/m^3 for all the mixes. Table 5 shows the concrete composition and the compressive strength values at 28 days.

Table 5. Composition of adopted concrete mixes

Material	CEM type	w/c	Admixture [%CEM]	Density [kg/m^3]	Slump [mm]	Air [%]	$\text{Rc}_{28\text{d}}$ [MPa]
32S40	32.5R II/A-L	0.40	1.5% Superflux	2477	60	-	48.4
32N50	32.5R II/A-L	0.50	-	2394	20	1,7	37.8
42N50	42.5R II/A-L	0,50	-	2409	10	1.8	44.6

42A58	42.5R II/A-L	0,58	0.5 %Aermix	2278	170	5.1	31.2

4. RESULTS

4.1 Detected quantities

Figure 6 shows the typical results from two freeze/thaw cycles in terms of longitudinal strain versus concrete temperature; the same figure shows the quantities adopted to evaluate the frost sensitivity of the test specimens.

In particular the following quantities were detected (Figure 6):

- residual strain ($\epsilon_{\text{res,cum}}$) exhibited by the specimen at the end of each freeze/thaw cycle;
- net thermal strain (ϵ_T) computed at the bottom limit of the cycle. To evaluate this quantity, a linear extrapolation (up to the minimum temperature of the cycle; Figure 5) of the strain-temperature curve measured for positive values of temperature must be considered;
- maximum strain ($\epsilon_{\text{max,cum}}$) recorded during each cycle and referred to the net thermal strain;
- cumulative area (A_{cum}) computed as the sum of the areas included by the strain-temperature curves.

Figure 5. Detected quantities

Taking into account that hysteresis and residual strain are typical display of occurrence of internal frost damage of concrete [1-4], all the above quantities, with the only exception of the net thermal strain, may be considered as useful tools to evaluate the frost sensitivity of concrete.

4.2. Experimental data

4.2.1 Sensitivity of the method to concrete composition and to testing parameters

A typical result of a complete freeze/thaw test is reported in Figure 7 that shows the (longitudinal) concrete strain versus the temperature for the concrete specimen 42N58. It can be observed that the increase in the residual strain at the end of each cycle is quite constant, thus determining a quasi-linear increase in cumulative residual strains. The hysteresis area shows a slight increase at each cycle; therefore, also the cumulative hysteresis area increases continuously. A similar behaviour can be observed also for the maximum strain. These results point out the growth of a cumulative (and non-reversible) internal damage that is already evident after the first cycle. Furthermore, it can be observed that, in this case, a very small number of cycles (not more than 3-5 cycles) is sufficient to confirm the presence of concrete damage.

Figure 7 shows the curves related to an air entrained concrete specimen (42A58) subjected to 5 cycles. It can be observed that both residual and maximum strain is significantly reduced with respect to that exhibited by the corresponding non-aerated concrete (42N58). In addition, the hysteresis area is appreciably reduced and, after the first cycle, it no longer increases. For comparative purposes, the same figure gives the strain-temperature relationship related to an oven dried specimen (32N58). The comparison clearly indicates how the behaviour of the air entrained specimen, even if less susceptible to frost damage than the non-aerated specimen, nevertheless exhibits evidence of the frost action.

Figure 6. Result of the freeze/thaw test by the dilatometric method for concrete 42N58

Figure 7. Result of the freeze/thaw test by the dilatometric method for concrete 42N58 compared with the measured strain for a dry specimen made with concrete mix 32N50.

In Figure 8 the sensitivity of the test method to w/c ratio, other parameters being constant, is shown. By passing from w/c=0.4 to w/c=0.58 all the damage indexes (maximum strain, residual strain, hysteresis area) are appreciably increased just after the fourth cycle.

Figure 8. Diagram of the strain versus the temperature as obtained from specimen 32S40, 32N50 and 32N58

Figure 9 shows the dilatometric curves obtained for three specimens subjected to freeze/thaw cycles, and characterised respectively by three different cooling thermal gradients: 1.5, 5 and 10 °C/h. A clear dependency of concrete behaviour on the imposed cooling gradient can be noted. In fact, all the above-defined parameters, chosen to evaluate the frost sensitivity, increase markedly with the cooling gradient.

Figure 9. Diagram of the strain versus the temperature as obtained from specimen 32N50 for three different cooling rates

4.2.2 Comparison with Italian standard test method

In order to verify the relationship between the results obtained with the proposed freeze/thaw test and the standard methods according to UNI 7087 [11], tests on specimens prepared with the mixes listed in Table 2 were carried out. The results obtained after five cycles according to the dilatometric method have been compared to those obtained after 50 cycles carried out according to UNI 7087. The relationship between the UNI degradation factor and the detected quantities according to the dilatometric method has been investigated. In Figures 10a, 10b and 10c, the damage indexes detected after five cycles are plotted versus the degradation factor measured after 50 cycles according to UNI 7087. The correlation coefficient is generally good; in particular, the relationships between the maximum strain and the degradation factor, with $r^2 = 0.92$, confirm that the early response given by the dilatometric method provides a reliable assessment.

Figure 10. Correlation between results obtained with the proposed method and with UNI 7087

5. CONCLUSIONS

All the current standard test methods aimed at evaluating the evolution of internal damage due to freeze-thaw cycles are very time-consuming. In the present work, a fast test method able to provide an assessment of frost resistance after few days is presented.

A testing apparatus has been set up and its reliability has been verified by calibration and repeatability tests.

The equipment allows continuous monitoring of axial displacement during freeze/thaw cycles. In this way the test can be stopped whenever evidence of degradation is apparent, and it is therefore no longer necessary to wait until completion of the scheduled number of cycles. This equipment has shown that the dilatometric method is very sensitive to the composition parameters of concrete and to the cooling rate of the cycles.

The experimental data obtained after five cycles are in very good agreement with the results after 50 cycles carried out by the UNI standard method, which has been proven to furnish test results comparable with ASTM C666 [12].

ABSTRACT

White cement is a key ingredient in architectural and decorative concrete. By using it, in particular, the resulting concrete not only becomes an expressive material that having an infinite range of colour tones, intensifying one of its aesthetic qualities, but can also be used to produce high-strength in concrete for structural applications.

This paper is intended to provide technical information to both designers, architects, and contractors in order to obtain a high performance concrete that is similar to natural materials like marble and which possesses relevant properties in terms of durability, performance and added environmental benefits. Indeed, the new type of white cement proposed here contains TiO₂ and possesses photocatalytic properties, which allow the maintenance of the aesthetic characteristics of concrete over time. It also contributes to eliminating dangerous pollutants from the urban environment.

A remarkable application is also described, concerning the innovative construction of a church in Rome, named “Dives in Misericordia” whose sails were built using white High Performance Concrete, based on this new cement. The main physical and mechanical properties of this HPC are described.

1. WHITE CEMENT

Thanks to the continuous laboratory research efforts aimed at obtaining outstanding properties in addition to an excellent degree of whiteness, white cement has been rendered increasingly and noticeably a high performance binder. White clinker is produced by taking care that the content of ferrous composites and other heavy metal composites (not exceeding 0.15%), whose presence give common Portland cement its distinctive grey colour. For this purpose, it is first of all necessary to carefully select the raw materials: only mineralogically pure kaolins and white limestone are used.

1.1 Colorimetric properties

Chromatic control (especially in the case of white cement) takes the form of reflected light colorimetry using highly reflective materials such as magnesium oxide or titanium.

Briefly, the “white” quality of the cement is measured using three parameters:

- purity, i.e. the intensity of the shade. Purity is measured by colour percentage;
- dominant wave length, i.e. the tonality of the shade that accompanies and characterises each white (for this reason, not all white bodies are equal). The length of the dominant wave lies between yellow and blue;

- brilliance, i.e. the power to reflect incident light (the most distinctive characteristic of white bodies), expressed as the difference in percentage between the light reflected by a surface of white cement and that reflected by a similar surface of magnesium oxide, traditionally considered as the ideal white body.

As far as cements are concerned the colorimetric characteristic can only be represented by two parameters: brilliance and purity, as the third parameter (i.e. the basic wave length), which is normally requested for the various powders in the cements, remains roughly the same (for ordinary cements, $\lambda = 577 \pm 2$ nm; for white cements, $\lambda = 567 \pm 2$ nm).

Figure 1 shows the brilliance/purity curve with the colorimetric data for different types of hydraulic binders: ordinary cements, clear binders and white binders [1].

Figure 1. Brilliance/purity for the various types of cement

Reading from the left to right, the chromatic component increases: this is between 8 and 17% for grey cements; 5-7% for light cements and 4-5% for white cements: The brilliance also increases from 25 to 40, from 50 to 60 and from 80 to 90 respectively.

This graph allows us to compare the variability in purity with that of the brilliance. It is worth noting that the inaccuracy of visual evaluation of the brilliance (at least in the case of white cements) is about 2 points.

1.2 Photocatalytic properties

Scientific studies on photocatalysis were started about three decades ago [2-9]. Since then research has taken several turns, but it is in the last 10 years only that the most exciting potential of this technology has emerged: the application of photocatalysis to environmental clean-up [10].

This also gave impetus to industrial and institutional applications research. A huge increase in worldwide patent applications was observed and in 1999 more than 400 international applications were filed [11].

The strict environmental regulations imposed by the authorities have stimulated academic and industrial research groups to develop new strategies for the abatement of dangerous aqueous and gaseous pollutants. As regards the latter, much attention has been focused on the removal of NO_x, hydrocarbons and organic chlorides, since these pollutants are an issue of high social impact in everyday life.

In particular, it should be noted that reactions in the atmosphere between NO_x and several hydrocarbons, under solar irradiation (Photochemical Smog), increase health hazards especially within heavy-traffic urban areas.

1.2.1 Cement containing photocatalysts

Within the framework of a strategy aimed at remedying environmental pollution through the use of construction materials containing photocatalysts, a system comprising Titanium dioxide (TiO_2) and white cement was investigated.

A first technology including the photocatalytic degradation of organic pollutants was utilised for maintaining the aesthaetic characteristics of concrete structures [12-15]. The introduction of suitable amounts of TiO_2 into cement mixes made the surface of cementitious structures photocatalitically active. In fact, concrete products are expected to maintain their aesthetic characteristics unchanged over time (particularly colour), even in the presence of aggressive urban environments.

The maintenance of the aesthetic appearance of cementitious materials, in particular those based on white cement, is specially desired. Indeed, the main reason that brings about a colour change in cementitious materials is the presence of coloured organic compounds that remain on their surfaces.

The inorganic powders adhere to the surface of the cementitious material in the presence of an organic interface or of macroporosities. The technology of heterogeneous photocatalysis is based on the irradiation of a semiconductor photocatalyst. Semiconductors are characterized by a narrow band gap between their valence and the conduction bands.

The absorption of a quantity of luminous energy being greater than or the same as the band gap (E_{BG}) of the semiconductor results in an abrupt transfer of electrons from the valence to the conduction band and the consequent creation of holes (h^+) in the valence band.

Such charge transfer introduces some unbalanced conditions which in turn lead to the reduction or oxidation of the species adsorbed onto the surface of the semiconductor.

In order to verify the efficacy of the photocatalytic activity on a cement matrix containing TiO_2 , many experiments focusing on the oxidation of several kinds of aromatic organic compounds were carried out.

Figure 2 shows the surface restoration by irradiation of cementitious mortar samples containing TiO_2 and phenanthroquinone. TiO_2 can form two different cristallographic forms: rutile and anatase. The photocatalytic activity is much higher when TiO_2 is mainly in the anatase form.

Figure 2. Reflectance spectra versus wavelength for a white cement sample

Samples of white cement having a thickness of 2 mm were placed on supports having a discoid form with a diameter of 3.2 cm and a thickness of 7 mm, containing 5% of TiO_2 (P-25 Degussa type).

In order to obtain reproducible organic substances on the sample, a phenanthroquinone solution in methanol was deposited by means of an aerograph thereby giving to the surface an amount of phenanthroquinone equal to 0.1 mg/cm^2 . At the end of the treatment, the sample showed a homogenous surface having a yellow colour.

Both before and after the deposition of phenanthroquinone, reflectance spectrophotometric analyses were carried out with a Perkin Elmer lambda type spectrophotometer. The instrument was fitted with an integrating sphere to eliminate any scattered light responsible for anisotropy and surface irregularities. The samples were irradiated by means of a solar flow simulator, emitting radiation with a wavelength greater than 290 nm. The device used for irradiating purposes consisted of four 400 Watt lamps placed at the vertices of a square having at its center a carrying sample roundabout rotating on its own axis. By means of that device, simultaneous irradiation of more samples with the same amount of photons per time unit was possible.

The irradiation device SOLAR SIMULATOR SET-UP12/24 allowed accelerated ageing tests to be carried out, whereby approximately 100 irradiation hours correspond to 1 year of sunlight. For samples at different times and various percentages reflectance values ($R\%$) as a function of wavelength (nm) were obtained. The percentage of reflectance of the samples was reported in Figure 2 at different times as a function of the wavelength (nm). With particular regard to Figure 2, curve A represents the spectrum before depositing the organic substance, curve B represents the situation after deposition of the substance, curve C represents the situation after 8 hours of irradiation.

As can be seen, after 8 hours of irradiation the situation is almost the same as before the treatment with the pollutant.

1.2.2 Photocatalysis and the removal of NO_x

Two main practical directions of NO_x elimination can be cited:

- i) Reduction by hydrocarbons or ammonia
- ii) A two-step adsorption-reduction or thermal destruction process

Photocatalysis has recently gained considerable recognition as a reliable method of NO_x abatement under mild experimental conditions, employing sunlight as a low cost renewable energy source. It is interesting that, in this field too, recent developments suggest the use of mixed catalysts in which a photoactive component such as TiO_2 is mixed with adsorbents, e.g. zeolites [16]. As reported, this improves the overall efficiency of NO_x elimination since the high absorbing capacity of zeolites compensates for or complements the low adsorbing power of TiO_2 .

The use of mixed catalysts therefore seems a promising research direction in photocatalysis, too. Realising that a composite system consisting of TiO_2 dispersed into a cementitious matrix is one of such photocatalysts holds important practical implications. Research under way at our laboratories and at other research institutions [17] shows that concrete containing TiO_2 has very good potential application as a resolving technology in pollution control.

The mechanism of nitrogen oxide removal by photocatalysis is not simple. It is assumed that NO in the air is oxidised when the catalyst is exposed to light. Through the intermediate step of nitrogen dioxide (NO_2), it is then converted to nitrate. When NO_2 is formed, part of the gas may escape from

the photocatalytic surface but, in the presence of the cement matrix, the gas may be effectively entrapped together with the nitrate salt formed.

Laboratory tests of photoconversion of NO_x were carried out on films of:

- TiO_2 mixed with cement (5% by cement weight)
- Cement matrix without photocatalyst

Figure 3 summarises the tests carried out in the dark. NO_x is considered as a residual amount; a percentage is referred to an initial concentration of 100%. In this case, the observed concentration decrease is only due to adsorption. It is probable that such absorption is attributed to the ability of alkaline oxides forming the cement matrix to adsorb NO_x .

Photochemical tests after 7 hours of light of the samples, still considered as a percentage referred to an initial concentration of 100% are reported in Figure 4 below

It can be noted the removal of NO_x by action of the photocatalyst plus the cementitious matrix which is higher than the photocatalyst alone.

The reason is that on the surface NO is oxidised to NO_2 by reaction with OH radicals:

NO_2 is oxidised and, like nitrate, remains adsorbed :

Figure 3. NO_x treatment in the dark

Figure 4. NO_x treatment under UV light

Furthermore, the examination of the data of Figure 4 shows that the cementitious matrix without TiO_2 also holds a certain catalytic effect, as is often observed in the case of organic substrates, probably due to the presence of photocatalytic oxides in the matrix itself.

A white cement containing TiO_2 (TX Millennium) has already been used for the construction of the Church for the Jubilee “Dives in Misericordia” in Rome [18], for the construction of the “City of Music” in Chamb rie (France) and for the construction of a school in Mortara (Italy). Cementitious paints containing photocatalysts were also developed. [19].

2. WHITE CEMENT CONCRETE: MIX DESIGN

The mix design for a concrete made with white cement needs to be developed taking into consideration two fundamental aspects:

- the aesthetics or surface finish (including final photocatalytic properties);
- the strength or structural suitability

In other words, the right materials need to be chosen to create a delicate balance between the mix components and to guarantee the rheological behaviour of the resulting mix.

In the particular case of High Performance Concrete (HPC), the raw materials are: water, cement and aggregates (the same as in the ordinary cement mix), to which mineral and superplasticizer admixtures may be added as required. As a result, HPC has a microstructure significantly different from that of ordinary concrete: high density, low porosity and improved interfacial binding between cement paste and aggregates thus leading to different macroproperties in terms of strength and durability [20].

2.1 Aggregates

In the case of white cement concrete, an adequate choice of aggregates is absolutely necessary, in order to achieve the white colour in the concrete.

All aggregates must be clean, free from clay, mineral dusts and impurities. Contamination with other materials must be avoided.

Coarse aggregates. Their colour is of utmost importance for those surfaces to be treated to reveal the aggregate (e.g. bush-hammered, sand-blasted and washed). They should be reasonably uniform in colour.

Fine sands. Their use is decisive for the colouring of the open surfaces without further treatment after the removal of the formworks (extremely light coloured sand is needed if we specifically want a perfectly white surface, while a coloured sand may be adequate if the whiteness is less critical).

In both cases, the use of white cement in the “open” concrete allows to obtain a far more brilliant mortar in contrast to the colour of the aggregate, thus enhancing this if the surfaces are “worked” and making casts brighter if the surfaces are left “as they are”. The surface of a mortar obtained with white cement:

- acquires more brilliance, the less brilliant the sand
- assumes an increasingly less pinkish and more bluish tone than that of the sands. In fact, the wavelength of the loose materials is longer than that of the hardened surfaces.
- loses colour percentage (the colour is weaker) and thus the use of coloured sands is not enough on its own to get a concrete with distinctly coloured surfaces.

The results of the sand/mortar colour experiments show that it is not necessary to use particularly white sands, which are often hard to find, to create a white cement concrete: we can quite easily use normal sands.

The “colour loss” or rather the shades obtained by passing from sand to mortar can have a very pleasing chromatic effect, often preferable to pure white.

However, when the designer wants to achieve a brilliant and definite colour, he changes the colour of the surface by adding a mortar of the relevant colour capable of accentuating the colouring and giving the required dominant wave length.

In this way, it is possible to get a virtually infinite spectrum of colour tones.

2.2 Mineral additions

For the improvement of strength, chemical and physical durability, mineral additions can be included in the mix design.

In the case of white cement concrete, it is clear that fine pozzolanic materials (such as silica fume, blastfurnace slag, fly ash, rice husk ash and metakaolin) must be white and among all the materials currently available only the latter can be considered [21-23]. Indeed, particular types of white silica fume or precipitated silica are too expensive.

Metakaolin is by nature white and is highly reactive, sometimes used as a valid alternative to silica fume. It is an aluminium silicate obtained through calcination of pure kaolin within a set temperature range. The average size of the particles is 1.5 microns (ten times finer than Portland cement CEM I 52.5 R). Metakaolin works in different ways:

- as a filler, with immediate action
- by accelerating the hydration at greater intensity within the first 24 hours
- by means of a pozzolanic reaction with the C-H between the 7th and 28th days

In addition, other advantages can be obtained:

- reducing water permeability
- limiting efflorescence problems - presence of $(\text{CaOH})_2$
- controlling the hygrometric shrinkage
- improving the paste/aggregate bond
- controlling bleeding.

2.3 Water-reducing admixtures

Since water demand levels in HPC correspond to a water/binder ratio of 0.20-0.35, the use of acrylic superplasticizers is preferable, rather than melamine-formaldehyde or naphthalene-formaldehyde sulphonate condensates. In the particular case of white concrete, the choice of admixtures is also strictly connected with their colour.

Besides, if there are possibilities of cement-admixture incompatibility, the use of a compatibility agent is absolutely necessary. Recently, this problem was solved by using a system of admixtures supported by the metakaolin used as the pozzolanic addition [24].

3. WHITE SAILS FOR THE CHURCH “DIVES IN MISERICORDIA”, IN ROME

The Church “Dives in Misericordia”, a project of Richard Meier, a master of contemporary architecture, is the first example in which Italcementi participated using photocatalytic innovative materials. The simple yet severe design which manages to combine the sacredness of the inside of the building with the liveability of large external spaces, is characterised by three large white concrete sails which swell as though driven by a wind from the East.

In the church there are two distinct architectural bodies: the sacred building, approximately 2,500 sq.m, which occupies the southern part; the community centre, approximately 4,300 m² situated in the northern part. The churchyard connects the Church to the centre of the residential area. The church roof is a glass skylight which runs along the entire length and impressive glazed windows characterise the lateral facades. Four large shells in reinforced white concrete measuring 16 and 28 metres in height embrace the central body of the nave occupying more than 700 m²; the main hall, the weekday chapel and the baptistery separate the spaces inside the building. There is a 26 m high pillar-bell-tower near the central body. The impressiveness of the work and the specifications of the project: 20,000 m³, 22 metres high, the tall bell-tower and the three immense curved shells, required Italcementi's contribution for the bold technical-structural solutions. Italcementi, technical sponsor

of the project, is participating in the construction of the Church, by supplying know-how, technical assistance and structural calculations, in addition to the highly technological and innovative products amongst which is the new white cement “TX Millennium”, whose formulation (patented) guarantees unparalleled whiteness which remains constant over time.

The three sails are made of 346 white, reinforced, precast concrete blocks (mean dimensions: 3x2x0.8 m), Figures 5 and 6. They are spherical, curving horizontally and vertically. A single stainless-steel form, adjustable on the ends only, was used for every block.

All the rows are post-tensioned vertically and horizontally with steel rods and cables so that the entire shell is in continuous compression.

3.1 Mix design of white HPC for the sails

For this application, Italcementi’s R&D Department developed the white HPC for the project, including photocatalytic particles in the mixture which oxidize organic and inorganic atmospheric pollutants, so that the brightness and the colour will not degrade over time [18].

Figure 5. Construction of the Church (sails)

Figure 6. Church in Rome – Internal view

Thanks to the possibility of staying close to a w/b ratio of roughly 0.38 and to the double-admixture technique (compatibility agent + acrylic superplasticizer), the actual amount of white TX Millennium cement needed was quite low (380 kg/m^3) and the workability of the concrete was high. The compatibility agent increases substantially the action of the acrylic superplasticizer in order to maintain the workability of the fresh white concrete till about 60 minutes. As this structure had to be entirely white, a white Apuan marble aggregate was selected (from the Carrara area), consisting of a crushed metamorphic limestone with a fine grain, compact and uniform saccharoid structure. The maximum particle size was limited to 20 mm to ensure that the concrete would flow through the reinforcement and covers (40 mm) and at the same time to contain or at least greatly reduce surface defects (bug holes, gravel clusters, etc.) also linked to the elevated bulk of the aggregate due to the wall effect. A white metakaolin and an acrylic superplasticizer were also used. Table 1 shows the typical composition of the white HPC utilized [18].

Table 1. Mixture proportions

White cement TX Millenium	380 kg/m^3
White metakaolin (with special compatibility agent)	38.7 kg/m^3
Aggregates: Crushed marble $d_{\max} = 20 \text{ mm}$	1850 kg/m^3
Acrylic superplasticizer (solution, 30% dry extract)	10.5 kg/m^3
Water	160 l/m^3

3.2 Physical and mechanical properties

The consistency class was S5, the mean volumic mass weight was 2430 kg/m³.

Table 2 below shows the varying compressive strength of the concrete at different stages in the curing process. Other mechanical properties are shown in Table 3.

Table 2. Compressive strength, MPa

24 hours	35.0
30 hours	41.0
2 days	47.7
3 days	58.2
7 days	69.8
9 days	72.5
28 days	86.2
90 days	89.8

Table 3. Other mechanical properties

Flexural strength, 7 days	7.0 MPa
Flexural strength, 28 days	10.4 MPa
Indirect tensile strength, 28 days	7.0 MPa
Dynamic elastic modulus, 28 days	44.6 GPa
Static elastic modulus, 28 days	41.0 GPa

Further information concerning hygrometric deformation (shrinkage), creep values, freeze-thaw behaviour and thermal behaviour are reported in [18, 25].

4. CONCLUSIONS

Cementitious materials containing TiO₂ mainly in the form of anatase, when irradiated with adequate light, enhance the oxidation efficiency on organic substances with which they come into contact.

Building elements containing white cements to which TiO₂ has been added are capable of maintaining their aesthetic appearance unaltered with time.

With respect to the improvement in our living standards, we believe that a massive and continuous use of photocatalysts in construction materials can be a new way of contributing to minimizing the contaminants attacking the urban environment.

Many applications are possible, using white cement: dry pre-mix mortar for aesthetic and structural rehabilitation of deteriorated surfaces, cement-based paints, cladding and flooring, urban settings, art restoration and mortars for plasters and spray coatings.

DIFFERENT ASPECTS FOR THE HYDRATION OF C₃A AT ROOM TEMPERATURE

H.Y. Ghorab

Faculty of Science, Helwan University, Cairo, Egypt. E-mail: h_ghorab@hotmail.com
G & W Science and Engineering Company, Cairo, Egypt.

ABSTRACT

The mechanism of hydration of C₃A in water, alkali hydroxide and alkali sulfate solutions, also in the presence of gypsum, lime and alite is interpreted in terms of the change in the concentrations of the dissolved sulfate, aluminate and calcium ions, with time, in correlation with the stability of the solids. In the absence and the presence of gypsum, the dissolved lime enhances the gel-like character of the hydrate coat around the C₃A and retards its hydration. The composition of the gel varies between that of the calcium aluminate- carbo- and sulfoaluminate hydrates. C₃A is directly consumed by excess lime, but its hydration is strongly retarded by a mixture of gypsum and excess lime. Excess lime in strong alkali hydroxide solution causes a direct consumption of both C₃A and gypsum. Alkali hydroxide depresses the solubility of lime and favors the formation of the monophases.

The dissolved lime is responsible for the decomposition of the monophases to ettringite in the absence of an external sulfate supply, for the precipitation of syngenite and hydroglauberite in $\geq 0.5M$ alkali sulfate solutions and for the transformation of hydroglauberite to ettringite with time. The ettringite forms as a result of different types of interactions and with various morphology depending on the solution composition and the hydration time.

1. INTRODUCTION

The hydration of C₃A is quite a complicated process and depends on the types of the reactants and the respective solution composition. It was the subject of work by many researchers starting a few decades ago [1-5]. Because of its importance in phenomena occurring in cement and concrete such as delayed ettringite formation [6-10] and the function of superplasticizer [11-12], its chemistry needs further understanding. The present work presents a contribution to this field of research.

2. EXPERIMENTAL

The C₃A and alite samples were prepared through burning stoichiometric mixes of calcite with alumina at 1350 °C and calcite with quartz with minor additions of alumina and magnesia at 1450°C. Gypsum, lime, alkali hydroxides and alkali sulfates were reagent grade. The system no I studied included mixtures of C₃A with different gypsum additions of SO₃/Al₂O₃ ratio of 0.6, 0.8, 1 and 1.5 [13,14]. The mixture with a ratio of 1.5 was taken as reference to study the effect of lime and alite. In system II, the reaction was carried out in an unsaturated lime solution of 0.6 g CaO/l as well as in the presence of an excess amount of lime (6g/ l) [13,15]. In system III and IV, three concentrations of alite were added to the reference mixture and to that containing lime [16,17]. ~ 0.3g of the C₃A was used in each system, and the weights of the reactants corresponding to the

ratios taken were applied. In system V, 0.3g of alite was hydrated with different gypsum additions in the absence of C_3A [16,17].

The mixture of C_3A and gypsum chosen as the reference mixture, with a mole ratio of SO_3/Al_2O_3 equal to 1.5, also in the presence of lime and alite were used to study the hydration reaction in 0.1, 0.5 and 1M alkali sulfate solutions [18,21] and in 0.01, 0.1 and 1M alkali hydroxide solutions at room temperature [22,23]. 1M potassium sulfate solution could not be prepared because it formed a supersaturated solution. The systems studied are cited in table [1].

The reactants were stirred in 100ml of redistilled water in tightly closed glass flasks at room temperature for time intervals 2, 15, 30 minutes, 1, 3, 6, 24 hours and 3, 5, 7 days. At the definite interval, the solutions were filtered off, and in the filtrate, the sulfate ions were determined turbidimetrically [24] and the aluminium colourimetrically using aluminon indicator [25]; the pH-values were also determined. The solids obtained after filtration were dried for 24 hours at 50°C then analyzed by means of X-ray diffraction. A few samples were examined by the scanning electron microscope and analyzed by EDAX.

Table1. The systems studied on the reaction of C_3A and gypsum in water at room temperature.

Sys.	Mixture	Mole ratio and reaction media

3. RESULTS

The reaction mechanism of the C_3A in water is well known to occur in three steps: The instantaneous reaction, the dormant period and the acceleration period. These stages can be described on the basis of the solution composition of the different systems studied as follows:

3.1 The instantaneous reaction

3.1.1 The aluminate of the solution

The absolute solubility values of the C_3A depends on the reactivity of the prepared crystals, the solution composition and the W/S ratio; the one cited may be considered as a guide.

The reaction of the C_3A with water leads to a quick release of hydroxyl ions to reach a pH- value of around 11 with the solubilization of 70ppm aluminium. Close values are found in the presence of a low gypsum addition (mole ratio $G:C_3A = 0.6$) as well as in 0.1M Na_2SO_4 solution. The solubility of C_3A increases to 160 ppm Al in 1M Na_2SO_4 . By increasing the gypsum addition to a mole ratio of 0.8 to 1.5, also in 1M NaOH and 0.1M K_2SO_4 solutions, the solubility of C_3A is depressed to a range of 13-19 ppm Al. In 0.6g CaO/l the aluminium concentration is depleted to 4ppm in the absence of gypsum, and to a zero value in its presence.

3.1.2 The sulfate of the solution

As soon as water is added to a mixture of C_3A with gypsum (mole ratio $G:C_3A=0.6-1.5$), 21 to 33% of gypsum dissolves releasing calcium and sulfate ions to the solution, and around 55% are left in the solid. The concentration of the dissolved ions increases, the higher the gypsum content. Meanwhile a thin coat of hydration products forms around the C_3A grains and the coated crystals remains in an intimate adherence to the gypsum left.

The calcium sulfate concentration of the solution measured after 2 minutes from the reaction start is less than the solubility value of gypsum at room temperature in spite of having enough solid to attain this value. This indicates that the hydrate coat formed around the C_3A results from the uptake of the calcium sulfate of the solution and should therefore incorporate the respective calcium sulfate concentration in its structure, a process which must have occurred within the first few seconds of the reaction. The amount of calcium sulfate consumed from the liquid phase was found to be in the range of 33 to 22% of the gypsum added. In the presence of alite there is an additional uptake of the dissolved calcium sulfate by the calcium silicate hydrate coat of the C_3S grains with a further depression of the calcium sulfate from the solution.

The initial solubility of gypsum is not influenced by lime which, however, affects the morphology and the type of the hydrate coat. Alkali hydroxide solutions tend to retain the sulfate of gypsum as sodium sulfate and to precipitate portlandite. Gypsum dissolves in 0.1M NaOH. In a solution of $\geq 0.1M$ alkali sulfate, the gypsum phase, does release no more of its sulfate because of the common ion effect.

3.1.3 The calcium ions of the solution.

The calcium ion concentration in the water solution of C_3A and gypsum is expected to be parallel to that of the sulfate with a minor contribution of the calcium aluminate phase. It decreases with alkali hydroxide content because of the precipitation of the less basic portlandite. Alkali sulfate solutions may accommodate calcium ions up to the solubility value of lime at room temperature. This is reached by the addition lime and/or alite. Because of the common ion effect, the amount of calcium released from gypsum in alkali sulfate solutions is slightly depressed.

3.1.4 The hydrate coats around the C_3A grains:

It is to be remembered that the carbonation effect plays an important role in the hydration of the C_3A especially in the absence of gypsum. The tetracalcium aluminate hydrate is very susceptible to atmospheric CO_2 , and forms a series of solid solutions including different concentrations of hydrated lime and carbonate ions which are called the sulfate-free monophases (Mo). A complete carbonation of the tetracalcium aluminate hydrate results in the formation of the monocarboaluminate hydrate (Mc). Hydrated lime and sodium hydroxide are also subjected to carbonation. The process seems to proceed at a rate slower than that of the carbonation of the tetracalcium aluminate hydrate. The tetracalcium aluminate hydrate and its carbonated forms may form a solid solution with the monosulfate hydrate (Ms) which may be called the sulfate bearing monophases..

The crystalline tetracalcium aluminate hydrate or some of its carbonated solid solution, forms a coat around the C_3A grains as soon as the reaction begins in water or sodium hydroxide solution. This occurs in a solution of a calcium ion concentration $< 0.6g\ CaO/l$, and 10 to 70 ppm aluminium. At a CaO solution $\geq 0.6g/l$ with no dissolved aluminium, hydrogarnet forms. The hydrate coat may incorporate calcium sulfate with a concentration equal to the amount taken from that instantaneously released from gypsum to the solution. The low and high sulfate forms of the calcium sulfoaluminate hydrate are formed instantaneously in a solution with 240-940 ppm SO_4^{--} and 70 to 13 ppm Al. At a calcium ion concentration equal to $0.6g\ CaO/l$, and less than the solubility

value of lime, the reaction occurs with no contribution of C_3A to the liquid phase because the aluminium is totally depleted from the solution. Under these conditions a gel-like ettringite forms. In the presence of gypsum and excess lime a gel-like monophase forms. In the presence of gypsum, excess lime and 1M NaOH C_3A and gypsum are consumed and only portlandite remains. In alkali sulfate solution of 0.1M, a more crystallized ettringite forms which increases its gel-like properties by lime addition. At 0.5M K_2SO_4 and in the presence of lime, syngenite precipitates beside the ettringite, but in 1M Na_2SO_4 solution rich in lime, the sodium sulfate salt precipitates and not hydroglauberite because of the supersaturation effect.

Tables (2) and (3) give a short summary on some of the phases composing the instantaneous coat of the C_3A grain as soon as its reaction begins with the aqueous medium, in the absence and presence of gypsum.

Table 2. The phases formed instantaneously around the C_3A grains during its hydration in the absence of gypsum and the respective solution composition.

Phases formed	CaO (g/l)	Al (ppm)	Reaction medium	Remarks
Sulfate –free Mo/Mc*)	<0.6	10-70	H ₂ O/0.01-1M NaOH	
Mc-Hg*	0.6	4	H ₂ O	
CH*	1.13	Zero	H ₂ O/1M NaOH	Excess lime. Quick consumption of C_3A

Table 3. The phases formed instantaneously around the C_3A grains during its hydration in the presence of gypsum and the respective solution composition.

Phases formed	CaO (g/l)	Al (ppm)	SO ₄ ²⁻ (ppm)	Reaction medium	Remarks
Ms+E*	<0.6	13-70	240-940	H ₂ O	
E	<0.6	160	~8000	0.1M Alkali sulfate	
Gel-like E	≥0.6- <1.13	Zero-4	≤8000 ≥940	H ₂ O/0.1M Alkali sulfate	
Gel-like Mo	1.13	Zero	940	H ₂ O	Excess lime
Sulfate-bearing Mo*	<0.6	Zero-38	~1400	0.01 to 1M NaOH

E+Syngenite	≥0.6	Zero	≥48000	≥ 0.5M K_2SO_4	

*Sulfate-free Mo: Solid solution between tetracalcium aluminate hydrate and its carbonated forms
Mc: Monocarboaluminate hydrate

Hg : Hydrogarnet

CH : Hydrated lime (portlandite)

Sulfate-bearing Mo: Solid solution between tetracalcium aluminate hydrate, its carbonated forms and monosulfate hydrate

Ms : Monosulfate hydrate

E : Ettringite

3.2 The dormant period and the acceleration reaction

The reaction of C_3A with water decelerates after the instantaneous formation of the hydrate coat around the surface of its grains. This stage lasts until the hydrates precipitate as a result of

increasing the crystallization pressure, and new surfaces of C_3A are exposed to further reactions. The behavior of the ions in the liquid phase are mostly indicative of the dormant period and the acceleration reaction. The duration times of the reactions described below are a useful guide for the different interactions but their absolute values may vary with the reactivity of the phases and the W/S ratio.

In the absence of gypsum, the crystallized calcium aluminate hydrates coat first formed during the hydration of C_3A in water, continues to form over 15 minutes while the aluminium increases in the solution from 70 to 90 ppm, then remains constant. The C_3A is consumed at 3 hours with the precipitation of a well crystallized hydrate. The hydration of C_3A in 1M NaOH solution leads to a steady increase of the aluminium concentration in the solution from 19 to 80 ppm with an accompanying formation of amorphous calcium aluminate hydrates which crystallize as monocarboaluminate hydrate at a later time. In 1M NaOH, the C_3A consumption is delayed to 1 day. 0.6 g CaO/l depresses the initial solubility of C_3A to 4 ppm and leads to the formation of hydrogarnet. The dissolved aluminium rises to 7 ppm within few minutes then becomes constant. In this unsaturated lime solution, the C_3A is consumed at 1 day. In the presence of excess lime, the aluminium ion is totally depressed from the solution but the C_3A is consumed within the first two minutes as a result of a solid-solid reaction. Under these conditions, mainly portlandite precipitates beside weakly crystallized carbonated tetracalcium aluminate hydrate which then transforms to hydrogarnet with time.

In the presence of gypsum, the hydration of C_3A decelerates as a result of the formation of a coat of calcium sulfoaluminate hydrates around its surface. In a solution of CaO concentration $<0.6\text{g/l}$, the dormant period is indicated by a constant sulfate ion concentration of the liquid phase, and lasts 15 minutes. The gypsum left in the solid then reacts with the dissolved aluminium which decreases in the solution from a highest value of 70 ppm to a minimum of 8 ppm Al in the different mixtures studied. The solubility curves of aluminium are lower, the higher the gypsum content. During this duration, both types of the calcium sulfoaluminate hydrates continue to form while the initial sulfate concentration of the solutions is constant. In this system, the dormant period is controlled by the consumption of gypsum and ends with the crystallization of the hydrate coat from around its grains. The new C_3A surface reacts then with the dissolved calcium sulfate with the precipitation of ettringite crystals. When all the dissolved calcium sulfate is used up, the excess C_3A reacts with the ettringite to form the monosulfate hydrate with the evolution of aluminium to the solution.

In solution with 0.6g CaO/l, the initial solubility of C_3A is totally depressed and results of an instantaneous formation of a gel-like ettringite coat. This hydrate continues to form with the progress of the reaction as a result of the diffusion of the gypsum left in the solid through its layer. Under these conditions, gypsum is consumed in 5 hours with a marked prolongation of the dormant period compared to that in the absence of lime. The dissolved calcium sulfate does not take part in this reaction and is seen to even increase slightly to approach the solubility of gypsum at room temperature. After the dormant period, the fresh C_3A surface reacts with the dissolved calcium sulfate to form ettringite and in a calcium sulfate-free solution the ettringite reacts with the excess C_3A to form the monosulfate hydrate. This in turns decomposes partially to ettringite because of the availability of calcium ion in solution.

In the presence of excess lime, the coat is composed of gel-like monophase, rich in calcium hydroxide. This further retards the gypsum diffusion and its consequent consumption to 1 day, the calcium sulfate of the solution remaining constant. At the end of the dormant period the fresh C_3A surfaces reacts with the dissolved calcium sulfate precipitating the ettringite. After the depletion of the dissolved sulfate, however, the ettringite phase does not convert to the monophase. This is attributed to the increased usage of the C_3A by lime over the progress of the reaction and little is available for the stage of the ettringite-monophase conversion.

In a solution $<0.6\text{g CaO/l}$, the alite phase contributes to the reaction of C_3A with gypsum by releasing part of the incorporated calcium sulfate taken up from the solution at the first moment of the reaction, while gypsum is reacting with the dissolved aluminate in a way similar to that of C_3A with gypsum; and with a similar duration of 15 minutes. The increased alite addition leads to the rise of lime concentration of the solution which process does not take place directly but needs an appreciable duration of time. When the lime concentration of the solution reaches a value $\geq 0.6\text{ CaO/l}$, the aluminium is depleted, and a long lasting diffusion control mechanism occurs.

In an alkali sulfate solution and in the absence of gypsum, the C_3A releases more aluminium to the solution, the higher the concentration of the alkali sulfate. The instantaneous value of aluminium is as high as 160 ppm in $1\text{M Na}_2\text{SO}_4$ at a lime concentration of 0.1g CaO/l and a sulfate concentration of $96\text{g SO}_4^{2-}/\text{l}$. This sulfate-rich solution precipitates both ettringite and the sodium sulfate salt all over the reaction period. An ettringite coat around the C_3A grains must have occurred because the C_3A consumption takes place after 3 hours during which constant values of the dissolved aluminium and calcium are maintained. After the dormant period, the fresh C_3A reacts with some of the existing sulfate of the solution with a further precipitation of ettringite, the calcium ion of the solution decreases and aluminium is released. When gypsum is added to the C_3A , it reacts with the dissolved aluminium in a way similar to that occurring in water while the calcium ion is kept constant in solution. In $\geq 0.5\text{M Na}_2\text{SO}_4$ solution, lime enhances the precipitation of sodium sulfate hydrate crystals which takes up the dissolved calcium and sulfate ions with time to form hydroglauberite. This in turn transforms to the more stable ettringite with a further uptake of calcium from the solution. Syngenite is more basic than hydroglauberite and precipitates more readily from $0.5\text{M K}_2\text{SO}_4$ solution of C_3A , gypsum in the presence of enough lime. It should be noted that, in 1M alkali sulfate solution, the C_3A reaction is quite fast because of the precipitation of the salts and double salts, but if the solution becomes saturated with lime and alite, it is slightly retarded. The retardation effect is, however, more clear in a solution of a lower alkali sulfate concentration of 0.1M ($9.6\text{g SO}_4^{2-}/\text{l}$) and a lime concentration $>0.6\text{ CaO/l}$, which sulfate concentration is lower than that needed for the precipitation of the double salts or the saturation value of the salts. A mixture of C_3A , gypsum, lime and alite with a mole ratio of $1:1.5:1:1$ may cause a dormant period of C_3A of 7 days long as indicated by a constant calcium ion concentration in an aluminium-free solution. At the acceleration period, the calcium ion decreases with a slight decrease of the sulfate from the solution.

Alkali hydroxide tends to retain the sulfate of gypsum as sodium sulfate as well as some of the aluminate and to precipitate portlandite. The hydrate coat becomes rich in calcium hydroxide and poor in sulfate and causes the retardation of C_3A hydration. In the acceleration period the fresh C_3A surface reacts with the dissolved calcium sulfate left in solution rather than taking up the sulfate dissolved as sodium salt. In an extreme case for the reaction of C_3A in 1M NaOH and in the presence of excess lime, both gypsum and C_3A are consumed instantaneously, the completion of the precipitation of portlandite is the rate determining step for the reaction while the dissolved sulfate remains constant in solution. The portlandite then reacts with some alumina with the formation of monophases.

3.3 Summary of the mechanism of the C_3A hydration

The above described reactions of the C_3A hydration are seen to be strongly dependent on the concentrations of the solid reactants as well as the respective ions in the solutions. The hydration kinetics of the C_3A is mainly governed by the behavior of the calcium oxide in the solution, rather than that of the calcium sulfates. The dissolved calcium oxide controls the solubility of C_3A with respect to the release of aluminium to the solution. The aluminium is evolved to the solution at a lime concentration less than 0.6g CaO/l and leads to the formation of a sulfate-free or sulfate-bearing hydrate coat of a crystalline character, in water, alkali hydroxide solution, in the absence or

the presence of a sulfate supply. At a limited supply of calcium sulfate as in the presence of gypsum (mole ratio to $C_3A \leq 1.5$) the monosulfate hydrate appears beside the ettringite as long as the calcium aluminate is available in the solution. At an excess supply of sulfate as in alkali sulfate, only ettringite forms. The hydration of C_3A is thus quite rapid if the calcium aluminate in the solution contributes to the reaction. If the aluminate is, however, in the form of sodium aluminate with no calcium ions in solution the reaction may be retarded because of the interaction of C_3A with the precipitated portlandite.

The depletion of the aluminium concentration of the solution by a lime concentration ≥ 0.6 g CaO/l and < 1.13 g CaO/l leads to a gel-like hydrates around the surface of the C_3A grains and the hydration of C_3A is retarded. This occurs when the reaction of C_3A proceeds in water, alkali hydroxide solution also in the presence of gypsum and in alkali sulfate solutions. The successive reaction of C_3A is then governed by a diffusion reaction either of more hydroxyl ions or of gypsum and is a slow process. This occurs in the presence of alite which releases few lime to the solution at the beginning of the reaction with a slight delay of the precipitation of portlandite.

The C_3A hydration may be accelerated in an aluminium-free solution in the presence of excess lime because of a quick solid-solid reaction but is, however, strongly retarded by gypsum addition which has to diffuse through the thick hydrate coat of the monophases. This occurs in water, in < 0.1 M alkali sulfate solution but in strong alkali hydroxide solution of 1M, gypsum dissolves and the C_3A hydration is again accelerated.

The double salts syngenite and hydroglauberite precipitate from alkali sulfate solutions ≥ 0.5 M and a CaO concentration ≥ 0.6 g/l. Because of the strong basic character of potassium the syngenite precipitates directly but the hydroglauberite precipitation is delayed.

3.4 Interpretation of some results of the literature

Stark et al [26] used two types of cement with low and high alkali content (soluble potassium oxide of 0.33% and 1.09%). The ettringite formed directly in paste with a W/S of 0.3 in the low alkali cement and together syngenite in that of the high alkali. The syngenite appears at later stages of the alkali-poor cement but transforms to ettringite with time. According to the present results, the syngenite must have precipitated from a potassium sulfate solution ≥ 0.5 M and a lime concentration ≥ 0.6 g CaO/l. The transformation of syngenite to ettringite must take place in a way similar to that of hydroglauberite, i.e. through the uptake of more lime available in the solution, the expected consequence is the release of the potassium ion to the solution either as potassium hydroxide or in the presence of enough sulfate as potassium sulfate.

The present work shows that, at the stage following the acceleration period, the monosulfate hydrate remains as the only calcium sulfoaluminate hydrate if the solution of C_3A and gypsum with a mole ratio of 1:1.5, has a CaO concentration < 0.6 g/l which allows the release of the aluminium to the solution. At a lime concentration equal to 0.6 g CaO/l part of the monosulfate hydrate decomposes to ettringite and both phases remain in the solid. The sulfate content in both the ettringite and the monophase are of actual discussion [27] and is suggested to be lower than the stoichiometric value. This explains the existence of both ettringite and the tetracalcium-sulfoaluminate hydrate as final product in the work of Stark et al [26]. The uptake of sulfate ions from alkali sulfate solution by sulfate deficient calcium sulfoaluminate hydrate is not favored if the solution is poor in calcium.

Sakai et al [28] reported that the production of gel containing SO_4^{2-} on the C_3A surface is important for the retardation of C_3A with various types of calcium sulfates. The present work shows that, the gel coat forms at a lime concentration of the solution ≥ 0.6 g CaO/l because of the depression of the aluminium which process occurs in the presence or absence of gypsum. Gypsum leads to the formation of an X-ray amorphous ettringite coat instead of the an X-ray amorphous calcium

aluminate or carboaluminate hydrate formed in its absence. The concentration of the sulfate in the gel increases with the increase of gypsum content and the decrease of the lime concentration in the solid. Hemihydrate contributes to the reaction by supplying more calcium sulfate to the solution compared to gypsum and the amount of the gypsum left in the solid to control the diffusion mechanism with C_3A decreases. The presence of lime with hemihydrate contribute to the reaction by increasing the monophases coat around the C_3A grains and causing a further retardation.

The crystalline character of the hydrate coat is gained at a lime concentration of the solution below $<0.6g\text{ CaO/l}$ which allows the release of aluminium. In the presence of gypsum, an uptake of the calcium sulfate from the solution occurs with the formation of both types of the calcium sulfoaluminate hydrate and the hydration reaction of C_3A is not retarded.

ON LINE QUALITY CONTROL INSTRUMENTATION FOR THE COMPLETE CEMENT MANUFACTURING PROCESS

A. Haider

Iteca, France.

ABSTRACT

New instrumentation is now available on the market that provides an effective way of controlling the complete cement manufacturing process.

Traditionally these controls were carried out by taking samples from the process, and analyzing them in a central laboratory, either manually or in some cases automatically.

This approach is being challenged in modern cement plants, by the installation of an 'On Line measurement systems', that present a number of advantages over the traditional methods, notably in terms of higher frequency and more timely controls, resulting in energy savings and better and more stable product quality.

These instruments also have the advantage of being cheaper, and simpler to operate than central automatic laboratories.

The object of this article is to give a brief description of each of these instruments and the main cost justifications.

1. RAW MIX CONTROL

A stable raw mix with the right concentration of each of the 4 major oxides (Ca, Si, Al, Fe) is essential for the stability of the kiln operation, and the quality of the finished product. Fluctuations in the composition result in a harder to burn raw mix, resulting in energy loss and a poor quality clinker, with lower strengths that needs to be ground finer (more energy loss) to achieve the required strengths.

Traditionally a sample is brought back to the laboratory to be analyzed every 1 to 2 hours, and the results of the analysis are used to correct the component mix.

With the online instrument the analysis is carried out on site every 5 minutes, and the corrections to the mix can be done automatically.

1.1 Components of the system

1.1.1 Sampling system

The material is sampled in a chute after the separator using a screw sampler. A volumetric sampler grabs the sample to be analyzed at the discharge of this sampler, and the sampled material drops by gravity into the analyzer. The excess material is returned into the material flow. The whole system is airtight and is not affected by pressure fluctuations in the chute.

1.1.2 The raw mix analyzer

A 25 gram sample of raw mix is ground using a high efficiency patented grinder. The average particle size of the ground powder is less than 4 microns, ensuring an accurate analysis.

The knowledge of the calcination level of the material at the kiln inlet, is essential to control the firing conditions in the precalciner, and thus to optimize the fuel consumption.

Traditionally a grab sample is collected manually at a considerable risk to the operator, and brought back to the laboratory to be analyzed every 8 to 24 hours.

With the online instrument the analysis is carried out on site every 30 minutes.

2.1 The components of the system

A sample is collected automatically from the kiln inlet chute. It is air cooled to freeze the calcination reaction and is then conveyed to the analyzer located near the sampling point.

2.2 The sampler

2.3 The ignition loss analyzer

The sample is introduced into a special stainless steel alloy crucible, it is weighed, heated to 975°C for 25 minutes and weighed again. The loss in weight gives the calcination level of the material.

3. CLINKER CONTROL

Free lime determination is an essential element to determine the quality of Portland cement. A high free lime (CaO) in cement causes the finished concrete to expand as the free lime hydrates to form hydrated lime (Ca(OH)_2), resulting in cracks and flakes in the concrete structure.

High free lime rates in correctly prepared raw material are generally the result of an underburnt clinker. The percentage of free lime in clinker decreases as the burning zone temperature in the kiln is increased.

Traditionally, so as to avoid excessive free lime, kiln operators are instructed to operate the kiln so as to have, on average, a free lime value that is significantly lower than the authorized level. The free lime is commonly determined by a laboratory technician, on a frequency of once an hour to once a shift. The clinker sample in such cases is taken manually on the pan conveyor after the cooler discharge and analyzed in the laboratory using a titration after a glycol extraction.

With the online instrument the analysis is carried out on site every 10 minutes, and the corrections to the firing conditions in the kiln can be done automatically. It is therefore possible to operate the kiln in the optimum range of free lime, saving costs on the burning process as well as on the grinding process, as hard burnt clinker is also harder to grind.

3.1 Components of the system

The clinker can be sampled in various locations in the cooler, either at the fall of the kiln before the cooler, underneath the grate plates in the 2nd or 3rd chamber of the cooler, or after the crusher at the cooler outlet.

The clinker sample is then transported to the analyzer located near the sampling point.

3.2 Sampling equipment

3.2.1 Sampling at the kiln outlet

The sampling system is installed in the throat of the cooler.

Clinker is collected directly at the fall of the kiln, using an air-cooled refractory steel beam. The beam is pushed into the material stream using a pneumatic actuator. About 300 grams of material is collected. The beam is retracted, and the sample is removed from inside the beam.

3.2.2 Sampling under the grate plates

The sampling system is installed in the 2nd or 3rd chamber of the grate cooler (depending on the clinker temperature - maximum temperature 500°C).

The clinker continuously falls through 2 to 4 fixed grate plates in which 30 to 50 mm holes have been drilled.

When a sample is required, the screw sampler is operated and about 300 g of material is extracted from the side of the cooler. Excess clinker falls into the under grate drag chain.

3.3 The free lime analyzer

Clinker is ground using a disk mill. The ground clinker and the glycol are weighed using an electronic scale, and are then fed into a reaction beaker. The solution is heated and stirred. Once the free lime is dissolved, the electroconductivity of the solution is measured and the result is converted into the FCaO value that is shown on the front display panel, and sent electronically to the central control room.

3.4 Kiln Control strategies using an On Line Free Lime Analyzer

3.4.1 On line measurement values and kiln operation data

The following graph shows the data obtained by Tokuyama Soda (Japan) a few months after having installed a free lime analyzer system.

The data shows the correlation between free lime values and kiln operation data that was measured by changing the feed volume of coal (energy) intentionally while the kiln was operating in a stable condition.

It can be seen that as the coal feed is decreased the free lime values increase and the burning zone temperature decreases, and as the coal feed is increased the free lime values decrease and the burning zone temperature increases.

From this data we can see the following facts:

- a change in fuel feed results in a noticeable change in free lime prior to a change in kiln amps, and about the same time as a change in burning zone temperature.
- burning zone temperature is an unstable measurement for higher values of free lime, as the kiln tends to be dustier, and therefore the clinkering zone more difficult to see.
- the kiln amps only show significant signs of change for large fluctuations in free lime.
- kiln amps are not a stable indicator of the burning zone conditions. It can be seen on the graph that the kiln amps for the second half of the graph are higher than in the first part, for a free lime value that is about the same.
- free lime peaks can last less than 1 hour on precalciner kilns, as can be seen between hours 5 and 6

3.4.2 Possible kiln control strategies

Free lime as measured by the on line analyzer is an absolute number that is not dependent on factors that may otherwise affect the other control parameters normally used for kiln control purposes :

- Kiln Amps, the most widely used parameter for kiln control, is typically affected by buildup in the kiln.
- Burning zone temperature measurement may be influenced by a change of concentration of dust or a buildup between the pyrometer and the clinkering zone being measured.

- NO_x, can be influenced by several factors including quality of the fuel, or the accuracy of the gas sampling system at the back end of the kiln.

Based on these facts some of the strategies currently being used, use the following logic :

- Incremental instantaneous control is based on either NO_x, BZT, or Kiln Amps, or a weighted combination of these factors, around given set points.
- Free Lime is measured automatically at a high frequency (typically every 10 to 20 minutes so as to see the trends developing). The clinker is sampled as close as possible to the clinkering zone, so as to reduce the lag time between the free lime result, and the kiln operational data. The free lime result is then used to update/correct the set points for each of the factors.

3.4.3 Application at the Blue Circle Ravena Plant USA

A system was installed in June 98 at the Ravena plant on 2 wet kilns. The graph below shows the average monthly values of free lime.

From June 1998 to January 1999, the free lime data was collected but was not used to control the kiln. From January 1999 to December 1999, the kiln expert control system was shut down for modification, and the kiln was controlled manually by the kiln operator, using the free lime data as the main control factor. As it can be seen the average free lime values were higher, but with some variances.

From January 2000 and onwards, the kiln expert control system was reconnected using free lime as the main control factor. The kiln is now running at stable values around 0.5% to 0.6% higher than they were at the start of the project.

This resulted in fuel savings of about 15 Kcal/KgKK as well as about 1 Kwh/tonKK of savings on the cost of grinding as the clinker was easier to grind (not over burnt). The high frequency control also had the advantage of producing better clinker, as it was possible to catch and deal with off specification clinker faster.

Given the savings and the 2 million ton per annum capacity of the plant, the system paid for itself in much less than a year.

4. CEMENT CONTROL

The main controls that are normally carried out to determine the quality of cement are :

- Gypsum addition : by measuring the SO_3 content of the finished cement.
- Limestone addition : by measuring the carbon content in the finished cement
- Blaine analysis : traditional method that uses air permeability to characterize the fineness of the cement.
- PSD analysis : this newer technology gives the complete grain size distribution of the finished cement, and has now replaced Blaine measurement as the de facto control method in all the modern plants

Traditionally a sample is brought back to the laboratory to be analyzed every 1 to 2 hours, and the results of the analysis are used to correct the process.

4.1 Cement additions control

It is essential to control gypsum additions as this has a direct impact on the setting time of the finished cement. With the same instrument it is also possible to determine the limestone additions. The close monitoring of limestone additions can lead to substantial savings as it is possible to replace expensive clinker with cheap limestone without exceeding the maximum regulatory limits.

4.1.2 The CO_2/SO_3 analyzer

A cement sample is dosed into a ceramic crucible. The cement sample is weighed. Tungsten and iron are added to the crucible. The crucible is then introduced into an inductive furnace, and the cement sample is heated up to 1400°C under a constant flow of oxygen. The Carbon and Sulfur present in the cement combine with the oxygen to form CO_2 and SO_3 . These gases are then measured using Infrared detectors. Knowing the concentration of CO_2 and SO_3 as well as the mass of the cement sample it is possible to determine the C and S present in the cement, and therefore the gypsum and limestone content.

4.2 Fineness control

Using an On Line PSD analyzer, giving a real time continuous measurement, it is possible to dynamically control the speed of the separator, and therefore optimize the fineness, and hence save on the cost of the energy required for grinding.

4.2.1 The particle size analyser

The photograph is of the optical head and real-time sampling interface of the EPCS system. Particles pass through an air purged flow cell, which supports a fixed alignment laser transmitter and solid state detector based on the classical ensemble laser diffraction technique. As particles pass through the laser beam, light scattered in the forward direction is collected by the receiver lens and focused onto a log-scaled annular ring detector. The detector is scanned at high speed, recorded, digitized for continuous real-time analysis.

Material is sampled using a screw sampler in a chute at the discharge of the separator. A bypass/dilution system is used to extract a portion of the flow, pass it through the instrument, and then back into the primary flow line. This system incorporates a near iso-kinetic tap that is driven by a venturi eductor.

This system provides real time information on the particle size distribution of the cement, and the data can be tied in directly to control the separator speed as shown below (data provided by the Ashgrove Lemington plant USA).

It can be seen in this case that the 30 micron residue and the change in the separator speed match very closely, whereas the manual Blaine value does not.

DISPERSING MECHANISM OF PNS SUPERPLASTICIZER IN HIGH-PERFORMANCE CONCRETE

ABSTRACT

The interaction between superplasticizer and cement has not been well understood up to now due to its complexity. This study examines the effect of alkali content in cement on the properties of cement pastes containing different alkali contents. In addition, superplasticizer/cement interactions are discussed with respect to the adsorption of polynaphthalene sulfonate (PNS) on cement and its hydration. Moreover, quantitative relationships have been established between the fluidity of cement pastes, the amount of adsorbed superplasticizer, the concentration of sulfate ions, and the pH of the interstitial solution. Results show that the fluidity at a specific time is strongly controlled by the amount of PNS remaining in the interstitial solution in the fresh cement paste, which in turn depends on the sulfate ion concentration, as well as the pH. The dispersing mechanism of PNS based superplasticizer is explained, and, the role of alkalis in the dispersing mechanism is discussed.

1. INTRODUCTION

It is generally acknowledged that when a PNS superplasticizer is adsorbed onto cement particles, this adsorption conveys a net negative electrical charge (electrostatic repulsive force) to the surface of cement particles and short-range steric repulsive forces between cement particles [1-6]. These repulsive forces induced by the superplasticizer adsorption can be established by measuring the zeta-potential of cement particles [1-2], or measuring the thickness of the layer of superplasticizer adsorbed [5]. On the other hand, a depletion effect of superplasticizer remaining ("free superplasticizer") in the interstitial solution on dispersing cement particles was proposed by Napper *et al* [7]. Moreover, other effects, such as Tom's and tribology effects, of the available free superplasticizer on the dispersing mechanism were put forward by Tanaka *et al* [8].

The interaction between a PNS superplasticizer and C₃A phases has been investigated [9-10]. Fernon *et al* [9] showed that when a PNS superplasticizer is added to a cement paste where there are not enough SO₄²⁻ ions, some PNS molecules are trapped within C₄AH_x. As a result, these superplasticizer molecules are no longer available to neutralize the electrical charges present on the cement particles. On the contrary, when there are enough SO₄²⁻ ions in solution, ettringite is formed around C₃A. This ettringite temporarily prevents further hydration of C₃A, so that cement setting can be controlled. Baussant [10] has shown that PNS molecules influenced the morphology of the ettringite crystals that are formed. He pointed out that the usual long ettringite needles appearing on the C₃A surface when C₃A hydrates in the presence of calcium sulfate are no longer visible. When a PNS is introduced in the system, the ettringite needles are replaced by small spheroidal particles. He also found that the higher the molecular weight of the PNS molecules, the smaller the spheroidal

particles. According to his work, PNS molecules can be trapped in ettringite crystals.

The interaction between calcium sulfate and a PNS superplasticizer has been studied in the literature[11-15]. Their results showed some disagreement on the effect of the PNS on the dissolution rate of calcium sulfate. Some [11-13] explain that the early stiffening as a result of cement–PNS incompatibility may occur because the presence of PNS leads to an insufficient supply of dissolved calcium sulfate to form ettringite. Others [14-15] showed that the presence of PNS increases the solubility of calcium sulfate.

Although several studies have investigated the dispersing mechanism of superplasticizer in cement pastes and the interaction between superplasticizer and C_3A or calcium sulfate, they provide only partial information to understand the dispersing mechanism of the superplasticizer, or they did not fully consider that the repulsive and attractive forces derived from superplasticizers vary with hydration time. There is no single model which can fully explain the dispersing mechanism of PNS superplasticizer and all the interactions between cement (mostly C_3A) and PNS superplasticizer. Therefore, an integral model is needed in order to explain the dispersing mechanism of superplasticizer from an overall perspective. When proposing an integral model, it should be considered that the repulsive forces induced by superplasticizers are modified with hydration time because cement particles continuously react with available water.

The purpose of this paper is to study the influence of the alkali content of a cement on the rheological properties of a cement paste and concrete. In addition, the dispersing mechanism of PNS superplasticizer is explained more integrally considering the amounts of PNS adsorbed or remaining in solution and the chemical composition of the interstitial solution, and cement hydration during hydration time.

2. MATERIALS AND EXPERIMENTAL METHODS

The phase composition of the six cements tested and their alkali contents is presented in Table 1. The cements display a wide range in C_3A and total Na_2O eq. contents. A liquid sodium salt of PNS, having an average molecular weight of 14 000 g/mol measured by Gel Permeation Chromatography, was used [16].

Table 1. Phase composition and alkali content of the six cements used

Phase composition (%)	C1	C2	C3	C4	C5	C6
C_3S	73	66	53	51	69	56
C_2S	6	12	18	20	5	17
C_3A	3	2	10	6	7	11
C_4AF	12	13	7	9	10	6
Na_2O eq.	0.31	0.52	0.92	0.74	0.35	0.31
Soluble alkalies*	0.19	0.41	0.57	0.72	0.07	0.06

* Jiang et. al. [17]

The cement pastes were prepared at a water/cement ratio (W/C) of 0.35. The superplasticizer dosage in the mix is expressed on a dry mass basis. The fluidity of cement pastes was evaluated by the mini-slump test [17]. The adsorption of PNS superplasticizer was evaluated by measuring the amount of PNS remaining in the interstitial solution extracted from the fresh cement pastes using a UV spectrometer. This concentration was determined at the peak absorbance wavelength between 293 nm and 276 nm bands. The amount of adsorbed PNS was calculated by subtracting the

measured concentration in the extracted solution from the initial concentration (initial dosage of PNS). The sulfate content dissolved from the cement was calculated by subtracting the sulfur content originating from the PNS superplasticizer from the total sulfur content of the filtrate measured by the ICP. The pH of the filtrate was also measured using an Orion pH-meter.

Figure 1 shows that the cement pastes made with cements C2, C3 and C4 keep a high mini-slump value over 90 minutes. In contrast, the pastes made with cements C1 and C5 present a high initial mini-slump, followed by a rapid slump loss. The paste made with cement C6 has a relatively low initial mini-slump at 5 minutes. It can be said that cements C1, C5, and C6 containing relatively low-alkali contents are not compatible with the PNS, while cements C2, C3, and C4 containing high-alkali content are compatible. Therefore, these results clearly indicate that the alkali content, especially the soluble alkali content, is an important parameter affecting the compatibility of cement and PNS superplasticizer.

Figure 1. Slump area as a function of hydration time

Figure 2. Amount of PNS adsorbed as a function of hydration time

The amount of PNS adsorbed by the six cements as a function of time is presented in Figure 2. This figure shows that the incompatible cements have a tendency to rapidly adsorb a large amount of

PNS superplasticizer (C1 and C6) or to continuously adsorb the PNS superplasticizer with time (C5), while the compatible cements do not, leaving a substantial amount of PNS superplasticizer in solution. The addition of Na_2SO_4 can significantly reduce the amount of PNS adsorbed on the cement pastes made with the three incompatible cements C1, C5, and C6. It can be clearly seen in Fig. 3 that the percentage of adsorbed PNS decreases as the amount of Na_2SO_4 increases.

Figure 3. Effect of Na_2SO_4 addition on the amount of PNS adsorbed

As shown in Figure 4, a direct relationship between the amount of PNS remaining in the interstitial solution at 60 minutes and the mini-slump value at 60 minutes was found. That is, the higher the amount of PNS remaining in the interstitial solution, the higher the fluidity of cement pastes. This result can be understood when the role of PNS remaining (“free PNS”) in the dispersing mechanism is considered. The PNS molecules, which are initially adsorbed on cement particles, become ineffective as hydration proceeds because of their incorporation into newly formed hydration products. The PNS remaining in solution is then progressively adsorbed on the newly hydrated surfaces; the continuous supply of PNS molecules maintains the electrostatic and steric repulsive forces which conserve paste fluidity. In the case of incompatible cements, the excessive early PNS adsorption leaves little free PNS molecules for replacing the PNS consumed into the hydration product. In such a case, the fluidity of cement pastes decreases with hydration time.

Figure 4. Relationship between mini-slump area and PNS remaining in solution

The relationship between the adsorption of PNS and sulfate concentration/pH in the solution of the cement pastes was established as shown in Figure 5 where the dependence of the amount of adsorbed PNS on the sulfate concentration and pH in the interstitial solution is shown. The decrease of PNS adsorption due to the addition of an alkali sulfate can be explained by the increase in both sulfate ions concentration and the pH of the interstitial solution. Both SO_4^{2-} ions and OH^- ions in the initial solution inhibit the adsorption of PNS on C_3A and C_4AF , thus reducing the amount of PNS adsorption on cement. Based on our results, and those from other investigators [18-19], a plausible mechanism of rapid slump loss in a superplasticized, low W/C ratio concrete can be proposed. In a superplasticized concrete having a low w/c ratio, the workability is related to the dispersing effect of the superplasticizer, which is related to the adsorption rate of the superplasticizer and to the hydration rate of the cement pastes in presence of a superplasticizer. In order to maintain the dispersing effect of a superplasticizer, the adsorption rate of the superplasticizer and the hydration rate of the cement have to be reduced, so that a certain amount of superplasticizer remains in the solution. When the residual concentration of the superplasticizer becomes so low that the residual superplasticizer is primarily composed of monomer or low molecular weight PNS because of their lower adsorption affinity [16, 20], the dispersion effect of the superplasticizer disappears: concrete stiffens and exhibits a significant slump loss. Hence, maintaining a certain concentration of a superplasticizer in solution is necessary to maintain a fluidized state within the concrete. Therefore, the concentration of the superplasticizer remaining in solution could be considered as a good indicator of the workability of concrete. According to this mechanism, any action which reduces the rate of superplasticizer consumption may be explored to maintain concrete workability. Some actions, such as a delayed addition of superplasticizer, the addition of Na_2SO_4 , and the addition of a retarder can be explained by this mechanism. It was found that the most effective way to lower the slump loss was to adjust the amount of soluble alkalis or soluble sulfate content in the cement [17, 21]. The presence of enough alkali sulfate in the interstitial solution maintains enough PNS in solution, which effectively disperses the cement particles. Therefore, the presence of enough alkali sulfate in the interstitial solution is crucial to prevent premature slump loss of concrete.

3. DISCUSSION

The results obtained in this study of the adsorption of the PNS molecules clearly show the different adsorption behavior in high- and low-alkali cements. The different adsorption behaviors of PNS superplasticizer in high- and low-alkali cement with hydration time are schematically presented in Figure 6. These figures indicate which superplasticizer molecules contribute to dispersing cement particles, and which superplasticizers do not, as a function of hydration time.

As found in Fig. 2, low-alkali cements (C1, C5, and C6) adsorb large amounts of PNS superplasticizer, while high-alkali cements adsorb smaller amounts. Therefore, the multi-layers of PNS adsorbed are much thicker in low-alkali cements than in high-alkali cements at initial state, as shown in Figure 6.

In low-alkali cements, large amounts of PNS adsorbed in the multi-layers are rapidly consumed to form an organomineral compound as proposed by Fernon *et al* [9] and/or hydration products [10, 22] in the intermediate state and shown in Figure 6. In addition, larger PNS molecules are consumed because they are more likely to adsorb on cement particles, leaving PNS molecules in the interstitial solution which consist of monomers, dimers, and smaller PNS molecules [20, 23]. Consequently, a much thinner layer of PNS adsorbed generates weakly repulsive forces between cement particles because of insufficiency of PNS remaining (“free” PNS) and large PNS molecules in solution. In such a case, some slump loss is likely to occur. Finally, the thin layer is also gradually incorporated by the newly formed hydration products, so that there are little repulsive forces in this system (Final state).

In contrast, in the case of high-alkali cements (C2, C3, and C4), a smaller amount of PNS is adsorbed and large amounts of PNS remain in the interstitial solution, which contains many larger PNS molecules. Consequently, a smaller amount of PNS is consumed by the organomineral compounds [9] and/or the hydration products [10, 22], as shown in the previous intermediate state in Figure 6. Moreover, the multi-layers of the PNS structure adsorbed on cement particles maintain their thickness because there are many free and large PNS molecules in solution, which adsorb continuously on the cement particles. Therefore, the multi-layers of PNS adsorbed generate strong repulsive forces between cement particles, as shown in Figure 7.1 (Intermediate I state).

Figure 6. Schematic representation of PNS adsorption on high- and low-alkali cements

In such a case, the cement paste can maintain its initial slump much longer. As the cement hydration proceeds, the multi-layers of PNS adsorbed are gradually consumed by the organomineral compounds and/or the newly hydration products (Intermediate II state). Consequently, some slump loss occurs. Finally, when all the layers of PNS are adsorbed or incorporated, there are few repulsive forces in this system (Final state).

As seen in Figure 6, the time from initial to final state is longer for high-alkali cements than for low-alkali cements. Therefore the cement pastes made with a high-alkali cement can maintain their initial fluidity much longer than those made with a low-alkali cement.

As found earlier in our study, the alkalis of a cement play an important role in improving the fluidity of cement pastes and concrete when a PNS superplasticizer is used because the alkalies

influence significantly the amount of PNS adsorbed. The role of the alkali was explained by Nawa *et al* [24] and Vernet *et al* [25], proposing the competition mechanism between PNS and sulfate ions. However, in our study, it was found that the addition of alkalis increased not only the amount of sulfate ions, but also the amount of hydroxyl ions in the interstitial solution. Moreover, it decreased the concentration of calcium ions. Consequently the addition of alkalis reduced the amount of PNS adsorbed on cement particles. From the results obtained from our study, it was clearly seen that although the difference in pH between high- and low-alkali cements is in the range of 0.3 – 0.8, this difference near the zero-point of zeta potential of C₃A significantly influences the amount of PNS adsorbed on C₃A [26]. Therefore, the competition mechanism between PNS and sulfate ions proposed needs to be modified to the competition between PNS and hydroxyl as well as sulfate ions, as schematized in Figure 7. This mechanism of action results in a reduction of the amount of PNS consumed by the formation of organomineral compounds and/or the hydrated products incorporating PNS, leaving greater amount of PNS and large PNS molecules in solution that could be adsorbed on the silicate phases as well.

In our study, it was also shown how alkalis significantly reduce the amount of PNS removed from the interstitial solution. The results obtained from the measurement of the amount of ettringite formed showed that this amount does not significantly increase when the amount of sodium sulfate increases. Therefore, it can be said that alkali sulfates neutralize the active sites on cement particles without increasing significantly the amount of ettringite formed. Therefore they inhibit the adsorption of the PNS molecules by effectively reducing the positive zeta potential of C₃A and C₄AF [27] and leave more PNS molecules in solution.

Figure 7. Schematic representation of the competition mechanism between PNS and sulfate/hydroxyl ions derived from the alkalis

The free PNS molecules remaining in solution may act as an additional repulsive barrier between cement particles, and play an important role in the fluidification of the paste. The additional forces induced by the free superplasticizer molecules were reviewed by Tanaka *et al* [8]. They reported that these additional forces are generated from the depletion effect, depletion coagulation effect, Tom's effect, and the tribology effect of the free superplasticizer polymers that remain in solution. Moreover, Uchikawa [28] considered these additional forces in representing the acting forces between cement and superplasticizer as follows:

$$F = F_A + F_{RE} + F_{RS} + R \quad (1)$$

Where, F_A is the van der Waal's forces (F_A),
 F_{RE} is the electrostatic repulsive forces (F_{RE})

F_{RS} is the steric repulsive forces (F_{RS})

R is the acting forces of the free superplasticizer induced by the surface tension effect, the depletion effect, and tribology effect etc.

When it is considered that the size of PNS molecules is much smaller than the cement particles, the R , as shown in equation (1) could probably be considered as just the repulsive forces because there are no attractive forces from the free PNS molecules induced by the depletion coagulation effect mentioned by Tanaka *et al* [8]. Therefore, when considering the additional forces from the free PNS molecules, the repulsive forces between the free PNS/adsorbed PNS and cement particles can be illustrated in Figure 8.

These figures show that cement particles are well dispersed when the free PNS is present. As hydration proceeds, the PNS adsorbed on the solid surface becomes ineffective as a dispersant because it is incorporated into the organomineral compounds [9] and/or the hydration products [10, 22]. The free PNS in solution is then progressively adsorbed onto the newly hydrated surfaces. The continuous supply of PNS molecules maintains the fluidity of the paste because the additional repulsive forces (R) from the free PNS are gradually converted to the electrostatic (F_{RE}) and steric repulsive forces (F_{RS}) generated after being adsorbed on cement particles. In conclusion, in order to increase the efficiency of a PNS superplasticizer to disperse cement particles at equal PNS dosages, it is necessary to reduce the amount of PNS consumed (or removed) by cement particles.

Figure 8. Schematic representation of the repulsive forces from the PNS adsorbed and the free PNS, a) without, b) with the free PNS

4. CONCLUSION

Quantitative relationships between the fluidity of cement pastes, the amount of the superplasticizer adsorbed, the sulfate concentration, and the pH in the interstitial solution have been established. These relationships clearly indicate that the fluidity at a specific time is strongly controlled by the amount of PNS remaining in the interstitial solution at that time. Moreover, the amount of adsorbed PNS decreases when the sulfate concentration or pH in the interstitial solution increases. A plausible mechanism of rapid slump loss in a superplasticized concrete having low W/C ratio is presented. Maintaining a certain amount of superplasticizer in the solution is of primary importance to control concrete workability. In addition, the dispersing mechanism of PNS superplasticizer is integrally discussed considering the soluble alkali content. In addition, the role of the soluble alkali in the dispersing mechanism of PNS superplasticizer is explained.

PROCESS EFFICIENCY AND OPERATIONAL IMPROVEMENT THROUGH THE CEMSTARSM TECHNOLOGY

¹D. Perkins and ²M. Wortley

¹TXI/CemStar, Dallas, Texas, USA.

²Hatch Africa, Johannesburg, South Africa.

ABSTRACT

CemStar has helped to increase production at several cement plants in the U.S., including TXI's Midlothian Plant expansion project, which was completed in May 2001. A significant lowering of both NO_x and CO₂ emissions has also been demonstrated while using this technology. This paper provides an overview, discusses how the technology was developed and provides a more detailed process description. Operational experiences are discussed with respect to production and emissions benefits, with a discussion on CemStar's integration with TXI's new Midlothian kiln line.

1. INTRODUCTION

Despite the slowing worldwide economy, with U.S. recession and terrorism impacts stemming from the events of September 11, the U.S. cement industry has continued to face relatively resilient demand. Consumption has remained steady because of such factors as low mortgage rates and federal paving projects. Moreover, 2001 import levels hovered at approximately 25 million metric tons - comparable to quantities of immediate past years. To help meet this excess demand, numerous expansion projects across the country have been undertaken – between 1998 and 2004 U.S. production capacity is projected to grow by nearly 25% (Queen, 2002). However, it is not likely that this strong pace will continue, given the increasing stringency that environmental regulations are placing on the permitting process. Unless such expansion can be achieved without significantly increasing emissions – typically through extensive air pollution control equipment and more efficient process technologies – governmental permitting of additional greenfield or brownfield expansion projects is likely to continue to become prohibitively restrictive.

Specifically, there has been an increasing focus on emissions from cement production facilities during the past decade, primarily resulting from regulatory requirements to address ground-level ozone levels and NO_x emissions along with heightened awareness of the potential impact that greenhouse gas can have on the environment. These factors have together presented cement producers with the challenge of raising production levels in a cost-effective manner that maintains process efficiency but also has minimal impact on the environment.

While exploring ways to improve production and reduce the quantity of byproducts that were produced from its operations, Texas Industries, Inc. (TXI), discovered one such process that achieves production increase in an environmentally-beneficial manner. TXI is a U.S.-based producer of cement, steel, lightweight and heavy aggregates, brick, and ready-mixed concrete, and has developed an innovative technology that enables cement producers to address these vital issues concerning production and emissions. The CemStarSM process was first developed in 1994, as the company began to explore potential synergies between its Midlothian, Texas cement and steel

facilities. Two U.S. patents were granted for this process: the first being in June of 1995 and the second issued in February of 1996, along with multiple foreign patents.

2. HISTORY OF DEVELOPMENT

During the early 1990's, TXI began to inspect its operations for ways to improve production efficiency, minimize or eliminate waste and ultimately to achieve a more sustainable approach to manufacturing in its energy- and raw material-intensive businesses. To identify solutions and potential synergies, a task force was formed, which was termed STAR - Systems and Technologies for Advanced Recycling. The task force focused on identifying waste and byproduct materials generated from the Midlothian, Texas cement and steel operations and examining production processes to determine whether any synergies existed that could minimize or eliminate any of the byproducts. Slag from TXI Chaparral's Midlothian steel mill, an electric arc furnace line capable of producing greater than 1.6 million metric tons of steel, was evaluated during this process. One of the electric arc furnaces at the Chaparral plant is shown in Figure 1. After an extensive laboratory testing and evaluation project overseen by Rom Young, TXI's Director for Research and Development, the process was tested in a full-scale demonstration in one of the four wet process cement kilns at the Midlothian plant.

Figure 1. Midlothian Kiln Line #5 Commissioned in 2001

After sufficient operational knowledge was gained through testing and analysis and as familiarity with the process increased, the technology was fully implemented. CemStar was subsequently employed at TXI's Hunter, Texas cement plant, a 2,500 mtpd preheater/precalciner facility, as well as TXI's Oro Grande, California cement plant, a 3,000 mtpd long dry facility, thereby demonstrating the flexibility of this process across all cement kiln technologies. In addition, the process was incorporated into the design of the Midlothian expansion project, undertaken in 1999 to expand production at the plant from 1.1 million metric tons per year to just over 2.5 million metric tons per year. This four-stage preheater/precalciner line was completed in May of 2001, with the process being employed from day one. Figure 2 shows the new kiln line at Midlothian.

TXI has also begun a licensing and support program to other U.S. cement companies, which include Holcim, Inc., North Texas Cement Company, RMC Pacific Materials, Inc., and Rio Grande Portland Cement Co. In addition to domestic licensing, TXI has initiated an effort in certain

markets outside the U.S. to promote the technology. These countries include Brazil, Australia and South Africa.

Figure 2. TXI Chaparral Midlothian Electric Arc Furnace Steel Making Operation

3. CEMSTAR TECHNOLOGY OVERVIEW

In the CemStar process, slag – a byproduct of steel production, is added to the cement clinker manufacturing process. This slag comes from three primary sources: 1) Electric Arc Furnace slag – referred to as the “mini-mill” process which uses scrap as the raw material; 2) Basic Oxygen Furnace slag – from integrated operations that use pig iron produced from ore; and 3) Blast Furnace slag – from integrated operations smelting the raw ore material. The result is an increase in clinker production of as much as 15% with no net increase in emissions. More specifically, the process involves the addition of slag into the back or feed end of the kiln through a relatively uncomplicated and inexpensive delivery and metering system. Due to the chemical composition of the slag and the energy-intensive nature of the steel production process, the material requires little or no additional fuel to convert it into cement clinker. In other words, the great majority of the thermal work has already been done in the steel mill and significant amounts of energy can be saved when the process is added to a cement clinker line.

The result is improved fuel efficiency - lower total fuel consumption per ton of clinker is a direct result of CemStar. This translates into a net reduction in of carbon dioxide (CO₂) and oxides of nitrogen (NO_x) emissions per ton of clinker produced. In fact, process testing, as described in more detail below, has shown a direct and statistically significant correlation between use of the technology and lowered NO_x emissions, and the U.S. Environmental Protection Agency has recognized this process as alternative control technology for NO_x in cement kilns (U.S. EPA, 2000).

Additionally, the flexibility of this technology has allowed it to be implemented at preheater/precalciner plants, wet process plants and long dry process plants – both in existing lines and designed as an integral component of a new line. The overall result is a process that can easily be designed into a new production line or integrated into virtually any existing cement plant at low capital cost which will provide a significant increase in production. Additional major benefits are lowered emissions and reduced fuel consumption with the potential of eliminating or reducing the need for traditional raw material components such as shale, clay or mill scale.

4. SPECIFIC PROCESS DESCRIPTION

During the steel manufacturing process, lime - calcium oxide - (CaO) is added to the molten steel as a flux to remove impurities. This process, which takes place at around 1,650 degrees Celsius, results in the lime combining chemically with silica, magnesium, aluminum and other oxides present in the steel. These oxides, which are considered to be undesirable in the steelmaking process, produce compounds that are also found in cement clinker – namely calcium silicates, aluminates and aluminoferrites. The slag material floats to the top of the molten steel and is ultimately poured off as the byproduct known as slag. This process, which occurs at temperatures equivalent to those in a cement kiln, converts the CaO to silicates that are similar to those in cement clinker. In addition, the slag incorporates mineralizers that promote clinker formation.

During the CemStar process, slag is crushed and screened to approximately 18 to 22 millimeter diameter, and added as a component of the raw material mix into the back or feed end of the kiln. Because of the amount of heat the slag has been subjected to during the steel making process, it has a relatively low melting temperature and does not require significant pre-processing before being placed into the kiln.

CemStar generally has the potential to increase clinker production by as much as 15%, but the specific amount at a particular clinker producing line is controlled by mix design that takes into account such factors as the chemical composition of the slag, the type or types of clinker being produced, as well as the traditional raw material inputs which are used at a specific plant. Feed chemistry is adjusted to compensate for the iron, aluminum, silica and calcium in the steel slag that is being added to the kiln.

During the kiln pyro process, the slag mixes with the raw materials and a number of chemical reactions take place. Because the melting point of slag is typically between 1,260 and 1,315 degrees Celsius, it begins to react with the other raw feed components before the clinkering temperature zone. In the liquid phase, the slag becomes extremely reactive and will seek other material with which to combine, i.e., the raw feed being supplied to the kiln. As the process moves through the kiln, mineralizers present in the slag, such as manganese, help to catalyze clinker formation reactions. In addition, dicalcium silicate, which is also present in varying amounts in slag, is converted into tricalcium silicate by combining with the calcined limestone (CaO) from the raw feed. This exothermic reaction results in slag being an energy efficient and highly effective addition to the cement manufacturing process.

5. CEMSTAR AND KILN OPERATIONS – PRODUCTION IMPACTS

Reflecting on 7+ years of operational experience in utilizing the process, significant production and operational advantages are derived from implementation of the technology. These include improved production rates of clinker, minimal capital investment required, little or no additional fuel consumption, and more stable kiln operations.

Testing has been performed to evaluate the specific impact that CemStar has on production and operations as well as emissions, which is described in more detail in the following section. In addition, long-term review of production levels at TXI facilities employing the process has confirmed what the relatively short-term testing has shown. Production is directly increased by the addition of slag into the kiln.

5.1 Testing

More specifically, testing performed in 1999 on a single wet process kiln line at TXI's Midlothian plant showed an increase in production of greater than 9% - with the amount of increase directly

coming from the mass of slag being added to the kiln. The test closely monitored all inputs to the kiln and maintained constant all inputs but the slag feed rate variable. The testing involved analysis of two basic conditions: Mode 1 - without CemStar; and, Mode 2 with CemStar. Figure 3 more closely illustrates the production results. In addition to the production increase measured during this test, heat input was reduced on a mass basis by almost 6%, translating to a greater than 13% reduction on a kilocalorie per kilogram of clinker basis. This demonstrated the ability of the slag to act as a flux that enables fusion of the calcined materials into clinker with less heat demand (En-Tellect, 1999).

Figure 3. 1999 CemStar Testing Data from TXI Midlothian Wet Kiln

5.2 Long-Term Data

In addition, the long-term benefits of the CemStar technology from a production perspective are illustrated by a review of production data at TXI's Hunter, Texas plant. While more difficult to evaluate because of factors exogenous to usage of the technology (i.e., roller mill up time, fuel sulfur, raw material alkali levels, fuel quality, etc.), a review of twelve years of production shows a nearly 6 percent increase in production on average with CemStar in place. Using 1988 as a baseline year at 100, Figure 4 makes an indexed representation of the relative changes on a year-on-year basis in production level of the kiln on a tons-per-hour basis.

Figure 4. TXI Hunter Plant - Indexed Changes in Kiln Production TPH 1988 through 2001

5.3 Integration and Impact Upon Kiln Operations

Merging the technology into kiln operations requires analysis of a plant's existing raw material composition and developing a mix design that will accommodate the chemistry of the slag material. These mix design considerations determine the optimum slag addition rates. Additionally, based on raw material compositions at individual plants, incorporation of the CemStar process has allowed a significant reduction or elimination altogether of traditional raw materials such as shale, clay or iron

additive such as mill scale. This, in turn results in lower sulfur and alkali input into the system and can potentially increase raw mill production rates.

As discussed, lower kiln temperatures result from implementation of the process, and pyro-processing adjustments must be made to accommodate the mix. As kiln operation is modified accordingly, control operators will see improved kiln stability and will find it easier to recover from kiln upsets and slow downs. In addition, an overall improvement of refractory life has been noted, based on increased annual clinker production rates with no additional downtime for kiln brick jobs. Finally, steadier clinker control has been achieved, which also reflects improved overall process balance and efficiency.

Traditional methods of expanding clinker production capacity are typically very costly and time consuming, require a large quantity of resources and can disrupt continuous facility operations. Conversely, installation of a CemStar process system at a facility can be accomplished in a relatively short period of time, with minimal disruption in continuous kiln operations, all at a significantly lower cost than required for more traditional process capacity upgrades. Moreover, the process can be implemented in as little as three to four months upon the final decision of the facility to use the technology.

5.4 Clinker Chemistry Changes

Due to the individual nature of cement plants as well as the varied chemistry of slags that are produced, the chemical impact of the process is understandably diverse. There are some general chemical impacts that are associated with using slag in the clinker manufacturing process however, due to the conditions under which the slags are formed in the steelmaking process. A typical chemical analysis range for slag produced from an electric arc furnace or basic oxygen furnace, commonly referred to as “steel slags,” is represented as follows:

SiO ₂	10 – 15%
Al ₂ O ₃	5 – 10
Fe ₂ O ₃	25 – 35
CaO	30 – 40
MgO	5 – 12
SO ₃	0 – 0.5
Cr ₂ O ₃	0.5 – 2.0
Mn ₂ O ₃	4 – 8
Na ₂ O	0 – 0.3
K ₂ O	0 – 0.1
ZnO	0 – 0.1
SrO	0 – 0.1

Based on these ranges of constituents in slag chemistry, general chemical impacts on the clinker can include a lowering of tricalcium aluminate (C₃A), due to the higher Fe content in the mix. This impact is mitigated somewhat if the general chemical mix of the raw materials is deficient in Fe, and it must be added through incorporation of iron ore, mill scale, or some other high-Fe material. The Fe can be added through use of slag, and the overall chemistry can be maintained fairly close to the original proportions.

Also, addition of slag can contribute to a higher liquid phase in the mix along with a lower silica ratio, which indicates improved burnability. These two impacts must be managed, however, to prevent excessive liquid phase, which can lead to kiln condition problems and reduced clinker quality. Overall, the slag chemistry can be incorporated into the mix design the same as any other

raw material, with impacts on the final clinker chemistry varying based on the nature of the slag, of the raw materials, and finally of the desired clinker chemistry outcome.

6. MIDLOTHIAN, TEXAS EXPANSION PROJECT

Drawing on the amount of operational experience derived from using the CemStar process since 1995, TXI made the decision to incorporate a slag handling and feeding system into the design of its new kiln line for the Midlothian, Texas plant. The facility, designed to produce 1,800,000 metric tons per year, was designed and supplied by F.L. Smidth, Inc. and more than doubled the annual capacity at the Midlothian plant. In order to meet stringent air permitting requirements, the facility incorporated a number of innovative technologies, including a sulfur scrubber for SO₂ emissions, a regenerative thermal oxidizer system for carbon monoxide (CO) emissions, and a low NO_x ILC calciner. Along with these technologies, the CemStar process was incorporated to the new line to assist in meeting strict regulatory permit requirements as well as to enhance the clinker production levels.

Ground was broken on the new facility in 1999 and the line began commissioning in May of 2001. When the first feed was added to the preheater tower, the system was tied in and slag was fed to the kiln: the plant has used slag as a production component the entire period of commissioning. The CemStar handling and feeding system for the new line is shown in Figure 5.

Figure 5. CemStar Handling and Feeding System, TXI Midlothian Kiln Line Expansion

Since startup, slag usage has hovered between 6 and 7% of clinker production, with an annual consumption at approximately 90,000 metric tons. As all components of the facility begin to consistently run at full capacity, the usage of the process is projected to rise by another 50%. In summary, the decision to incorporate CemStar into the new clinker production line which was a major capital investment for TXI, and utilize it at the outset of commissioning of this facility, was based on the extensive operational experience and success that TXI has had with the process at its facilities.

7. ENVIRONMENTAL BENEFITS

Because of the characteristics of slag, implementation of the process has been shown to have a beneficial net effect on emissions from the cement manufacturing process. The primary benefits

derived from this process are an overall reduction of greenhouse gas emissions (CO_2) as well as a decrease in NO_x emissions. Tied in with these is the overall reduction in fuel consumption per unit of clinker produced as well as an overall increase in process efficiency. Finally, employing a byproduct material that has been traditionally underutilized by converting it into high value clinker is a significant benefit.

7.1 Emissions Reductions and Testing

Extensive testing has been conducted to quantify the emissions reductions gained from implementation of the CemStar technology. These tests were conducted at the two Texas facilities operated by TXI – one wet process kiln at the Midlothian facility and the preheater/precalciner line at the Hunter facility. In addition, the testing employed certified continuous emissions monitors and independent consultants to quantify the changes in stack emissions of a number of common gaseous compounds. During these tests, implementation of the process showed significant decreases of NO_x and CO_2 emissions when compared to baseline data.

7.1.1 Short-Term Testing

The first round of testing was conducted at the Hunter, Texas plant and yielded an average reduction in NO_x of 35% (kg NO_x /metric ton clinker) from baseline conditions. The second round of testing was conducted at the Midlothian, Texas plant, where an average reduction in NO_x of about 45% from baseline conditions was observed. In both sets of testing, CO_2 reductions between 5 and 10% were also observed (measured per metric ton of clinker produced). The reductions of CO_2 were observed primarily as a result of the chemical composition of slag, which requires no additional calcining and emits no additional CO_2 , unlike limestone, which liberates significant quantities of CO_2 from the cement production process.

7.1.2 Long-Term Testing

Long-term testing was subsequently conducted at the Midlothian facility over a number of weeks, and reductions in emissions of NO_x of about 25% were observed as a result of the analysis, measured on a kg/metric ton clinker basis. Moreover, burning zone temperatures were lower by an average of 200 degrees Fahrenheit when compared to baseline conditions. Correspondingly, thermal NO_x , which is temperature dependent and exponentially sensitive to changes in this parameter, was significantly reduced when the CemStar process was in place.

7.2 EPA Awards and Recognition

TXI received two awards from the U.S. Environmental Protection Agency (U.S. EPA) in 1999 recognizing the environmental benefits of the CemStar process. TXI was awarded the Climate Protection Award to recognize the potential of the technology to reduce CO_2 emissions as well as its positive effects on NO_x emissions. TXI was also honored by the U.S. EPA with a special recognition award through the Climate Wise program, again for the contribution of the process in reducing emissions of CO_2 and NO_x .

TXI has also worked with the U.S. EPA in their development of a report outlining NO_x control technologies for the cement industry. This report, which was issued at the end of 2000, outlines available technologies for the U.S. cement industry to reduce NO_x emissions, and includes the CemStar technology as a recognized control method.

Furthermore, as tighter rules are developed in industrialized countries around the world, achieving emission reductions will become an ever-growing priority. NO_x emissions allowance trading programs, such as the Ozone Transport Region in the northeastern 22 states of the U.S., are one method that is utilized to help areas meet ozone reduction goals. The market value of reductions in emissions provides a significant incentive to implement the most cost-effective method of NO_x control. Considering a conservative range of \$3,000 to \$5,000 U.S. market price per ton of NO_x in

different regions of the U.S., the technology may provide facilities with an economically beneficial method to meet these requirements.

8. CONCLUSIONS

CemStar has been shown to be a cost-effective method to help in meeting additional demand requirements while requiring minimal time for implementation and has positive environmental benefits. Overall, the process offers producers simultaneous means to produce more clinker, improve operational efficiency and stability while providing significant net emission reductions.

ABSTRACT

Particle size is more and more recognized as a major quality criterion for dry powders and a decisive parameter for production processes. Therefore real time particle analysis is needed to optimize processes, especially regarding energy efficiency and can be applied to close the control loop. Demanding challenges can be found in many industrial applications.

Most industrial processes use pipes as the connection between different process stages. Without sampling it is quite often not possible to measure correctly in the process. Measurements in the particle production stream extend the capabilities of laser diffraction instruments for particle size analysis. The sampling must be representative in order to obtain meaningful results.

The sample preparation should be adaptable to the properties of the product to be analyzed. The dispersion of the sample must be complete but breaking or milling of particles has to be avoided in order to achieve the correct information about the particles in the product and the process.

Many successful installations in the cement industry as well as in other fields of application prove the suitability of in-line measurements under process conditions.

The paper will present the MYTOS family, rugged instruments for -in-on- and at-line particle size analysis that meet the abovementioned demands and cover a variety of applications where real time particle size analysis is crucial for the product, energy efficiency and process quality.

1. INTRODUCTION

In production of cement, the particle size distribution of the final product is one of the important parameters for quality and is decisive for the final strength of the concrete. The required particle size distribution is normally achieved by milling and classifying. Since milling of cement is extremely energy consuming, on-line particle size control of the milled product can improve not only the quality but increase the energy efficiency and the throughput since the recirculated coarse fraction can be reduced.

Today particle size analysis by laser diffraction is an increasingly standard procedure for quality control of cement. The first generation of laser diffraction instruments was presented in the early 1970's. At this time all products, even cement, had to be analysed exclusively in wet suspension since no suitable dry dispersers were available. For cement analysis the liquid had to be isopropanol which required additional challenges for proper treatment after being used.

In 1984 a new generation of laser diffraction instruments was introduced. It is based on the simple idea that the instrument used for the characterisation of quality parameters has to adapt to the demands of the products and the process and not vice versa, i.e. that the products have to be adaptable to the instrument. Dry powders should be dispersed dry, wet products and suspensions should be dispersed in the wet state. This is the practical and logical conclusion, and the new idea led to the development of a range of laser diffraction analysers and dispersing systems that are of modular design thus being easily adaptable to a wide variety of products and process.

Sympatec GmbH from Germany has developed an unrivalled disperser for dry powders in the particle size range from 0.1 micron to nearly 10mm. The patented disperser RODOS allows for a smooth, complete and product-adaptable dispersion of all kinds of powders. In combination with the well established laser diffraction instrument HELOS, a powerful and proven system for industrial particle size analysis of dry powders is available.

The HELOS & RODOS combination has been successfully installed in nearly 150 cement plants all around the world and is on its way to becoming the standard laboratory equipment for dry particle size analysis of cement. This also applies for automated labs where the unit is fed continuously by a robot to perform up to several hundred measurements per day. Of course this only became possible by using a fast dry dispersion module, since wet dispersion does not allow this analysis frequency by nature. Besides this aspect, fast on-line analysis of dry cement powder using a wet dispersion method would lead to an enormous amount of liquid waste even if pressure filtration for the required isopropanol is applied. Therefore dry dispersion is the only sustainable approach for on-line particle size analysis of dry powders.

Today the HELOS & RODOS core technology is combined in the compact MYTOS system which is especially designed for in- and on-line particle size analysis under process conditions.

2. MYTOS LASER DIFFRACTION AND DISPERSING

The principle of laser diffraction requires three main components to be integrated into an analytical instrument as presented in Figure 1.

Figure 1. Optical setup of a Sympatec laser diffraction instrument in general

1. At first a laser light source is required. Even today the performance of laser diodes is quite poor from the analytical point of view, so a helium neon laser is preferred. To perfectly adapt the laser beam diameter to the demands of the product and the optical setup, a beam expander is used.
2. A Fourier transformation lens of a distinctive focal distance projects the laser diffraction pattern generated by the interaction between laser light and particles passing the measuring zone to the detector. Depending on the required focal distances, optical modules are available

today that allow virtual focal distance up to 5m on a real distance of less than 50cm which leads to more compact and rugged instruments.

3. The core part of a laser diffraction analyser is the detector. Built up from 31 semicircular elements it detects the diffraction pattern which is converted by a mathematical algorithm into a particle size distribution. From the physical point of view a detector equipped with a semicircular allocation of the detector elements is crucial for highest sensitivity and optimum results, especially for non-spherical particles like cement. Since only a perfect alignment of the complete optical setup guarantees best results, a 3-D auto focus system is a must.

The powder dispersing unit is a fully integrated part of the MYTOS system. Originating from the well established RODOS dry disperser applied for laboratory and automated systems, it disperses even the finest powder successfully. Dispersing is of extremely high importance since a milling process is not characterised by agglomerates, but the produced primary particles. Since laser diffraction instruments analyse all particles presented to the laser beam it becomes clear that full dispersion of agglomerates is required.

In the cement industry very often the Blaine value is still used to characterise the final product. The specific surface area (equivalent to the Blaine value) measured by laser diffraction and calculated from the complete particle size distribution can only be derived from perfectly dispersed powder.

Figure 2 presents MYTOS integrated into a process pipe and shows the details of the laser diffraction and dispersion unit.

Figure 2. Cutaway view of MYTOS, the unique combination of core parts of HELOS & RODOS, integrated in a production pipe

In the above figure, MYTOS is integrated into a pipe as an in-line measuring device as one possible example of an installation. The required sampling procedure and possibilities of adaptation to existing samplers will be presented in chapter 4.

The sampled particles enter the instrument at the sample inlet. Using compressed air the dispersing takes place in the dispersing line. The dispersed particles are introduced to the measuring zone. Additional rinsing air is applied to focus the particles in the centre of the measuring zone in order to keep the protection windows clean. The analysed particles leave the instrument by the sample feedback stage. Since MYTOS is designed for fully automatic operation, cleaning of the optical components is minimized. No need for cleaning of the windows for periods of several months is documented. If cleaning should be required it is a matter of less than 3 minutes and can be performed without the need to shut down the process.

3. MYTOS FAMILY

Since process and product requirements vary, MYTOS comes as a complete family of instruments introduced in this chapter. Besides the presented in-line solution of MYTOS (Figure 2), on- and at-line versions are available. Figure 3 presents an on-line version to be mounted outside of the process pipe and directly connected to a sampler. Figure 4 shows an at-line solution equipped with the vibration feeder VIBRI mounted on top of the sampler which can be either fed manually or fully automatically.

Figure 3. On-line MYTOS

Figure 4. At-line MYTOS

MYTOS & VIBRI are also available as a module solution shown in Figure 5. The module was developed for the German company Krupp Polysius and is used in their AMT (Advanced Modular Technology) modules as the standard solution for particle size analysis of cement.

Supplied with wheels the rollable module can be used in automated laboratories or directly in the process environment. All required parts are integrated into this compact solution. The evaluation computer is connected to the module by fibre optical cables up to several hundred meters long. As an alternative a laptop computer can be used for full mobility.

As with all other MYTOS family members, the MYTOS & VIBRI module is adaptable to a variety of samplers and extendable to a full on-line solution for automatic particle size analysis of dry powders.

4. SAMPLING

The principle of laser diffraction requires representative sampling since the product concentration in the production pipe typically exceeds the possibilities of the sensors. In the cement industry additional challenges can be found since the product is very abrasive and large throughputs and high product velocity are normal. Figure 6 shows the in-line sampler TWISTER which is designed to be combined with the previously discussed MYTOS system. TWISTER is proven in the main stream of many industrial applications like chemistry, pharma, iron-powder or silica, to name just a few. Nevertheless the typical process conditions of a cement plant require a pre-sampling stage and a by-pass to avoid extraordinary wear of the sampler. A screw feeder sampling into a by-pass line will be sufficient as a pre-sampling stage, for example.

Figure 5. Opened MYTOS & VIBRI module

Figure 6. Representative in-line sampler TWISTER in parking position

Starting from a shielded parking position, TWISTER scans the complete cross-section of the pipe in a spiral path so that all areas of the pipe contribute equally weighted to the result. This leads to truly representative sampling. The unit is adaptable to a very wide concentration range by variation of the inlet port.

If a by-pass installation of TWISTER is not possible for whatever reason, then use of a stationary and easy to access sampling tube in the main pipe is recommended. The stationary probe is connected directly to the inlet of MYTOS. A valve between the probe and MYTOS shuts off the powder flow through MYTOS for regular background measurements. Back blowing through the probe ensures that the stationary sampler is not filled with material if no measurements are performed. Since a stationary sampling point is used in this case, the location of the probe should be considered carefully.

In the case of an existing automatic sampler MYTOS & VIBRI are adaptable to it as well. As soon as the funnel of the vibration feeder is filled with product, the analysis starts automatically by a level sensor signal. A solution including an additional sample splitter also acting as a dosing device for VIBRI is designed especially for cement applications. In this case a screw feeder transports a certain amount of cement into a bypass-line where the dosing device is mounted. The doser feeds a partial sample into the VIBRI funnel. After the particle size analysis by MYTOS the cement is re-introduced into the main line.

5. RESULTS

Figure 7 presents typical results for very fine cement and standard PZ35 as an example of comparison of the cumulative and frequency distribution.

Figure 7. Comparison of measured particle size distributions of fine cement and PZ35

It becomes obvious that the significant difference in the product behaviour of both kinds of cement are resulting from completely different particle size distribution. For on-line control every characteristic value of the measured particle size distribution, or calculated parameters like the

specific surface area, will be displayed as a trend over time to monitor the milling process and to close the control loop.

6. CONCLUSION

The MYTOS & TWISTER concept for real-time particle size analysis combines representative sampling, powerful dispersion and well-known particle size analysis of dry powder by laserdiffraction. The various members of the MYTOS family allow the adaptation to all kind of dry processes. Using real time particle size analysis for closing the control loop of milling process, i.e. in cement, faster response times to process changes guarantees a better efficiency, higher throughput, optimum use of energy-input and finally a better product quality.

The Material Structure Institute of Yangtze Academy of Science Wuhan China 430010

ABSTRACT

The gravel made of diorite-plagioclase granite will be used as coarse aggregate, and the sand made of flecky granite will be used as fine aggregate for the dam concrete of the Three-Gorges project. Because of the strained quartz in the granite, undulance extinction appears in the granite, furthermore, in the the stress concentration area, quartz will form different kinds of dislocation, so the alkali activity reaction will be very slow and will last a long time. In this paper we study the geomorphology, the petrographic, physical and chemical aspects, and also used several methods for comparison. The experimental results show that the granite is mainly composed of feldspar, quartz, biotite and some hornblende or chlorite, etc. The granite aggregate is assessed as non-active aggregate by means of the petrography method, chemical method, mortar bar length method, small bar ultra-accelerated method, mortar bar ultra-accelerated method and the concrete prism experiment. Where there is a low content alkali, there will be no harmful expansion, but if the content of alkali is high, the expansion rate of concrete will still increase even after several years. In order to ensure the safety of the dam, it is very important to control the alkali content of the cement strictly.

Keywords: Three-Gorges project, alkali-aggregate reaction, granite aggregate, concrete

1. INTRODUCTION

The Three-Gorges project is a key project for both governing and developing the Yangze river. It has the functions of flood control, generating electricity, shipping, water supply, etc. The concrete used for the second phase of the project will use the gravel made of diorite-plagioclase granite from footing excavation as coarse aggregate, and a sand made of flecky granite from the basin at Xiaanxi of the dam will be used as the fine aggregate. Because the granite distributes at folded zones of different eras and also shields areas of pre-Cambrian, it bears the stress from strong geologic structure. The rocky mineral will have strongly plastic deformation, and the crystal will have many kinds of dislocation, the defect includes dislocation bow crook, dislocation net and dislocation tangle, thus the energy is stored at the lattice of crystal. So the granite sometimes will have the character of slowly-reacting type alkali activity, the time for the dam to crack because of expansion can last several decades^[1]. Once the concrete dam and construction is damaged by alkali aggregate reaction, it is very difficult to fix it, and the economic loss is also very large.

As for the reason of alkali activity of granite, one deduces that it may be related to the strained quartz. B.S.Gogte^[2] pointed out: in cases where the content of strained quartz is greater than 20%, and the average undulance extinction angle of the strained quartz is geater than 15 degrees, then the aggregate has potential activity. On the other hand, A.K.Mullick^[3] suggested when the undulance extinction angle of strained quartz is greater than 25 degree, and the content is greater than 25%, then the aggregate has potential activity. And there are also some others who don't think there is relationship between the alkali activity and the strained quartz. The defects will be formed in the

crystal because of the stress, and then the crystals characterize undulance extinction. P.E.Grattan-Bellew^[4] studied three kinds of granite, and found that the undulance extinction angle of quartz is approximately proportional to the alkali activity expansion rate, that means, the larger the undulance extinction angle of quartz, the larger alkali activity expansion rate.

The granite used at the Three-Gorges project contains strained quartz which generates the undulance extinction. Furthermore, in the stress concentration area, quartz will form different kinds of dislocation, such as dislocation bow crook, dislocation net and dislocation tangle, and they are the main sources of alkali activity of the granite used ont the Three-Gorges project. Because of the complexity of the alkali aggregate reaction, the alkali activity reaction of granite will be very slow and will last a long time. To ensure the safety of the project, the granite aggregate used at the project was studied from geomorphology, petrographic, physical and chemical aspects, and also many methods are used for comparing and testing in order to evaluate the alkali activity of the granite.

2. ALKALI-AGGREGATE REACTION AND THE EXPERIMENT METHODS

2.1 Alkali-Aggregate Reaction

Alkali-Aggregate Reaction (briefly named “AAR”), is where the alkali in cement reacts with some active aggregate, which may cause uneven expansion in concrete, and finally result in damage. Since T.E.Stanton found this problem in 1940, there are many examples of engineering damage because of AAR in US, France, India and other countries. The Moxot Power Dam in brazil used biotite granite as concrete aggregate, and it suffered harmful AAR eight years later. The Shambon Dam in France used gneiss and isinglass granite as aggregate; the vertical expansion of the dam is over 10cm, and the top of the dam inclined about 15cm towards upstream. So careful attention is paid to AAR all over the world.

AAR can be divided to two types: Alkali-Silica Reaction(briefly named “ASR”) and Alkali-Carbonate Reaction(briefly named “ACR”). ASR is where the alkali in cement reacts with the active SiO_2 , such as micro-crystalline SiO_2 , cryptocrystalline SiO_2 , glassy SiO_2 , strained quartz and flint, and alkali silicate gel will be produced. The gel will absorb water and expand, which will result in the expansion and even cracking of concrete. Opal, flint, quartzite, sandstone and scoriae all contain active SiO_2 .

ACR is where the alkali in cement reacts with some carbonate aggregate, such as dolomite reacts with the alkali and results in the concrete cracking. Dolomite contains clay, the alkali ions can penetrate the clay wrapped on the dolomite particles and then diffuse to the dolomite particles. The reactant can not diffuse to the outside passing by the clay particles, this will lead to the aggregate expansion, and crack of the concrete.

The following are conditions necessary for AAR; and thus the alkali content in cement should be over the safe quantity, there is a significant amount of active aggregate, and sufficient water. If there is no water, the reaction will be reduced or completely stopped.

Many factors can affect AAR, such as alkali content in cement, humidity, temperature, additive, dopant material, the cement content in concrete or mortar, the quantity of active aggregate, etc.

Where the non-active aggregate is used in concrete, AAR will not happen. But if there is a moist environment, the alkali content in concrete is high and there is active aggregate, then AAR can take place and result in the expansion and even cracking of concrete. So it is very necessary to appraise whether there are active components or not for the aggregate used in project, and also the alkali content in cement should be measured. Preventative actions should be taken if it is necessary.

2.2 Experiment method of AAR

There is not an international consensus on the method to determine the activity of aggregates. The petrographic method has important instruction for selecting the suitable measurement method. It is always considered as the preferential method to determine alkali activity of aggregate. It judges whether the aggregate has activity or not using microscopic means of evaluating the type and composition of aggregate, especially to identify those known mineral compositions. The disadvantage is that the quantitative relationship between the active aggregate quantity and the expansion rate is unknown. The chemical method is the common international traditional method. This method cannot show the slowly expanding aggregate caused by the micro-crystal quartz or strained quartz. The other disadvantage is there are always some disturbances from carbonate, gypsum and clay, which can result in errors. The sand slurry length method is a classical method, which is similar to ASTM227, but it is only suitable for highly active and rapid expanding rocks and minerals, and is not suitable for slowly expanding aggregate. The sand slurry bar ultra-accelerated method is a standard method adopted by America (ASTM 1260) and Canada (CSA A23.2-14A) in 1994. The result of comparing the research to application records indicates that this method has a good validity for silicious aggregates, especially for slow expanding aggregate. This method is considered as a relatively accurate one. The problem is that it is too strict. Sometimes, the aggregate proved to be harmless will be considered as harmful. The concrete prism method can be greatly affected by the cement fineness, water/cement ratio, curing condition (temperature, humidity) and the component ratio, and the experiment duration of time is also very long.

3. EXPERIMENT

3.1 The granite petrographic identification

The granite minerals from both basement excavation and the bottom of the dam at Xiaanxi were identified, the result is shown in Table 1. From Table 1, you can see that the main component is plagioclase, quartz, biotite and some hornblende and chlorite.

Table 1. The lithofacies identification result of granite from footing groove

Sample number	Main mineral component	Granite name	Quartz undulance extinction angle
96—52	plagioclase 61%, quartz 16%, biotite 10%, hornblende 5%, sericite 7%	Biotite-plagioclase gneiss	1 ~ 3
96—56	plagioclase 60%, quartz 23%, biotite 9%, hornblende 8%	Diorite-plagioclase granite	3 ~ 6
96—61	plagioclase 59%, quartz 25%, biotite 10%, hornblende 5%	Diorite-plagioclase granite	2 ~ 5
96—70	plagioclase 60%, quartz 28%, biotite 8%, hornblende 3%	Diorite-plagioclase granite	2 ~ 6

96—99	plagioclase43%, potash feldspar30%, quartz24%, chlorite2%	Porphyritic monzonitic granite	2 ~ 7

The granite of Three-Gorges Dam foundation and Xiaanxi basin is about 8 hundred million years old. The stratum came into being before sinian of superior proterozoic. The stratum is comparatively stable, but orogenic movement has had some influence on the granite of this area. The quartz is characterized by undulance extinction because of the stress effect, but the angle is not big, the biggest angle is only about 9°. Meanwhile there are different kinds of dislocation forms in the stress concentration area, including bow crook, dislocation net and dislocation tangle. The particle size of quartz is about 0.3~2 mm, and no micro particles were found.

The main minerals of the granite were determined by means of electron probe microanalysis. Plagioclase is in adamellite, and acidity of plagioclase is higher. The Ab concentration varies between 96.04 and 97.70. The category is albite. The acidity of plagioclase is low in diorite, the Ab concentration varies between 79.37 and 81.25, the category is potash feldspar. The category of diorite-plagioclase granite is andesine. Potash feldspar mainly belongs to kalifeldspath, and only the big phanerocryst belongs to barbierite.

3.2 The full chemical analysis of rock

The chemical composition of the sample is measured according to *the method of cement chemical analysis* (GB/T176-1996). The results which can be seen in Table 2, show that the main components of the rock are SiO₂, Al₂O₃, and also a few Fe₂O₃, FeO, MgO and CaO. The concentration of K₂O is about 0.54%~2.89%, and the average value is 1.54%, the concentration of Na₂O is about 1.40%~7.73%, and the average value is 4.91%, the equivalent weight of alkali (Na₂Oe) is about 2.47~8.20%, and the average value is 5.92%.

3.3 Granite measurement by means of the chemical method

The granite measurement by means of the chemical method is carried out according to the *experiment regulations of water power engineering concrete* (SD105-82). The appraising standard of active aggregate is as follows; if the experiment result meets with either of following conditions, $R_c > 70$ and $Sc > R_c$ or $R_c > 70$ and $Sc > 35 + R_c/2$, then this aggregate is considered to be potential active aggregate. The measurement results of the sample by means of the chemical method are shown in Table 3. The results show that all sample are non-active aggregates.

Table 2. The experiment result of granite chemical composition anlysis

Sample number	Granite name	Chemical composition (%)

3.4 The mortar bar length method

The mortar bar length method is carried out according to *the experiment regulations of water power engineering concrete* (SD105-82). The appraising standard of this experiment is as follows; if the expansion rate is over 0.1% within half year, then the aggregate is considered to be potentially active. The cement used for this experiment is moderate heat Portland cement 525#, except for the alkali contained in the cement itself. Extra alkali was added to the cement, and the equivalent weight of alkali reached 0.8%,1.2%. The experiment result in table 4 shows that the expansion rate

of the sample is related to the equivalent weight of alkali of cement, and also related to the age. The greater the equivalent weight of alkali in the cement, then the greater the expansion rate, and the expansion rate will increase as the age increases. The expansion rate of all samples with 180 day age are lower than 0.1%, which indicates that the aggregate is non-active when appraising it by means of *mortar bar length method*.

Table 3. The granite measurement by means of chemical method

Sample number	Granite name	The decreased value of alkalinity Rc(mmol/L)	soluble SiO ₂ Sc((mmol/L))	Appraising result
96—52	Biotite-plagioclase gneiss	223.1	15.4	Non-active

The diorite-plagioclase granite of Three-Gorges Dam base was observed over a long period by means of the mortar bar length method. The cement used is 600# dam cement(now is moderate heat Portland cement 525#). The alkali concentration is 0.78%, except for the alkali contained in the cement itself, extra alkali is added to the cement till the equivalent weight concentration of alkali reaches 0.8%,1.2%, 1.5%, 2.0%. The result is shown in Figure 1. We can see that the mortar sample expansion rate of diorite-plagioclase granite increases with age, and it reaches the greatest value when the age is 13 years. After 13 years, the expansion rate has the tendency of decreasing, and it seems that the reaction stagnates. The expansion rate also has relationship to the equivalent weight concentration of alkali in cement, it increases as the equivalent weight concentration of alkali in cement increases. When the alkali concentration reaches 1%, the expansion rate of the sample aged 14 years is still less than 0.1%, the threshold harmful value of expansion rate.

Figure 1. The relation curve of expansion rate vs. age time of Biotite-plagioclase gneiss by means of mortar bar length method

Table 5. The granite experiment result by means of small bar ultra-accelerated method

Sample number	Granite name	Expansion rate (%)	Appraising result
96—52	Biotite-plagioclase gneiss	0.037	Non-active
96—61	Diorite-plagioclase granite	0.030	Non-active
96—66	Plagio-diorite lamprophyre	0.041	Non-active
96—67	Broken plagioclase granite	0.064	Non-active
96—68	Broken granite	0.060	Non-active
96—71	plagioclase granite	0.034	Non-active
96—72	Chloritization dolerite	0.036	Non-active
96—73	quartzite	0.039	Non-active
96—74	Chloritization dolerite	0.039	Non-active

96—80	Granite diorite	0.056	Non-active
96—87	Chloritization dolerite	0.066	Non-active

3.5 Small bar ultra-accelerated method

Small bar ultra-accelerated method is carried out according to the method CECS48:93. The testing of the sample is as follows; one of the three samples which have the greatest expansion rate is used to appraise the alkali activity of aggregate. If the expansion rate is over or equal to 0.1%, then the aggregate is considered to be active, if the expansion rate is lower than 0.1%, then the aggregate is considered to be non-active. This method is only suitable for evaluating the alkali activity of

silicious aggregate. The experimental results of the aggregate by means of small bar ultra-accelerated method are shown in Table 5. From the results it can be seen that the biggest expansion rate of the sample is 0.064%, which is lower than 0.1%, and this indicates that the aggregate is non-active according to the small bar ultra-accelerated method.

3.6 Mortar bar ultra-accelerated method

Mortar bar ultra-accelerated method is carried out according to the method ASTM C1260-94. The testing standard of the experiment is as follows: if the sample expansion rate at the age of 14 days is lower than 0.1%, then the aggregate is harmless, if the expansion rate is over 0.2%, then the aggregate has potential alkali reactivity. If the expansion rate is within 0.1%~0.2%, then the other auxiliary experiments should be carried out, and it is also allowed to assess it when the age reaches 28 days. The result of the mortar bar ultra-accelerated method of the granite from two basins is shown in Table 6. From table 6 it can be seen that the expansion rate of the sample with the age of 14 days is lower than 0.1%, which indicates that the aggregate is non-active according to the mortar bar ultra-accelerated method.

Table 6. The sample experiment result by means of mortar bar ultra-accelerated method

96—99	Porphyritic monzonitic granite	0.017	0.023	0.035

3.7 The prism experiment of concrete

The common prism experiment of concrete is Canadian method, is CSA A23.2-14A. The alkali concentration of cement is set at $1.0\% \pm 0.2\%$, and by means of adding NaOH, it can make the alkali concentration of cement reach 1.25%. The expansion rate of the sample aged one year is used to assess the alkali activity of aggregate. If the expansion rate of sample aged one year is equal to or over 0.04%, then the aggregate is considered to be potentially harmfully active. If the expansion rate is lower than 0.04%, then the aggregate is considered to be non-active. The experiment result of *the prism experiment of concrete* of coarse and fine aggregate from the same granite is shown at table 7. From table 7 it can be seen that the expansion rate of the concrete with the age time of 364 days is lower than 0.04%, which indicates that the aggregate is non-active according to *the prism method*.

Table 7. The sample experiment result by means of *the prism experiment of concrete*.

4. CONCLUSION

The mineral composition of the granite in the foundation excavation of Three-Gorge Dam is mainly plagioclase, quartz, biotite, and some hornblende, the rock has granitoid and massive structure. The mineral composition of the granite from the basin at Xiaanxi is mainly plagioclase, potash feldspar, quartz, and some chlorite, the rock has granitoid, porphyritic structure and massive structure, the undulance extinction angle is small, and there is no micro-crystalline-quartz.

The diorite-plagioclase granite in the foundation excavation of Three-Gorge project and the porphyritic granite in the basin at Xiaanxi show to be non-active after being tested by means of the method of petrographic, chemical analysis method, mortar bar length method, small bar ultra-accelerated method, mortar bar ultra-accelerated method and the prism experiment of concrete.

Because of the complexity of AAR, there is no international common method for appraising the activity of aggregate. When considering the endurance of concrete and the safety of construction, it is important to strictly control the alkali concentration of cement.

NEW GENERATION OF ADMIXTURE POLYMERS AND ITS ROLE IN CONCRETE TECHNOLOGY

¹Sika Japan, ²Sika USA, ³Sika Technology Ag

1. INTRODUCTION

Polycarboxylic acid-Polyether-Polymers were first considered as an admixture 20 years ago in Japan. Since this time various polymers based on different mechanisms became available.

Compared to traditional admixtures based on lignosulfonate, naphthalene-sulfonate, melaminesulfonate or gluconate, the polycarboxylic based polymers show significant performance advantages: higher water reduction rate, extreme extended slump life, very low and stable concrete viscosity and finally, fast setting times. The key factor for Self Compacting High Strength Concrete (SCC) is very low concrete viscosity even at W/C ratios far below 20%.

Due to the threat of seismic activities and high land prices, the demand of Ultra High Strength Concrete in Japan is rapidly growing. The advantages for construction work are first a smaller number of columns and second an increased lettable area.

Concretes with a compressive strength of 100 N/mm² are currently produced. These concretes are applied only as SCC.

This presentation gives an overview of the potential of the Sika polycarboxylic based admixtures and their impact on concrete technology. Concrete mix designs and special binder systems are described. The focus lies on concretes with a W/C ratio of 15 - 35%.

A new construction system CFT (Concrete Filled Steel Tubes) is also briefly introduced. It is one of the application methods for SCC High Strength. Currently most of the high rise buildings under construction in Japan are based on CFT.

2. ULTRA HIGH STRENGTH CONCRETE: 60 – 150 N/mm²

As schematically illustrated, below a W/C ratio of 35% conventional construction methods can no longer be applied. To achieve strengths up to 150 N/mm² very high binder contents and very low W/C ratios are necessary.

This results in highly viscous concretes and makes it impossible to compact the concrete correctly. Dense reinforcement and complex structures also prevent a proper filling of the formwork.

The newly developed polymers extend the W/C ratios far below 20%, the concrete viscosity is low and stable for up to 120 minutes.

3. CONCRETE MIX DESIGNS AND BINDER SYSTEMS

In the past years new cements and binder systems were released. The application field and the composition of the cements are shown below. Low Heat Cement is currently widely used as well as a premix of low heat cement with silicafume. VKC 100 is a blend of cement with special slag and silicafume. Moderate Heat Cement is the newest among these cements and is used at W/C above 30%.

Low Heat Cement hydrates more slowly than Normal Portland Cement due to the high amount of belite clinker phase. The heat generated during the hydration process is less resulting in reduced thermal cracking. The final strength is also significantly higher than for normal portland cement.

Moderate Heat Cement is at the moment used for concrete with W/C between 30 – 45%.

The mix design of concretes with a design strength between 24 and 120 N/mm² is shown below, as they are actually used.

The aggregate factor (= vol% aggregate per m³ concrete) for 80, 100 and 120 N/mm² is kept constant as is the amount of water. Silicafume is used as an additive to improve workability and final strength.

Vol-%
 24 – 48: Normal Portland Cement
 60 – 80: Low Heat Cement
 100 – 120: Low Heat Cement + Silicafume

Different special cements and binder systems are used as a base for the SCC High Strength, as is shown in the table below.

Company	Notation	Density [g/cm³]	Specific Surface [cm²/g]	Chemical Composition			Clinker Component			
				MgO	SO ₃	Na ₂ O eq	C ₃ S	C ₂ S	C ₃ A	C ₄ AF
Taiheiyo	L	3.22	3450	0.7	2.2	0.46	29	54	3	8
Sumitomo Osaka	L	3.23	3300	0.8	2.4	0.5	25	56	2	10
Ube-Mitsubishi	L	3.24	3430	1.05	2.52	0.51	23	57	3	
Ube-Mitsubishi	L 5	3.22	3780	0.86	2.5	0.51	32	50	3	
Taiheiyo	HF	3.2	4100	0.7	2.7	0.5	34	47	3	8
Taiheiyo	M	3.21	3150	1.3	2.0	0.54	43	36	4	12
Sumitomo Osaka	M	3.21	3100	1.2	1.9	0.58	44	33	4	12
Taiheiyo	N	3.16	3310	1.4	2.0	0.62	52	24	9	9
Ube-Mitsubishi	N	3.15	3280	1.6	1.9	0.65	53	22	9	9

L: Low Heat- or Belite Cement. HF: High Flow Cement. M: Moderate Heat Cement
 N: Normal Portland Cement

4. CONCRETE TEST RESULTS

The sand and aggregate used for these mix design is also used for concretes with a design strength of 24 – 48 N/mm². Special aggregate is available but was not used.

Mixing of the concrete: 1) cement + sand + water + admixture
 2) + aggregate

The mixing times for the concretes described below were in the range of 2.5 to 4.5 min.

The ***SIKA polymers*** used for these mix designs showed excellent slump retention properties and the viscosity only slightly increased after 120 min.

Design Strength 100 - 150 N/mm², Binder: VKC 100

W/B	Water	VKC 100	Sand	Aggregate	Admixture	Slump Flow	Temperature
	[kg/m ³]				[%]	[cm]	[°C]
15	150	1000	567	802	2.1	75 x 75	25
18	150	834	647	802	1.6	70 x 69	25
21	150	715	749	802	1.5	68 x 67	25

W/B	Compressive Strength [N/mm ²]			
[%]	7 days	28	56	91
15	120	134	145	150
18	116	129	139	142
21	104	112	121	130

Design Strength 50 - 80 N/mm², Binder: Low Heat Cement
These mix designs currently have the biggest market share in Japan.

W/B	Water	L-Cement	Sand	Aggregate	Admixture	Slump Flow	Temperature
	[kg/m ³]				[%]	[cm]	[°C]
25	165	660	684	899	1.3	67 x 69	25
30	165	550	772	802	1.2	70 x 69	25
35	165	471	837	802	1.05	68 x 67	25

W/B	Compressive Strength [N/mm ²]			
[%]	7 days	28	56	91
25	36	70	82	87
30	45	79	90	97
35	61	95	107	113

Design Strength 100 - 150 N/mm², Binder: Silicafume Cement (10% silicafume)
The highest compressive strength was achieved with the premix low heat cement and silicafume. Compressive strength will also be tested after one year; data will be available soon.

W/B	Water	SFC	Sand	Aggregate	Admixture	Slump Flow	Temperature
	[kg/m ³]				[%]	[cm]	[°C]
15	155	1034	442	855	2.8	72 x 71	25
18	155	862	588	855	2.1	69 x 69	25

W/B	Compressive Strength [N/mm ²]			
[%]	7 days	28	56	91
14	98	138	151	162
18	92	130	139	148

5. NEW CONSTRUCTION METHOD: CFT

CFT, *Concrete Filled Steel Tubes*, is a new method used for the construction of high rise buildings.

The basic principle is very simple: the framework of the building consists of steel pillars connected with steel beams. SCC High Strength is filled into the steel pillars which up to now do not contain reinforcement. The slump flow is in the range of 60 – 70 cm, the slump flow must be constant for up to 120 min, the concrete viscosity soft and stable. The concrete is either filled into the pillars by pumping from the bottom of the pillar by connecting the pump hose or is pumped to the top of the pillar and dropped in. The pillar diameter reaches up to 2 m, the height of filling is in the range of 100 – 180 m.

The concrete must be easy to pump even to heights of up to 300 m, segregation of the concrete must be prevented as it would be reflected in the compressive strength. This construction method allows for extremely fast construction.

6. SUMMARY

The new generation of polymers is extending the application range of concrete as a construction material.

Extremely high compressive strengths can be achieved due to the water reduction rate of the Sika polycarboxylic polymers. The slump is stable for 120 minutes and the excellent workability of the concrete makes it easy to use on site even with W/C ratios far below 20 %.

As different polymers (water reduction – and slump retaining polymers) are used to formulate the admixture product, technical requirements like water reduction or slump life can easily be adjusted.

The usage of the new polymer based admixtures will not be limited to SCC applications, and is likely to make further inroads into conventional concrete supplied for site use.

These new polymers are the basis for the development of new construction methods.

CHEMICAL AND PHASE ANALYSIS IN CEMENT PROCESS AND QUALITY CONTROL: ROLE OF XRF AND XRD INSTRUMENTS AND THEIR INTEGRATION

ABSTRACT

The analytical needs of cement are constantly evolving from basic oxides analysis to comprehensive phase analysis of clinkers, additives and associated materials. Advances in X-ray instrumentation have shown that it is possible to integrate both XRF and XRD in one instrument as a total solution to the process and quality control. In addition, low or medium power WDXRF instruments are becoming cost effective with adequate analytical performance in small to medium size cement plants. Advances in the development of “standard-less” XRF and XRD analysis programs are providing powerful means of analysing non-routine samples in addition to monitoring the clinker phases. Various possible solutions will be presented: A combination of a stand-alone XRF and a stand-alone XRD is a more appropriate solution for a central service laboratory involved in method development and investigative work requiring flexibility and expertise with a view to analyse varying sample types. A fully integrated XRF-XRD platform is more suitable to a process or quality control laboratory requiring on-line, continuous analysis using dedicated, easy-to-use quantitative programs for a more comprehensive chemical and phase analysis. Results from different case studies will be presented and discussed.

1. INTRODUCTION

Analytical requirements in the cement industry are continuously evolving and different solutions are available for different situations. In particular, chemical analysis by X-ray fluorescence is being extended to cover materials and elements other than the usual oxides in raw materials through to the final products. This has become possible thanks to the development of more flexible XRF instruments and analytical programs referred to as “standard-less”. Moreover, analysis of phases in clinker including free lime by X-ray diffraction is being increasingly solicited. This latter application has become routine and on-line thanks to the development of integrated X-ray instruments. However, apart from these analytical criteria, there are other operational issues that need to be addressed in deciding on a suitable X-ray instrument. For example,

- Capital investment, running and maintenance costs for the lifetime of the instrument (sometimes referred to as total cost of ownership)
- Production capacity of the plant (small to large) with corresponding justification for investment
- Grinding station versus a production site
- Types of cement produced and additives used (limestone, slags, fly ash, silica dust, gypsum)
- Number of samples to be analyzed per hour or per day
- Typical response time for complete analysis (chemical and phase)
- Sample preparation methods available

- Need for automation or integration in process control

The type of X-ray instruments to be used in a cement industry can be broadly classified in three different scenarios, each with their own conditions or constraints.

2. PROCESS AND QUALITY CONTROL LABORATORIES IN MEDIUM TO LARGE CEMENT PLANTS

These laboratories are generally looking for:

- Routine quantitative analysis of all the oxides with high degree of accuracy and reliability
- Dedicated calibration programs for each major matrix involved
- Reliable on-line analysis of free lime in clinkers as one of the most important kiln control parameters
- Continuous monitoring of clinker phases if possible as quality indicators
- Quantification of additives such as limestone and slags in cement
- Occasional non-routine analysis

Instruments integrating XRF for chemical analysis and XRD for specific phase analysis are ideally suited for process and quality control (QC/QA laboratory) in medium to large capacity cement plants. In such applications, higher throughput, integration in the process and some degree of analytical flexibility are required. Complete and uncompromising chemical analysis is obtained through XRF and XRD is used for specific phase analysis such as Free Lime in clinkers, limestone additions in cement and other related phases.

Complete analysis is obtained using one instrument, one sample and one analytical program in about 3 to 5 minutes depending on the configuration. Quantitative analysis of routine oxides, free lime in clinkers and limestone additions in cement with such systems is well established.

When all sorts of various oxidic raw materials need to be controlled a single calibration program based on fusion beads technique covering elements from sodium to iron as given in Table 1 can be used. But in most instances pressed pellets preparation is used in the cement industry for specific material types.

Table 1. Elements/oxides and their corresponding concentration range and Standard Error of Estimate covered using a general program for oxides.

Element	Range [%] (on ignited samples)	Typical SEE [%]
CaO	0.02 - 94.4	0.26
SiO ₂	0.35 - 99.7	0.25
Fe ₂ O ₃	0.025 - 94	0.32
MgO	0.01 - 97.3	0.22
Al ₂ O ₃	0.16 - 89.2	0.19
K ₂ O	0.006 - 15.4	0.05
MnO	0.005 - 8	0.04
Cr ₂ O ₃	0.002 - 17.4	0.1
TiO ₂	0.011 - 3.8	0.03
P ₂ O ₅	0.014 - 40.0	0.04
SO ₃	0.015 - 3.7	0.05
Na ₂ O	0.045 - 10.4	0.15

Analysis of clinker phases - C_3S , C_2S , C_3A and C_4AF - is being increasingly considered for implementation in process and quality control laboratories. It is certainly advantageous to be able to accomplish this analysis alongside the usual XRF analysis with the same clinker sample and in a quantitative manner. There are different approaches to the analysis of clinker phases starting from the very approximate and empirical estimations from Bogue equations through microscopy to Rietveld based programs. There are debatable strengths and weaknesses in each of these methods in terms of their implementation in on-line process control. What is perhaps useful in a process control environment is a continuous monitoring of the clinker phases for their variations in conjunction with the corresponding free lime and related oxides. In this sense, an integrated analysis incorporating clinker phases by XRD and the oxides by XRF is likely to be more easily acceptable in a routine method.

Figure 1 shows the scan obtained using the integrated XRD system of a combined XRF-XRD instrument on different clinker samples. Apart from an intense free lime peak, the major clinker phases can be identified with their individual peaks. Other intense peaks are due to combination of several phases and cannot be used for quantification.

Figure 1. XRD scans obtained on different clinker samples using ARL Total Cement Analyzer showing clearly free lime and the four clinker phases.

A study has been performed in order to determine if the clinker phases of real world clinker can be estimated through XRD. As a first step a correlation has been established between the clinker concentration calculated through the Bogue equation.

Figure 2 shows a calibration curve obtained for C_3S using its XRD peak intensity and the estimated C_3S concentration from Bogue.

Analyte: C 3S LOD (40 s): 2727.6 ppm BEC: 12.083 % Q: 0.037 Kcps/% SEE: 1.4351

Figure 2. XRD calibration curve obtained for C_3S in a series of real clinker samples using levels calculated through Bogue equation. Analysis time 100 seconds.

Figure 3 shows a calibration curve obtained for C_3S using its XRD peak intensities of a series of clinker samples and C_3S concentrations estimated through microscopy counting. Similar curves were obtained for the three other clinker phases- C_2S , C_3A and C_4AF . The standard error of estimate or the accuracy depends, of course, on the relative accuracy of the reference technique used. It is therefore possible to implement calibration curves for the four clinker phases and to perform quantitative analysis of these phases using an integrated XRD system. The analysis of the clinker phases will be finished in 2 to 3 minutes.

Figure 3. XRD calibration curve obtained for C_3S in a series of real clinker samples characterized by optical microscopy. Analysis time 100 seconds.

3. CENTRAL LABORATORIES FOR INVESTIGATIVE WORK AND METHODS DEVELOPMENT

The principal activities of central laboratories

- Analysis of various types of samples (solids, liquids, loose powders) with known or totally unknown matrix
- Quantitative XRF analysis using both specific calibrations and general purpose “standard-less” analysis programs
- Qualitative and quantitative investigations of phases or minerals in raw materials, clinkers and cements using XRD in conjunction with Rietveld based programs
- Analytical support and development of methods in the context of new processes or materials manufacturing.

It is clear that full power of XRF and XRD techniques can be exploited in a central laboratory where there is expertise and the need for investigative work. Other complimentary analytical techniques are usually available in the central labs making the data correlation and verification process more easily achievable.

Given this profile and the nature of samples received in such laboratories, it is legitimate to think of two independent instruments of XRF and XRD with full flexibility and their corresponding analytical programs more open for investigation than needed for a routine analytical laboratory.

Figure 4. Combination of a sequential XRF and a powder XRD in a central laboratory

A summary of typical analytical tasks that can be handled (both routine and non-routine) using a conventional sequential XRF instrument (X-ray tube below the sample) as shown in Figure 4.

Analytical functions of a sequential XRF instrument using Universal Goniometer:

Quantitative analysis of known materials

- **CaO, SiO₂, Al₂O₃, Fe₂O₃, MgO, Na₂O, S, Cl, K₂O, etc. in raw materials, raw meal, clinker and cement.**
- **Analysis time < 2 min**
- **Analysis of sulphide versus sulphate in slags (as additive in cement)**

Standard-less analysis programs for samples from

- **Quarry**
- **Coal ash**
- **Additives**
- **By-pass (Na, Cl, S, ...)**
- **Gypsum (minors & traces)**
- **Oils & Waste Liquid Products used as alternate fuels**
- **Filters and other environmental control systems**

On the other hand, a powder XRD instrument is a powerful tool to study various cement related materials for their mineralogy and can be exploited for more advanced investigation related to the structures. A typical XRD scan on a clinker sample is shown in Figure 5.

Figure 5. XRD scan on a clinker sample obtained using a diffractometer equipped with a Peltier cooled Si(Li) detector. Thanks to the high sensitivity and resolution of this type of detector, faster acquisition of data is possible. Typical scan time - 3 minutes.

Results from Rietveld analysis using the SiroQuant™ program on cement samples are shown in Table 2.

Table 2. Rietveld analysis of cement compared with grain counting method

Cement Standard	Analysis Method	C3S	B-C2S	C3A		C4AF
				Ortho	Cubic	
E1	Siroquant	69.0 (1.0)	14.2 (0.7)	2.0 (0.7)	4.4 (0.7)	7.2 (0.6)
	Grain Counting	71.1 (3.4)	12.8 (7.6)	6.7 (1.3) (sum)		9.5 (2.4)
E2	Siroquant	79.2 (0.9)	7.2 (0.6)	0.3 (1.3)	8.3 (0.4)	3.3 (0.6)
	Grain Counting	80.7 (3.4)	7.7 (2.6)	6.3 (1.3) (sum)		4.9 (2.4)

4. SMALL CEMENT PLANTS, GRINDING STATIONS AND/OR BACK-UP IN CENTRAL LABORATORY

In this third and final situation, the analytical requirements are generally less demanding and they can be summarized as follows:

- Limited to the essential oxides for process control (small cement plants) and/or quality control in the final product (grinding stations)
- Lower sample throughput
- Much lower capital investment
- Easy to use, easy to maintain instrument with significantly lower running costs

Bench top energy dispersive XRF (ED-XRF) or non-dispersive XRF systems were used in the past in such situations because most wavelength dispersive XRF (WD-XRF) systems were either too expensive or too complicated for the performance required. With the development of entry-level WD-XRF instruments, small size cement plants and grinding stations can now benefit from high quality analysis even for sodium. Indeed, the new generation of XRF instruments does not require water cooling (neither external nor internal) and can be configured for simple, stand-alone operation with no peripheral dependence. Such units can be configured as sequential-simultaneous instruments fitted with compact goniometer for flexibility and/or a few fixed channels for simultaneous analysis of elements from sodium onwards.

WD-XRF brings a much better spectral resolution than conventional ED-XRF instrument as well as superior precision, short and long-term stability. Light elements like Na and Mg can be analysed without problem. Figure 6 shows a typical calibration curve obtained for Na, one of the critical elements to be determined in the cement industry with precision and reliability. These results were obtained with samples prepared as fusion beads and show quality data even when the sample is diluted with Lithium tetraborate in order to fuse it in the form of a glass bead.

Figure 6. Entry level WD-XRF instrument: calibration curve for Na in cement prepared as fusion bead. Standard error of estimate is 0.011% in a range from 0.02% to 0.32%

Table 3 shows precision data on various oxides obtained for such entry level WD-XRF instrument on a pressed pellet of cement. Precision usually demanded for the analysis of cement is given in this table in comparison with that obtained using this new instrument. This data was obtained by analyzing the pellet for three days continuously and *without drift correction* of the instrument. The precision for all the oxides including Na₂O is much better than what is generally required. The total analysis time can be reduced to about 3 minutes in order to meet the precision demanded for all the oxides.

Table 3. Excellent repeatability (precision) data obtained with ARL OPTIM'X on a cement pellet. Total analysis time: 3 minutes. Test done over three days of measurements without drift correction.

Elements	Concentration Range (%)	Precision demanded	Precision found
CaO	58 – 66	0.03-0.035	0.028
SiO ₂	18 – 23	0.02	0.018
Al ₂ O ₃	3 – 5	0.02	0.013
Fe ₂ O ₃	1.5 – 5	0.01-0.02	0.008
MgO	0.5 – 4	0.02	0.015
SO ₃	2 – 5	0.01-0.015	0.009
K ₂ O	0.1 – 0.6	0.02	0.005
Na ₂ O	0.1 – 0.7	0.015	0.007
P ₂ O ₅	0.05 – 0.3	0.01-0.015	0.009
MnO	0.05 – 0.3	0.015	0.003
TiO ₂	0.1 – 0.4	0.015	0.005

In addition to the analysis of cement and related materials in small size cement plants or in grinding stations, WD-XRF entry level instruments can also be a cost effective back up instrument for a main laboratory instrument. Further, analysis of liquids or loose powders can also be accomplished under a helium atmosphere using such instruments. This feature is particularly useful when alternate fuels or other waste products need to be monitored.

5. CONCLUSIONS

Continuous innovations in X-ray instrumentation and analytical techniques are providing the cement industry with a wider choice of solutions suitable for process and quality control or investigative laboratories with integrated platforms or stand-alone instruments respectively. Small cement plants or grinding stations can also obtain high-quality analysis thanks to the development of entry level WD-XRF instruments requiring significantly lower capital investment and running costs.

CEMENT STANDARDS

“THEIR ROLE IN REGULATING AND PROMOTING TRADE”

Julies, E.L.

South African Bureau Of Standards (SABS). Private Bag X191, Pretoria, 0001
Tel: +27 12 428-6002/6025. Fax: +27 12 428-6751. Cell: 083 632 4994

ABSTRACT

“If you control an industry’s standard, you control that industry lock, stock & ledger”^[1]
W Edwards Deming

In today's modern environment trade barriers are of concern. Standards can be used either to overcome these barriers or to establish them - the essence then is to know and understand how to effectively use the advantage standards provide.

Another issue is that trade barriers occur predominantly in the regulatory domain where countries are sometimes inadequately equipped to manage the process. A suggested form that such a regulatory regime should encompass is discussed; together with the benefits a well-defined and transparent regulatory domain can bring to any industry.

A brief comparison is made between activities of SABS and those, which any National Standards Body should undertake; with specific reference to the South African Cement Standards.

The conclusion is then reached that instead of seeing standards as a hindrance, it is in fact the basis for all trade, it acts as a means to transfer technology, and should be seen as a useful adjunct to any country's trade policies

1. USING INTERNATIONAL STANDARDS TO LEVERAGE WORLD MARKETS

The Greek mathematician and scientist Archimedes once boasted that given a spot to stand and place a lever, he could move the world. Today’s Archimedeans are still interested in leverage, but of the entrepreneurial type – gaining access to world markets and increasing trade. One of the levers used by the modern Archimedeans is international standards.^[2]

For many companies this is a challenging time - whilst it is a good time to “go global”, it is also a time for great caution as others seek the same opportunities. Whilst we have seen a decrease in certain trade barriers, they have become more subtle, both in nature and form. Tariff Trade Barriers are those, which have fallen most rapidly, to be replaced by sometimes-quantitative restrictions, import licensing or local content requirements as very effective barriers to trade. Conformance assessment can also create a trade problem. And sometimes, standards are the barrier.

2. INTERNATIONAL STANDARDS ARE STRATEGIC TRADE LEVERS

There are many ways in which companies can use international standards as strategic levers to avoid or evade trade barriers, or to create new trade opportunities. In the first instance, international

standards may provide companies (and their governments) with the means to challenge national standards as being restrictive trade barriers. This is especially true where national standards have no basis in fact or practice. It could be construed as having been implemented because of unique local conditions, which necessitate their use. An example of this could be the standard for iodised salt. Secondly, international standards can provide business opportunities since they may act as a unifying agent for technical requirements, thereby unifying markets. Thirdly, there is a strong link between global trade and global production. International standards allow companies to produce a product in one country, to the same performance and quality expectations as in any other country and then allow the marketing of the product globally. Finally, the rapidly changing political, social and economic landscape has opened many new markets around the world. But companies in less developed or emerging markets are new to the world of trading partners and thus find themselves in need of standards. In this case there are no (or very few) national standards, and so international standards are helpful for such companies to achieve market entry.

3. PROMOTE GLOBAL PRODUCTION

We are living in a world where we have globally spread suppliers, unlike in the past where production took place in a single country, by a single manufacturer, using local suppliers. Today the major manufacturers (so-called multinationals) in many instances have been reduced to assemblers of components manufactured by their many, geographically spread contract suppliers.

In this world the lines between competitors, suppliers, and contractors have become blurred. Mergers and acquisitions are the order of the day. Strategic alliances abound, where former competitors are now partners. One of the easiest ways to get access to markets is for a firm to acquire interests in foreign companies.

We find as well that products are becoming increasingly designed, manufactured and supported on a worldwide basis, taking advantage of the different talents around the world, while at the same time reducing the cost of labour, materials and transportation. This is the so-called “think global, act local” approach finding favour with most firms today. In the new era that we are entering no single company or even a single country, can hope to successfully compete in the global game by itself.

Under these trying circumstances the sole dependable feature is that if an international standard is used as the basis for specifying the performance, composition, quality requirements, manufacturing characteristics or even shape, of a product, then that product will, anywhere in the world, be exactly the same, no matter who manufactures it. (We are of course assuming here that manufacturing standards are equivalent and that skills, expertise etc. are similar). This is in a nutshell the key role that international standardisation plays.

4. STANDARDIZATION & REGULATION

We see that in order to regulate trade, it is to offer a level playing field to the competing firms, and to offer a measure of consumer protection, business and citizens need a regulatory environment, which is clear, effective and workable. Some organisations have postulated that in the rapidly changing global market place, formal regulation is not always the answer, and are pushing for alternative approaches.

The claim they make is that these alternative approaches are more effective, however the jury is still out on this issue.

The challenge here is to ensure high levels of protection while avoiding over-regulation. This is not possible in the absence of strict liability laws where the onus is placed on the individual, in the

context of representing the firm, to ensure that a product they supply conforms in all possible aspects with the legal (and sometimes, dare we say, moral) requirements.

It is the sad and unfortunate reality that those countries most in need of a regulatory regime (or strict liability laws) are often those without any, or where few exist. This makes them an easy target for companies whose sole objective is to make money for their shareholders.

It is therefore unlikely that governments will in the foreseeable future agree to, or buckle under the sometimes severe pressure being brought to bear upon them by large corporations (whose turnover often exceeds by far the total GDP of the country) to change either the standards by which they judge, or the manner in which they regulate products, which may negatively impact upon their citizen's health and/or safety.

Under these circumstances the voluntary use of standards in regulation requires a clear definition of each party's roles, responsibilities and competencies.

A Technical Regulation Best Practice Model was developed in South Africa to comply with WTO/TBT requirements; i.e. to protect the consumer through technical regulations without creating a technical trade barrier:

Above is a schematic representation of this model, which clearly shows the roles various sectors play in implementing the regulations.

5. STANDARDIZATION AND TRADE

A cursory glance at trade figures shows that global trade continues to increase year by year. We have earlier said that the use of international standards can enhance market access and facilitate trade. But standards may also give rise to “trade frictions”, in particular if there are no international standards with global recognition capable of being employed by a player in the market. International standardization via one of the recognised institutions such as ISO/IEC or ITU to name but three, offers globally applicable solutions to the parties concerned.

It is moot that internationally traded goods need international standards wherever possible so as to make buyers and sellers “ad idem” as to what it is they are exchanging, to provide a sound basis for contracts, and to ensure inter-changeability and inter-operability across national boundaries. Standardization and the use of standards are also an important part of any community's external trade policy, and that community must comply with international agreements concerning standards, amongst which is the WTO Agreement on Technical Barriers to Trade (TBT Agreement).

6. ADVANCING STANDARDIZATION AND CONFORMITY ASSESSMENT TO FOSTER TRADE [3]

To recap what we said before:

6.1 Standards are an important aspect of daily life, but play an even more important role in the economic development of a country, since they deal with issues as diverse as:

- Protection of the environment
- Promotion of health and safety
- Enhancing the quality of life
- Opening up of trade, both regional and international
- Facilitating delivery of quality
- Raising the overall levels of quality across industries in a nation
- Acting as consumer protection

6.2 Standards are many and varied in their actions:

- They facilitate trade by providing a basis for comparison and measurement.
- Act as a mechanism to transfer technology.
- Improve communication and mutual understanding of technical issues.
- Act as protection of health, safety and the environment.
- They are positive stimulus for innovation.

With this in mind, we can then come to the crux of our discussion, specifically what is the role of a national standards body (NSB) in this, and with particular reference to South Africa, both as a developing country and as a global player (we would like to think leader) in the field of international standardisation, what is SABS' role.

7. THE INVOLVEMENT OF A NATIONAL STANDARDS BODY (NSB) WITH SPECIFIC REFERENCE TO SABS INVOLVEMENT

It is becoming more and more clear these days that the role, which an NSB plays, is much more complex than was at first understood. If we are correct that standards are the basis for international trade and that a country should recognise that the basis for all of its trade in a large measure is supported by standards, then the role of the NSB is clear.

That is, it acts as a source of information, not only on standards, but also on the application of such standards to its business, and to trade specifically. It adopts, adapts or develops, international standards for local conditions and use. NSB's should form a part of all trade negotiation missions where they can provide technical support and input at the early stages of discussions.

Since standards form the basis for technical specifications they also form the basis for the conformity assessment regimes that measure compliance with such specifications, as well as form the basis for the measures of competency, not only of individuals, but also of organisations engaged in conformity assessment practices.

7.1 The following cement standards were adopted

7.1.1 EN/ENV 413 Series (adopted in 1996):

Generic Title: Masonry Cement

Part 1: Specification (ENV)

Part 2: Test methods (EN)

7.1.2 EN 196 Series (adopted in 1996):

Generic Title: Methods of testing Cement

Part 1: Determination of strength

Part 2: Chemical analysis of cement

Part 3: Determination of setting time and soundness

Part 4: Quantitative determination of constituents

Part 5: Pozzolanicity test for pozzolanic cement

Part 6: Determination of fineness

Part 7: Methods of taking and preparing samples of cement

7.1.3 EN 197 Series (adopted in 2002): [previously formed the ENV 197 series]

Generic Title: Cement

Part 1: Composition, specifications and conformity criteria for common cements

Part 2: Conformity evaluation

This has brought it in line with most of its major trading partners, and makes SA a leading country amongst developing economies adopting such modern standards.

By request of several stakeholders in the Southern Africa cement industry, and in order to prevent the fraudulent practices rife during the late 80's up until today, it was decided to regulate the sale of cement as a commodity having a serious impact on human safety.

In order to regulate the distribution and sale of cement, it was decided to turn the applicable voluntary specifications into compulsory specifications, and coupled this with a requirement that it would be illegal to sell cement in South Africa without a distinctive mark. The mark chosen, in the absence of any alternative at the time, was the SABS proprietary mark.

To obtain the SABS mark, a company needs to apply for a permit issued by an accredited holder of the SABS licence. Currently the licence holder is Global Conformity Services (GCS) and only they may issue the permit, valid for three years, which will enable firms to participate in the Product Certification Scheme run by GCS. Participation is open to all firms (national and international) that meet the strict requirements of the EN standards.

Over many years of successful construction activity in Southern Africa, the construction industry realized the importance of specifying and using only approved cement and cementitious products. These products are specified for use and tested according to the strict guidelines laid out in the standard and are thus the only ones approved for use in construction and building operations.

The certification of cement entails proper control of manufacturing - from raw material to the final product. The principle is that only a well defined, well known, stable and capable process can qualify for certification under any mark scheme, be it local or international. Under such a certification scheme, the service provider ensures that the process is monitored at various stages and that regular independent testing of the product is carried out.

Note that as an adjunct to this certification process, valuable assistance and advice on the proper utilization and use of cement is given by the Cement & Concrete Institute (C&CI) which does constant research in this regard and offers training to industry.

8. CONCLUSION

In conclusion it is clear that standardisation has come a long way from simply being a nuisance to those who wish to “get on and do it”, to where today it is an indispensable part of trade, both policy and implementation.

“ALL THAT GLITTERS IS NOT GOLD”

“King Hiero II of Syracuse knew that all that glitters is not gold” – which is precisely why he tasked Archimedes to devise a standard test method to determine the gold content in his crown.

 - Pinellas County Schools, youth co-ordinator (2 years)
 - Brevard County Schools, student tutor (4 years)
 - High school student tutor (maths, science) (2 years)

SUSTAINABLE DEVELOPMENT IN THE CEMENT INDUSTRY: THE SOUTH AFRICAN RECORD

de Rougemont, F.

Association of Cementitious Material Producers (ACMP)

ABSTRACT

The process of manufacturing cement results in the generation of emissions and wastes. With increasing international awareness of environmental issues and concern for the impacts of industrial operations on the environment, the international cement industry has taken a leading role to evaluate its responsibilities and a group of major producers has agreed on future actions to ensure sustainability of the industry.

The cement manufacturers in South Africa participated in the above evaluation process and have assessed the emissions being made in South Africa. While the record demonstrates a downward trend, the South African manufacturers have committed to an Action Plan in the interests of meeting future stakeholder needs in a sustainable manner.

1. INTRODUCTION

Cement is an essential material in today's society because, as a major constituent of concrete, it forms a fundamental element of any housing, commercial or infrastructure development. Measured on a kilogram per capita basis, concrete is the second most widely "consumed" material in the world, second only to water.

The cement manufacturing process, as is the case with any heavy industrial process, has significant impacts on the environment as it is very energy intensive. Cement manufacture includes long-term quarry management and is a major industrial operation at the scale of a local community. The typical impacts are:

- Local impacts
 - Landscape disturbance and modification
 - Dust emissions
- Global impacts
 - CO₂, SO_x, NO_x emissions

Because of these impacts sustainable development has recently become a major strategic issue for cement manufacturers around the world. For cement manufacturers, sustainable development is about positioning ourselves to ensure the long-term life of our industry, an industry which is so important for the wellbeing and comfort the world's people.

Our industry is giving very specific and serious attention to the managing of CO₂ emissions. The cement manufacturing process produces CO₂ emissions through the consumption of energy. In addition, the process involves the calcination of limestone by driving off the bound carbon dioxide. We know that CO₂ is one of the greenhouse gasses which are believed to be contributing to global warming.

The Kyoto protocol requires Annex B developed countries to make commitments to reducing national CO₂ emission levels to a level below that determined by national inventories in 1990.

Despite the failure of some major countries to sign the Kyoto protocol, many governments have, or are likely to, adopt carbon management policies. This may include taxes on carbon dioxide emissions and this is likely to remain as one of the main drivers for change in the cement industry.

In 2000, a group of ten major international cement companies collaborated as the “Working Group Cement” (WGC) to sponsor a study under the auspices of the World Business Council for Sustainable Development (WBCSD) into the sustainability of the cement industry. The WBCSD commissioned the independent organisation, the Batelle Memorial Institute to undertake the study. The study culminated in a report published in March 2002^[1] entitled “Towards A Sustainable Cement Industry”.

To reinforce the independence of the Batelle study, an external Assurance Group was set up to review the research and make certain that the work fairly represented the multiple viewpoints and the range of issues that needed to be included.

Facts which emerge from the report indicate that the cement industry:

- ❑ Provides the construction industry with a key ingredient in the most commonly used material for the world’s infrastructure – concrete
- ❑ Produces about 1.5 billion tonnes of cement per year
- ❑ Has grown at a rate of nearly 4 percent per year over the past decade
- ❑ Operates manufacturing or processing facilities in 150 countries
- ❑ Has an estimated annual turnover of \$97 billion (US)
- ❑ Directly employs an estimated 850,000 workers worldwide

It suggested that Sustainable Development (SD) represents a vision of industrial progress that respects both human needs and global ecosystems, preserving the foundations upon which human quality of life depends. Three dimensions of a sustainable business are defined as the triple bottom line, i.e.

- ❑ Economic prosperity
- ❑ Environmental stewardship
- ❑ Social responsibility

While clearly all three dimensions are important, this paper mainly focuses on the issue of environmental stewardship i.e. the steps that cement manufacturers can take to reduce the environmental impact of their operations.

2. ENVIRONMENTAL ISSUES ASSOCIATED WITH CEMENT INDUSTRY OPERATIONS

The environmental issues confronting the global cement industry were reported to include:

- ❑ Impacts of resource extraction (fossil fuel, limestone, and other minerals) upon environmental quality, biodiversity, and landscape aesthetics
- ❑ Depletion of non-renewable or slowly renewable resources (fossil fuels or groundwater)
- ❑ Dust emissions (from quarrying, cement production, and transport)
- ❑ Other emissions that can affect air quality: nitrogen oxides (NO_x), sulfur dioxide (SO₂), carbon monoxide (CO), volatile organic compounds (VOC), dioxins, metals, etc.
- ❑ Emissions of carbon dioxide (CO₂) involved in global climate change
- ❑ Solid wastes, including cement kiln dust (in some countries where standards restrict recycling back into the production process).

None of these issues are insurmountable and all are amenable to mitigation through careful management. The Batelle report suggests that the cement industry can ensure its continuity and prosperity by focussing on win-win opportunities to create value for society, and working with its stakeholder towards a long-term vision of sustainability.

Batelle offered the following vision: “By 2020 cement companies have integrated sustainable development into their global operations, are known as innovators in industrial ecology and carbon dioxide management, are regarded as attractive employers, and have established relationships of trust with the communities in which they operate.”

The actions leading to this integrated sustainable development were suggested to be:

- 1) **Resource productivity** - The industry makes productive use of specific materials that otherwise would be discarded as waste, and applies state-of-the-art technologies and operating practices to cost-effectively improve its efficiency in energy and material consumption.
- 2) **Climate protection** – The industry has implemented practical, technological, operational, and market-based strategies to significantly reduce emissions of CO₂ and is technologically positioned for even greater reductions in the future.
- 3) **Emission reduction** – The industry has continuously improved its environmental practices and controls to achieve a minimal release of wastes or emissions that could adversely affect human health, ecosystems, and aesthetics.
- 4) **Ecological stewardship** – The industry develops, operates, and retires its plants and quarries in a manner that minimises adverse impacts on the environment, including biodiversity and aesthetics, and protects and restores potentially impacted ecosystems. In doing so, it has earned support and recognition in the eyes of the community and regulators.
- 5) **Employee well-being** – The industry builds and operates its facilities in a way that fosters employee satisfaction and productivity, provides fair wages and benefits, and is a safe, clean, healthy and desirable place to work.
- 6) **Community well-being** – The industry is well understood and respected by the communities in which it operates because companies and plants make efforts to understand community needs and to help find ways to meet those needs. The industry has implemented measures to address nuisance disturbances associated with quarrying, transportation, and plant operations.
- 7) **Regional development** – The industry and its associated value chain are viewed as positive contributors to local and regional economies and countries welcome the growth and prosperity of the industry because it is considered a critical component of infrastructure development and maintenance.
- 8) **Shareholder value creation** – The industry provides competitive returns to investors and is able to readily secure capital resources. Cement companies that have adopted SD practices are desirable investments for sustainable development index funds, and have increased their profitability and market share.

The Batelle report went further to recommend sustainable development goals and key performance indicators for cement manufacturers using the same list of actions given above.

Their suggestions were:

Recommended SD Goals and Key Performance Indicators		
Issues	Goal	KPIs
Resource productivity	Conserve resources by using less energy and recycling wastes	Energy efficiency: Tonnes of cement per megajoule (quarry and plant) Fuel material substitution rate (%) Raw material substitution rate (%)
Climate protection	Reduce greenhouse gas emissions	Net CO ₂ (kg) emissions per tonne of cement
Emission reduction	Reduce environmental waste streams	Waste (non-product output) produced (kg) per tonne of cement (can include airborne emissions waterborne effluents, fugitive dust, and solid wastes)
Ecological stewardship	Reduce adverse impacts of quarrying	<i>Potential KPIs: investments in quarry restoration, overburden waste reduction, water use efficiency, biodiversity action plans etc</i>
Employee well-being	Assure worker health and safety	Incident rate (injury, work-related illness) per 200,000 hours (can include both employees and contractors)
Community well-being	Respect the needs of local communities	<i>Potential KPIs: frequency of community meetings, hours of volunteer community service, public health initiatives, community opinion surveys, etc</i>
Regional development	Support host region economies	Potential KPIs; job creation, local investment, technology transfer, contribution to GDP, etc
Shareholder value creation	Create superior value for shareholders	<i>Potential KPIs: return on investment (ROI), return on assets (ROA), return on net assets (RONA), return on capital employed (ROCE), economic value added (EVA), etc.</i>

2.1 The Working Group Cement's response

After publication of the Batelle report, the WGC developed their "Cement sustainability Initiative - Agenda for Action" in a document published in July 2002 ^[2].

The WGC identified the purpose of the initiative as:

- ❑ Explore what sustainable development means for these ten companies and the cement industry
- ❑ Identify and facilitate actions that companies can take as a group and individually to accelerate the move toward sustainable development.
- ❑ Provide a framework through which other cement companies can become involved.
- ❑ Provide a framework for engaging external stakeholders

The Agenda sets out a programme of work for the next 5 years for both joint project and individual company action, focusing on the main work areas listed below:

- ❑ **Climate protection** – Implement an industry protocol, developed as part of the research program, for monitoring and reporting CO₂ emissions from the cement manufacturing process. Each company will set individual CO₂ emissions targets.
- ❑ **Fuels and raw materials** – Develop guidelines for responsible use of all fuels and raw materials in cement kilns.

- ❑ **Employee health and safety** – A Health and Safety Task Force will ensure delivery of effective systems of measuring, monitoring and reporting on health and safety performance. Companies will share their experiences to identify causes of accidents and to reduce injuries.
- ❑ **Emissions reduction** – Develop an industry protocol for measuring, monitoring and reporting emissions, and individual companies will publicly report emissions targets.
- ❑ **Local impacts** – create guidelines for Economic and Social Impact Assessment by cement companies.
- ❑ **Internal business processes** – Integrate sustainable development as a set of principles into management systems, relationships with business partners and relationships with civil society.
- ❑ **An invitation to join** – Other cement companies are invited to join these activities, and third party stakeholder groups are encouraged to engage with the initiative.
- ❑ **Reporting progress** – There will be an interim progress report on all of this work in 3 years' time, with a full report to be published in 2007. Individual companies will continue to report their progress on their own activities.

The following summary lists the actions the WGC participants have committed to:

Joint projects	Individual company actions
<i>The Cement Sustainability Initiative intends to create joint projects to:</i>	<i>As part of our ongoing commitment to good practice and innovation in sustainable development, companies agree to:</i>
Climate projection	
<ul style="list-style-type: none"> ▪ Develop a Carbon Dioxide (CO₂) Protocol for the cement industry. (Project already delivered.) ▪ Work with WBCSD/World Resources Institute (WRI) and other organisations to investigate public policy and market mechanisms for reducing CO₂ emissions. 	<ul style="list-style-type: none"> ▪ Use the tools set out in the CO₂ protocol to define and make public their baseline emissions. ▪ Develop a climate change mitigation strategy, and publish targets and progress by 2006. ▪ Report annually on CO₂ emissions in line with the protocol.
Fuels and raw materials	
<ul style="list-style-type: none"> ▪ Develop a set of guidelines for the responsible use of conventional and alternative fuels and raw materials in cement kilns. 	<ul style="list-style-type: none"> ▪ Apply the guidelines developed for fuel and raw material use.
Employee health and safety	
<ul style="list-style-type: none"> ▪ Set up a Health and Safety Task Force. (Project already delivered.) ▪ Establish a Health and Safety information exchange. 	<ul style="list-style-type: none"> ▪ Respond to the recommendations of the Health and Safety Task Force on systems, measurement and public reporting.
Emissions reduction	
<ul style="list-style-type: none"> ▪ Develop an industry protocol for measurement, monitoring and reporting of emissions, and find solutions to more readily assess emissions of substances such as dioxins and volatile organic compounds. 	<ul style="list-style-type: none"> ▪ Apply the protocol for measurement, monitoring and reporting of emissions. ▪ Make emissions data publicly available and accessible to stakeholders by 2006. ▪ Set emissions targets on relevant materials and report publicly on progress

Local impacts	
<ul style="list-style-type: none"> Develop guidelines for an Environmental and Social Impact Assessment (ESIA) process which can be used at all cement plant sites and associated quarries. 	<ul style="list-style-type: none"> Apply the ESIA guidelines, and develop tools to integrate them into decision making processes. Draw up rehabilitation plans for their operating quarries and plant sites, and communicate them to local stakeholders by 2006.
Internal business processes	
<ul style="list-style-type: none"> Investigate methods to track the performance of the cement industry, including development and use of key performance indicators. Product a full progress report after 5 years, and an interim report after 3 years. 	<ul style="list-style-type: none"> Integrate sustainable development programs into existing management, monitoring and reporting systems. Publish a statement of business ethics by 2006. Establish a systematic dialogue process with stakeholders to understand and address their expectations. Report progress on developing stakeholder engagement programs. Develop documented and auditable environmental management systems at all plants.

3. MITIGATORY MEASURES UNDERTAKEN IN SOUTH AFRICA

Three of the four clinker producing cement manufacturing companies active in South Africa are members of the WGC, and have therefore committed themselves to the above-mentioned joint projects and individual company actions. The 4th company present in South Africa has a demonstrated track record of similar commitment to sustainable development initiatives.

The locations of the various cement industry facilities are shown in Figure 1 below.

A common commitment in the individual South African clinker manufacturing company's environmental policies is a policy of continuous environmental performance improvement and legal compliance.

All South African clinker manufacturers contributed information to the WBCSD cement sectoral report undertaken by Batelle.

Cement Industry Facilities

Figure 1. The locations of the various cement industry facilities

In addition, the following are examples of specific achievement by the South African clinker manufacturers:

- **Climate protection** – All South African clinker producers have already commenced with the production of blended cements which use less clinker per ton of cementitious material. This is illustrated in the trend of reducing specific CO₂ emissions shown in the graph given in Figure 2. This graph was compiled from a consolidation of data supplied on a confidential basis by each of the 4 clinker producing companies to the Association of Cementitious Material Producers, ACMP. While there have been improvements in operational energy efficiency through investment in modern manufacturing plant, the impact on CO₂ emissions has been relatively modest. The effect of reducing the clinker content of the product range produced has been more significant. Some South African clinker producers also have interests in the processing and direct sale of cement extenders to end-users. Figure 2 shows the impact of the inclusion of this additional consumption of cement extenders on the specific CO₂ emissions. (Specific CO₂ emission is the quantity (tons) of CO₂ emitted per ton of cementitious material produced).

Figure 2. Cementitious material produced and specific CO₂ emitted in South Africa

Table 1 provides additional evidence of this trend. It shows how the downward trend of CEM I sales accelerated in 2002.

Table 1.

Sales History (t/a) by Product Type						
Product Type	1998	1999	2000	2001	2002	% change 2002/2001
CEM I	3 670 166	3 289 051	3 155 490	2 977 067	2 146 527	-27.9
CEM IIA	2 821 896	2 523 738	2 522 163	2 714 994	3 605 823	32.8
CEM IIB	664 181	1 596 884	1 759 790	1 839 139	2 278 044	23.9
CEM III	619 770	506 991	483 261	488 212	494 416	1.3
Masonry MC 12.5	74 866	64 102	49 211	16 418	456	-97.2
Masonry MC 22.5X	887 501	86 926	1 401	0	0	0.0
GGBS Slag	308 774	343 763	372 652	495 645	501 777	1.2
Fly Ash	129 452	134 269	130 604	105 541	118 808	12.6
Other	404 877	461 875	516 857	528 170	478 419	-9.4
Totals	9 581 483	9 007 599	8 991 429	9 165 186	9 624 270	5.0

- ❑ **Fuels and raw materials** – All South African clinker producers have undertaken feasibility studies to evaluate the use of alternative fuels in their kilns. The clinker producers are members of the SA Tyre Recycling Process Company, a concern dedicated to the fight against pollution resulting from used tyres. All manufacturers are evaluating the use of power station wastes as alternative raw materials in their processes. Advantage is being taken of by-products of other industries to supply the gypsum needs of South African manufacturers.

While South African cement producers will be competing for alternative fuels, they are jointly developing guidelines for the safe and responsible use of such fuels while interacting with government to determine the role of the cement industry in achieving the National Waste Management Strategy and the commitments covered by the Polokwane Waste Declaration.

- ❑ **Emissions reduction** – Manufacturers have dust-capturing equipment in place at their manufacturing facilities and comply with South African legislation with regard to particulate emission. The South African manufacturers will develop an industry protocol for measuring, monitoring and reporting emissions.
- ❑ **Local impacts** – South African manufacturers have met all local legislation in rehabilitating quarries.
- ❑ **Social responsibility** – There is a clear commitment to safety management as well as actions on AIDS prevalence reduction.

4. ACTION PLAN AGREED BY SA CLINKER PRODUCERS

Action plan agreed by Association of Cementitious Material Producers

- ACMP members have committed to reducing CO₂ emissions per ton of cementitious material.
- ACMP members will submit safety statistics to ACMP for consolidation and subsequent analysis for trends that require corrective action.
- Members will undertake Employee Health Management Programmes with particular attention given to HIV/AIDS programmes for workers.
- Starting in 2005, individual companies will publicly report on emissions and emissions targets.
- ACMP will commence with reporting on the sustainability of member company operations starting in 2005.

1988 – 1989 : Visiting Scientist : IBM Research Center, Yorktown Heights, USA

Lafarge: 1990 – to date

1990 - 1993 : Development Engineer, Corneilles Cement Plant (France).

1993 - 1995 : Cement Institute Director, Lyon

1995 - 1997 : Senior VP Internationalisation HR , Paris

1997 - 2001 : Senior VP Corporate R&D

2001 – to date: CEO Lafarge South Africa

ACMP:

The Association of Cementitious Material Producers (ACMP) is a relatively new association founded in May 2002, to represent clinker and cementitious material producers, on industry related producer issues. The intention of ACMP is to target a broader membership base, and not only the traditional cement producers.

The main objectives of the association are as follows:

- To lobby with various bodies in order to further the common interests of members.
- To promote the broader interests of it's members relating to legislation impacting on the cementitious industry.
- To co-ordinate the activities of standing, sub and ad hoc committees established by the association and to monitor and report on matters relevant to the industry.

The Executive Director of ACMP is Naude Klopper.

The chairmanship of ACMP rotates on a two yearly period, Lafarge are currently tasked with the chairmanship.

SOME ASPECTS OF RHEOLOGY OF CEMENT BASED PARTICLE SUSPENSIONS SUCH AS FRESH CONCRETE

O.H. Wallevik

ABSTRACT

The application and benefits of rheology as a tool in evaluating the properties of fresh concrete are briefly discussed. A coaxial cylinder viscometer can be used to evaluate the rheological properties of fresh concrete. Several examples are shown using parameters such as increased water content, air content, silica fume content and different dispersing admixtures.

Increased use of high performance concretes such as High Strength Concrete and Self Compacting Concrete demands better knowledge of properties such as viscosity for their successful application.

Keywords: Fresh concrete, rheology, viscometer, application.

1. INTRODUCTION

Rheology is the science of flow and deformation of matter and should therefore be the appropriate tool to describe the workability and mobility of fresh cement-based materials like cement paste, mortar or concrete. The theory is already used by many concrete technologists in the evaluation of hardened concrete i.e. creep. The theory is also used for fresh cement-based materials, though most of the research has been concentrated on basic theoretical aspects. In some cases there have been difficulties applying rheological test results, as measurement techniques used were somewhat questionable.

The application of rheology to understanding the properties of fresh concrete is definitely relevant. However, without a tool to confirm the theory, it will always be questionable and it will be difficult to know if it is realistic and applicable for concrete.

During the past three years a research program has been ongoing at the Icelandic Building Research Institute (IBRI) named "Rheology of fresh cement-based coarse particle suspension such as cement paste, mortar and concrete". The scope of this work is to obtain a better basic understanding of the mechanism and the influencing factors as well as the effect of each constituent of the composite material.

2. VISCOMETER

The ConTec BML [1-2] Viscometer and the ConTec Viscometer 4U [3] are coaxial cylinder viscometers for coarse particle suspension. They have proven to be good tools to evaluate the rheological properties of cement suspensions. The BML Viscometer can be used to measure dilute suspensions such as cement paste as well as relatively stiff concrete mixes.

Ideally the viscometer is applicable for concrete with plastic to flowing consistency. When designed, it was made for concrete with a slump value of about 120 mm and higher. However, depending on the mix design, it is possible to get sufficiently good measurements when the slump is as low as 50 mm.

b)

Figure 1. The viscometers: a) The BML viscometer. b) The ConTec viscometer 4.

The viscometers are ideal instruments to measure the rheological behaviour of special concretes such as High Performance Concrete (HPC), Underwater Concrete (UWC) and Self-Compacting Concrete (SCC). They are also suitable to evaluate different variables such as; various admixtures, cement types, different deliveries of cement etc. The more fluid the testing material is or the higher the plastic viscosity is relative to the yield value, the more accurate are the test results.

Figure 2. Rate of shear as a function of time and torque-velocity (T-N) diagrams of a standard test in the BML Viscometer (including the segregation measurement).

The viscometer measures the resistance (torque) of the fresh concrete at various (rotation) speeds. From these measurements so-called G- and H-values are calculated. The G-value ("flow resistance") is a measure of the force necessary to start a movement of the concrete. The H-value ("viscosity factor") is a measure of the resistance of the concrete against an increased speed of movement. In most cases the Bingham parameters, the yield value and the plastic viscosity can be calculated from the G- and H-value, respectively. Notwithstanding, the G- and H-values should be

used if there occurs a significant plug during testing (even though there exist advanced mathematics to calculate the Bingham parameters when plug occurs).

Figure 2 illustrates testing as a function of time. In standard tests one always starts at the highest speed, thereafter stepwise reducing the velocity until the lowest speed is applied. Thereafter the segregation point is measured.

3. SOME EXAMPLES

A principal illustration of the effect on the yield value and the plastic viscosity when increasing the content of water, silica fume, “air” and superplasticizer in the concrete mix is given in Figure 3. The figure also shows the influence on the shear stress as a function of the rate of shear.

Figure 3. Illustration of the effects of water, air, SP and silica fume on the flow behavior of the fresh concrete.

In Figure 4 measurement values from testing 22 mortar mixes are shown. The sand:cement ratio in the mixes was 2:1. The plastisicer used was melamine based and the dosages used are shown as dry polymer per unit weight of cement.

Figure 4. Effect of water, air and plasticizer on the yield value and the plastic viscosity.

Figure 5 shows test results of four concrete mixes from a ready mix concrete plant where the water content of the mixes is variable. One result is from HSC in the strength category C100. The results in the figure with yield values below 100 Pa represents SCC (also from different countries).

Figure 5. Test results from SCC/HSC compared to test results of concrete from a ready mix concrete plant [4].

In Figure 6 are indicated the desired yield and plastic viscosity values of a concrete mix for different applications. For instance, the goal is to reduce the plastic viscosity of the high performance concrete (HSC) as the viscosity normally causes problems. Problems with the viscosity limit the strength potential of the concrete if it should remain workable.

Figure 6. Desired rheological values for different applications of concrete.

Figure 7 shows the workability loss over a period of 1.5 hours where some of the new generation dispersing admixtures were tested and compared to conventional melamine based super-plasticizers.

Figure 7. Workability loss of mortar mixes containing various dispersing admixtures.

4. FINAL REMARKS

Results of the current research project are promising and the research aims have been met. The research project also includes advanced theoretical aspects such as the coagulation rate theory (Hattori-Izumi theory).

Use of viscosimetry in concrete technology is not common for the time being as concrete is a very complex material. However, this will change with increased use of high performance concrete such as HSC and SCC. Knowledge of viscosity is essential for successful application of these concrete types. Hence further research in this field is valuable for further development of concrete.

ACKNOWLEDGEMENT

The author would like to thank the Icelandic Research Fund (Rannis) for their financial support of the project. The colleagues at IBRI are also thanked for their assistance.
